The Hawai´i beef industry is economically, culturally, and ecologically important to the state. Over 142,000 head of beef animals are managed across nearly 300,000 acres of rangelands (20% of Hawai´i's land mass) that are managed by over 1,300 ranches. The value of Hawai´i-raised beef cattle is estimated to be more than $48 million annually (USDA-NASS 2022). Over 60% of the beef cattle in the state are raised on the island of Hawai´i where the TLSB currently poses the most significant threat.

In highly infested areas, TLSB resulted in nearly 100% die back of key range grasses including Kikuyu (*Pennisetum clandestinum*) and pangola (*Digitaria eriantha*) grasses when nymph densities exceeded $50/m^2$ (Wilson et al. 2023). The loss of these important forages provided entry for the establishment of invasive plants including Pamakani (*Eupatorium adenophorum*), wild blackberry (*Rubus* spp.), and fireweed (*Senecio madagascariensis*) among others. Twolined Spittlebug's rapid rate of spread and devastating impact on important forage grasses in the South Kona district forced livestock producers to reduce stocking rates resulting in significant economic losses.

In 2020 we started development of a smartphone application to provide livestock producers struggling to manage rangelands in the wake of TLSB infestations a decision support tool. The app was designed with four main user portals. The first portal was an information guide that provided an overview of TLSB biology and ecology. Next, the app provided portal to help users identify TLSB in the field and distinguish it from other, non-pest species. A third portal allowed users to report sightings of TLSB. The fourth portal allowed users to determine the size of the TLSB population, and then, based on the potential damage threshold calculated, select from a series of integrated pest management decisions.

The user reporting portal was designed to facilitate tracking TLSB infestations and distribution. User reports included a geo-referenced image of TLSB nymph or adult, and basic details about the habitat and geographical location of the pest. Users also had the option to enter data on TLSB population density and provide estimates on spatial extent and observed damage in their report. The reported data was then captured in a database and displayed on a web-based mapping tool that was managed by the TLSB research team and yielded important information on the distribution and intensity of infestations, as well as early detection of incipient TLSB populations.

Methods

The purpose of the Twoline Spittlebug (TLSB) smartphone (mobile) application was twofold. First the app would provide a mechanism for users to report positively identified sightings of the pest to the TLSB research team (reporting tool). This information would assist researchers in understanding and mapping the distribution and density of TLSB populations, intensity of infestations, and early detection of incipient infestations. The second intent of the TLSB mobile app was to provide the user, and specifically, affected land managers, information on TLSB habitat, biology, and ecology (information tool), a means of proper identification (identification tool), and a decision support tool for the management of TLSB infestations.

We desired the TLSB mobile application to be available to users on both Android and Apple smartphones. When considering options for programming of the mobile application software we evaluated the advantages and disadvantages of three options: 1) University of Hawaii-Manoa computer science student led development; 2) in-house University of Hawaii-Manoa Informational Technology led development; and 3) professional smartphone application company development. Although the more expensive option ($33,024 mobile app programming, $8,192 administrative website development), the complexity of the mobile application functions we envisioned led us to select working with a professional mobile application software company (Zco Corporation, 58 Technology Way, Suite 2W10, Nashua NH 03060). Static and dynamic data content for the four mobile application portals (information, identification, reporting, and management decision support) were developed from our research on the ecology, biology, and impact of the TLSB on Hawai´i rangelands (Wilson et al. 2023, Wilson et al. 2024). Development of the mobile application began in August of 2020 and was completed in September of 2022.

Information Portal

The purpose of the TLSB mobile application information portal was to provide users with basic information on the habitat, biology and ecology of the pest. This information was static within the mobile application. The information in this portal included background information on the three species of spittlebugs found in Hawai´i including the Twolined Spittlebug, Meadow Spittlebug, and Sunflower Spittlebug. Only the TLSB causes significant damage to Hawai´i rangeland grasses thus recognition of the differences between the spittlebug species are critical to proper management decisions for the control of TLSB. Additionally, the information portal provided users with a general description and development of the three life stages of TLSB (egg, nymph, and adult). The biology and ecology of these three life stages are critical to successful management of the pest in Hawai´i rangelands. Pictures of the three spittlebug species, TLSB life stages, and damage from the pest were provided for visual reference for the user. Finally, links to the other portals (identification, reporting, and management decision support) were provided to guide the user on the use of the mobile application.

Identification Portal

The purpose of the pest identification portal was to provide a process through which the user could positively distinguish TLSB from the other two species of spittlebug found in Hawai´i, and through a positive identification of TLSB, provide an accurate report through the mobile application reporting portal. The identification portal was designed using static information organized as a dichotomous key to guide the user in evaluating spittlebug specimens in the field following Thorne et al. 2022.

Reporting Portal

The purpose of the reporting tool was to provide users a mechanism to report sightings of TLSB that could be verified and mapped providing researchers with critical data on the pest distribution, infestation intensity, and early detection of incipient populations, and provide feedback to users of the mobile app on the distribution and spread of the pest on lands they manage.

The reporting portal was designed to provide a geo-referenced data and picture cache of sightings of adult and/or nymphs by application users. Data collected included a geo-referenced photograph and descriptive information, date, time, and location description of reported sightings. Reported data were cached in an administrative website database and used to verify and map sightings. The map generated was viewable on the administrative website public facing map minus personal/landowner identification information.

Management Decision Support Portal

The purpose management decision support portal was to provide information to the mobile app user, and particularly those landowners affected by TLSB, a decision supported process to assess the level of damage and take economically feasible management actions. Static and dynamic information and data were used in the development of the portal functions with most being created specifically for the functionality of the management decision support portal or modified from existing information. Static information included descriptions of sampling protocols to guide users in determining nymph population densities and/or adult abundance, integrated pest management protocols, and monitoring guidelines for TSLB free areas, known areas of TLSB activity, and areas recovering from TLSB damage. Dynamic data included a scale for determining nymph age class, calculators for quantifying average nymph density by age class or adult abundance, a selection tool to estimate the percentage of area affected (0-25%, 26-50%, 51-75%, or 76-100%), and a cell to enter the total acreage of land affected. Sampling and monitoring protocols, based primarily on quantifying TLSB nymph densities and adult abundance were modified for the mobile application from field sampling protocols described by Wilson et al 2023.

Results and Discussion

Nymph Density by Age Class and Damage Threshold Rating

Assessment of the five TLSB instar stages indicated that the stage one and two, and three and four, could be combined into two age classes based on sharp distinctions in width and length (Table 1). Instar five, comprised a single and final age class for nymph development toward adulthood. Approximate days to adulthood, by age class was derived based on a 50-day egg to adult development of the nymphal stage and divided across the three age classes (Table 1). A tool within the mobile application assists the user in determining age class. The count of nymphs per age class are then input into an in mobile application calculator that yields an average nymph density by age class.

Field data relating nymph densities to observed pasture damage following adult emergence (Wilson et al. 2023, Wilson et al. 2024) were classified as light (< 10 nymph/m^2), medium (11-59 nymph/m^2), and critical (> 60 nymph/m^2) based on expected forage loss. These data were combined with the nymph density by age class and expected days to adult hood to derive a Damage Threshold Rating Scale (Table 2). Damage ratings (1-3) were linked to specific IPM recommendations.

Table 1. Twolined Spittlebug Age Classes (1, 2, or 3) with dimensions and expected days to adulthood.

Age Class	Age class dimensions (mm)		Approximate Days Expected to Adult
	Width	Length	
1	< 0.6 mm	< 2.1 mm	More than 35 days
2	1.0 -1.4 mm	2.1-5.2 mm	Between 15 and 35 days
3	>1.5 mm	> 5.3 mm	Within 15 days

Note: Approximate Days Expected to Adult assumes an average 50 days from egg hatch to adult and an even development rate of 10 days between instar stage and selected to be the half-way point between classes in days.

Table 2. Age Class distribution and Expected Days to Adult by Nymph Density estimates in relation to Potential Future Damage. Yellow (damage level 1) light to moderate forage loss; Orange (damage level 2) moderate to heavy forage loss; Red (damage level 3) heavy to catastrophic forage loss.

Age Class	Nymph Density/Potential Future Damage			Expected Days to Adult
	< 10/ m2	11-59/m2	> 60/m2	
1	1	2	3	More than 35
2	1	2	3	15-35
3	2	3	3	Within 15

Integrated Pest Management Strategies

Integrated Pest Management practices for the control of TLSB in Hawaii rangelands includes intensive grazing management and strategic applications of recommended pesticides. With increasing damage from adult TLSB feeding, additional measures include using herbicides to control emerging weeds, and reseeding with TLSB resistant forages. Recommendations on specific IPM measures to employ depend on the expected level of impact and progress from intensive grazing management (applied for damage ratings 1-3), strategic pesticide applications (applied for damage ratings 2-3), to weed management and seeding TLSB resistant grasses (applied at damage rating 3). Within the mobile application, the user is directed to a specific IPM recommendations depending on the calculated damage rating from their input data.

Abstract

Assessments of herbage biomass and forage quality using field hyperspectral (HS) sensing provide valuable support to farmers in making precise forage management decisions. The field HS data, which includes measurements of canopy reflectance in the visible and near-infrared wavelength range (400-2350 nm), has been extensively studied in grassland assessment research. Partial least squares (PLS) regression has been widely adopted as a standard calibration method for estimating herbage biomass (BM) and determining forage quality parameters, such as crude protein (CP) and neutral detergent fiber (NDF) concentrations. In this study, a one-dimensional convolutional neural network (1D-CNN) model was developed as a non-destructive and rapid method for evaluating forage composition. The relationships between HS measurements taken on the ground and forage components obtained through harvest and chemical analysis at ground level were analyzed. The dataset in the orchard grass-dominated meadow field consisted of 200 samples from seven fields in three regions of Hokkaido, Japan, surveyed prior to the first grass harvest in May/June 2023. Overall, the 1D-CNN models showed better predictive accuracies for most parameters (BM, CP, and NDF) than standard PLS regressions. The 1D-CNN model demonstrated a good predictive accuracy ($R^2 = 0.950$) for BM, but less accurate predictions for concentrations of CP ($R^2 = 0.650$) and NDF ($R^2 = 0.506$). However, when the content in percentage was converted to standing mass (g/m²), high predictive accuracies in CP mass ($R^2 = 0.814$) and NDF mass ($R^2 = 0.837$) were achieved. These results are expected to contribute to the advancement of forage management by enabling rapid and accurate evaluation of forage components.

Introduction

In Hokkaido, Japan's largest feed-producing region, the environmental impact of excessive fertilizer application on grassland ecosystems has become a significant concern (Takeda 2001). In the meadow fields, issues such as weed invasion and soil degradation diminish the nutritional value of forage grasses, adversely affecting livestock health and productivity (Nishida 2002; Otsuka 1995). These factors also contribute to spatial variation in grass yield and forage composition. Grass forages, including orchardgrass (OG; *Dactylis glomerata* L.) and timothy (TY; *Phleum pratense* L.), along with legume forages such as white clover (WC; *Trifolium repens* L.), red clover (RC; *T. pratense* L.), and alfalfa (AL; *Medicago sativa* L.) are widely utilized in Hokkaido (Yamada 2009). Consequently, the rapid and accurate evaluation of the nutrient composition of these forages is essential for maintaining livestock health and productivity (Coleman and Moore 2003).

To address these challenges, remote sensing technology, using satellites and drones, has been increasingly employed as a diagnostic tool to evaluate grass resources and vegetation conditions across extensive areas quantitatively (Kawamura et al. 2012). Among these technologies, hyperspectral (HS) remote sensing technology, which measures continuous wavelengths in the visible to near-infrared (NIR) spectrum, has proven to be a powerful method for estimating the nutritional value of forages in the field (Zarco-Tejada 2000). Specifically, field HS measurements at canopy scale employs spectral analysis that is sensitive to the unique structural and chemical characteristics of these plant communities, allowing for the successful estimation of herbage biomass (BM), crude protein (CP), neutral detergent fiber (NDF), and other quality-related parameters (Lim 2016; Pullanagari et al. 2012).

In HS data processing and laboratory NIR spectroscopy, partial least squares (PLS) regression has been widely employed to estimate herbage BM and forage quality status (Marten et al. 1983). However, existing models are dataset-dependent and cannot be universally applied to different pastures. Therefore, it is necessary to develop a new model for each grassland (Fernández-Habas et al. 2022). In contrast, deep learning enables highly accurate estimation independent of data, allowing a single model to be applied to different meadow fields. Consequently, the objective of this study was to develop a nondestructive and rapid estimation model of herbage BM and forage nutritive status (CP and NDF) through deep learning by examining the relationship between field HS data and herbage BM or forage quality conducted prior to the first grass cutting in seven OG-dominated meadow fields in Hokkaido, Japan. In the present study, a one-dimensional convolutional neural network (1D-CNN) (Kawamura et al. 2021) was utilized for deep learning and compared with PLS.

Methods

Field surveys were conducted across seven meadow fields of OG-legume mixtures at three research institutions: (1) Obihiro University of Agriculture and Veterinary Medicine (OBH), (2) NARO Hokkaido Agricultural Research Center (HRC), and (3) Rakuno Gakuen University (RGU) in Hokkaido, Japan (Figure 1). Both RGU, located in Ebetsu City, and HRC, located in Sapporo City, are in a region characterized by a harsh, cold, and snowy climate. The Obihiro City area in Tokachi, while experiencing less snowfall than Sapporo and Ebetsu during winter, encounters lower temperatures. According to data from the Japan Meteorological Agency's Automated Meteorological Data Acquisition System (AMeDAS), the mean annual temperatures in 2023 were recorded as 10.95°C in Sapporo, 8.89°C in Ebetsu, and 7.16°C in Obihiro. Additionally, annual precipitation in these cities was recorded as 966, 965, and 919 mm, respectively.

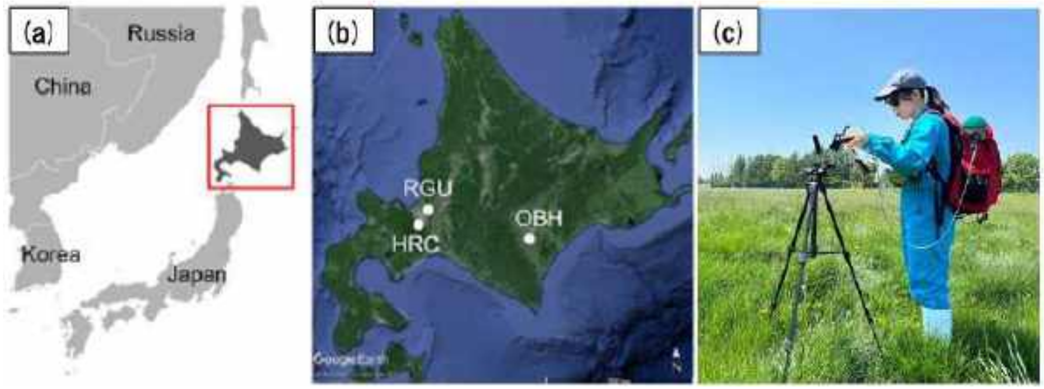

Fig 1 Location of Hokkaido, Japan (a) and three research institutions (b) with a photograph depicting the field HS measurement at HRC (c).

Field surveys were conducted between May 16 and May 29, 2023, during wich 200 samples were obtained. An ASD Fieldspec 4 Hi-Res spectroradiometer (Malvern Panalytical Ltd., UK) was employed to acquire field HS data (350–2500 nm). The sensor head was held approximately 50 cm above the canopy at the nadir position. The spectroradiometer had a 25° field of view (FOV), producing a view area with a 22 cm diameter at the canopy level.

Following the field HS measurements, grass height (5 points) was recorded and averaged as a surface sward height (SSH) within randomly placed quadrats (50 cm × 50 cm) in the field, and aboveground biomass was harvested at 0 cm above the ground surface. Grass samples were classified into five groups: OG, kentucky bluegrass (KB; *Poa pratensis* L.), legumes (WC + RC + AL), weeds, and dead materials, then dried in a dryer at 65°C for 72 hours and weighed for dry matter weight (g DM/m^2). Herbage BM was computed as the sum of the values for OG, KB, legumes, and weeds. Chemical analyses were then performed at the Federation of the Tokachi Agricultural Cooperative Association, Agricultural Product Chemical Research Laboratory.

Data preprocessing and PLS regression analyses were performed using Matlab software ver. 8.10 (MathWorks, Sherborn, MA, USA). In the development of the deep learning model, a one-dimensional convolutional neural network (1D-CNN) architecture was employed, which is suitable for one-dimensional spectral information. data set (n = 200) was sprit into training (80%, n = 160) and test (20%; n = 40) subsets. Then, the models were developed using training dataset, and the model accuracy was assessed using leave-one-out cross-validated R^2 and root mean squared error (RMSE). The predictive ability was evaluated using the test dataset.

Results

In PLS analyses, the cross-validated R^2 values indicated very low predictive accuracies (R^2= 0.095–0.266) andsubstantial errors, as denoted by the RMSE for herbage BM (111.343 g DM/m^2), CP (3.665%), NDF (7.351%), CPmass (21.167 g DM/m^2), and NDFmass (72.439 g DM/m^2), respectively.

The 1D-CNN models exhibited superior predictive accuracies for most parameters compared to standard PLS regressions. Specifically, the 1D-CNN model demonstrated commendable predictive accuracy (R^2 = 0.950) for BM, although it yielded less accurate predictions for the concentrations of CP (R^2 = 0.650) and NDF (R^2 = 0.506). In contrast, when the percentage content was converted to standing mass (g/m^2), high predictive accuracies were achieved for CP mass (R^2 = 0.814) and NDF mass (R^2 = 0.837).

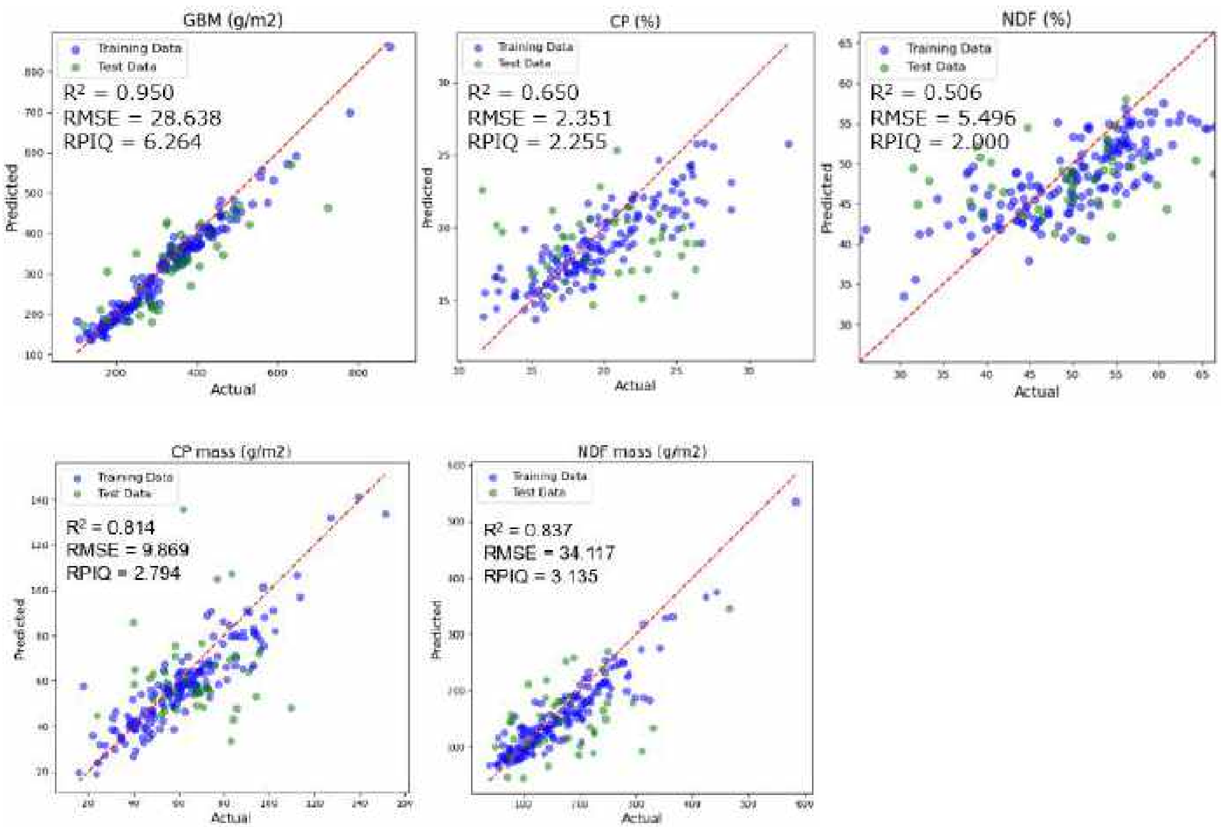

Fig 2 Relationships between observed- and predicted-values of herbage BM (a), CP content (b), NDF content (c), CP mass (d), and NDF mass (e).

Discussion

The PLS regression analysis conducted using the dataset collected from the seven fields did not exhibit the same level of estimation accuracy as observed in prior studies (Fernández-Habas et al. 2022). Conversely, the application of the 1D-CNN method from deep learning revealed a significant enhancement in predictive accuracy. Additionally, it has been suggested that the estimation accuracy for CP and NDF, which displayed low estimation performance, could be improved by converting these parameters into standing mass information.

These findings imply that the estimation accuracy can be enhanced through deep learning applied to the spectral data gathered from hyperspectral measurements utilizing 1D-CNN. Furthermore, the versatility of the model indicates its potential applicability across various fields. Moreover, given that the sensing data captures the surface reflectance of the plant community, it may be more advantageous to utilize standing mass over concentrations of CP or NDF.

In this investigation, we developed an estimation model to assess herbage BM and forage quality via deep learning from ground-based hyperspectral data. However, the dataset (n = 200) utilized in this study is relatively small in terms of data size for deep learning applications. Future efforts should focus on expanding the dataset to further enhance accuracy and versatility.

Key words: AI; biodiversity; Lar National Park; MLP

Abstract

The impact of livestock and tourism on vegetation includes a reduction in biodiversity and in some instances, species extinction. To assess these stressor-effect relationships and provide a management tool for protected rangelands of Iran's Lar National Park, we created a multilayer perceptron (MLP) artificial neural network model to forecast vegetation diversity in relation to human activities. Recreation and restricted zones, representing areas with the highest and lowest human impact, were chosen as sampling sites. Vegetation diversity, indicated by the number of species, was recorded in 210 sample plots. Additionally, twelve landform and soil variables were documented and utilized in developing the model. Sensitivity analyses revealed that the intensity of human activity (in four classes of livestock and tourism population) and soil moisture were the most critical inputs affecting the MLP. The MLP demonstrated strong performance, with R2 values of 0.91 for training, 0.83 for validation, and 0.88 for test datasets. A graphical user interface was created to integrate the MLP model into an environmental decision support system for protected rangelands managers, allowing them to predict impacts and formulate proactive plans to manage human activities affecting vegetation diversity.

Introduction

In Iran, the primary objective of national park management is to mitigate the adverse effects of human activities, particularly tourism and livestock husbandry. These activities have been linked to a range of negative impacts on vegetation, including biodiversity loss, degradation of plant communities, diminished plant regeneration, and, in some cases, species extinction. Numerous studies have documented a decline in species richness with increasing human activity in grasslands. Moreover, livestock grazing and tourism have been shown to negatively impact plant regeneration and elevate the risk of extinction for certain species (Newsome et al. 2013). To address these challenges, mathematical and quantitative methods are essential for analyzing the conditions of national parks where human activities are causing vegetation degradation. Recent advancements have led to the development of mathematical models for environmental impact assessment (Jahani 2016), which consider both human activities and ecosystem characteristics. This study aims to apply a Multi-Layer Perceptron (MLP) neural network model to predict the effects of human activities, such as livestock grazing and tourism, on vegetation diversity in Lar National Park, Iran.

Methods

To evaluate the effect of human activities on vegetation diversity, sampling areas were strategically chosen to represent sites with maximum (recreation zone) and minimum (restricted zone) human impact. Two sampling grids were employed, resulting in the selection of 105 sampling locations across the study areas. Given that the restricted zone covered a larger area compared to the recreation zone, the sampling sites were more widely spaced in the restricted zone. The grid dimensions were 200 × 500 meters in the recreation zone and 600 × 500 meters in the restricted zone. Plant species were identified and counted within 2 × 2-meter sample plots at each sampling location, and the number of species recorded served as a measure of vegetation diversity.

Species identification in each plot was conducted using local plant identification resources (Lar National Park Group, 2012). Additionally, 12 landform and soil variables were recorded at each 2 × 2-meter sample plot, including altitude (m), plot slope (%), hill direction exposure (north, east, south, and west), soil depth (cm), percentages of clay, silt, and sand in the soil texture, soil organic matter content (%), soil electrical conductivity (dS/m), soil porosity (%), and soil moisture (%). Four qualitative classes of human activity intensity were estimated by local park rangers: 1) no presence of livestock and tourists, 2) sporadic presence of tourists, 3) intensive presence of livestock and tourists, and 4) intensive presence of livestock and tourists with overnight stays. These predictor variables were used to develop a model to estimate the expected vegetation diversity (species count) in the sample plots, which served as the model output.

The dataset was randomly divided into three subsets: a training dataset comprising 60% of all samples (126 samples), a validation dataset comprising 20% of all samples (42 samples), and a test dataset comprising the remaining 20% of samples (42 samples). The ANN function in MATLAB (2018) was employed to design the MLP model structure and test the outcomes.

Results

In this study, a total of 210 sample plots were analyzed to assess vegetation diversity in both the recreation zone (characterized by maximum human activities) and the restricted zone (characterized by minimal human activities). Various combinations of layers and neurons, along with different activation functions for both hidden and output layers, were tested to optimize the ANN. Initially, the optimization process involved experimenting with a hidden layer containing between 5 and 30 neurons, selected randomly. Subsequently, the performance of the MLP was evaluated in configurations with 2 and 3 hidden layers, each containing the same number of neurons.

During neural network training, different numbers of hidden layers and neurons per layer were explored. The coefficients of determination (R^2) indicate the accuracy of these networks in predicting vegetation diversity based on the input variables. According to the results, Model with a structure of 12-6-6-1 (12 input variables, 6 neurons in each of the hidden layers, and 1 output variable), achieved the highest R^2 values across the training, validation, and test datasets (0.95, 0.87, and 0.93, respectively). This model demonstrated the best performance in structure optimization.

The MLP model demonstrated exceptional accuracy in predicting vegetation diversity in national parks, with the optimal network achieving a coefficient of determination (R^2) of 0.88 during the test phase. This indicates that the MLP is highly effective for assessing human impact in areas where vegetation cover is most affected by human activities. Consequently, a sensitivity analysis was conducted on the predicted outputs of the optimal MLP. Figure 1 highlights the sensitivities of the MLP to various input variables, revealing that the intensity of human activities and soil moisture were the most influential factors affecting the MLP's outputs.

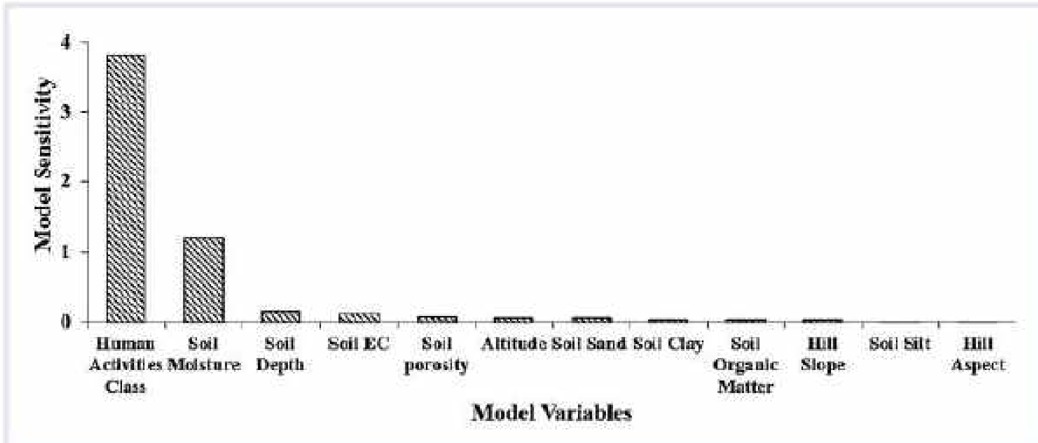

Figure 1: Sensitivity analysis of MLP model for prediction plant diversity

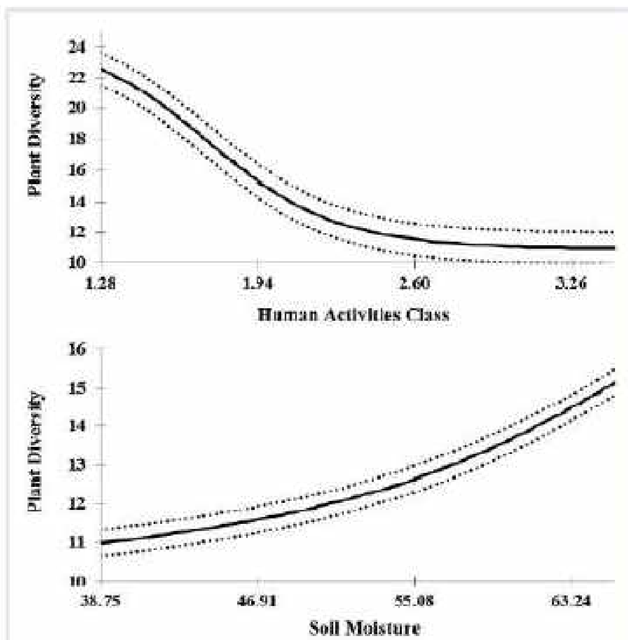

Figure 2: The trend of plant diversity changes in respond to human activity class and soil moisture.

The sensitivity analysis results show that the intensity of human activities and soil moisture had the greatest impact on vegetation diversity. Figure 2 illustrates that as the intensity of human activities increases, vegetation diversity declines; specifically, a 2-unit increase in activity intensity leads to a 10-unit decrease in vegetation diversity. This means that higher levels of human activity result in a significant reduction in the number of plant species observed in the sample plots. Additionally, an increase in soil moisture correlates with a rise in vegetation diversity—specifically, a 25% increase in soil moisture leads to an approximately 5-unit increase in vegetation diversity. Thus, higher soil moisture levels contribute to an increase in the number of plant species in the area.

Discussion [Conclusions/Implications]

In this study, an MLP model was developed to predict how human activities affect natural vegetation diversity. The goal is to aid managers in estimating the potential impact of human activities while balancing ecological conservation goals in national parks. Using MATLAB (2018) and appropriate validation techniques, the model described here is applicable to areas with ecological conditions similar to our study area in Iran. For regions with different ecological conditions, the model can be adapted by incorporating new data sets. From a planning perspective, areas with higher soil moisture are better able to withstand human activities and are more likely to recover quickly. This should be considered in national park management planning. The data used in this study are robust, consisting of 210 sample plots that provide reliable information on the impact of human activities and land properties, which were used to develop the quantitative model for predicting vegetation diversity.

Human activities have been used as variables in predicting environmental impacts to inform management decisions. Jahani et al. (2016) previously assessed the accuracy of neural network models in evaluating forestry impacts using the optimized forest degradation model (OFDM) with MLP, applied to predict forest degradation from human activities like livestock grazing and tourism.

Our study highlights the influence of both human activities and habitat conditions on vegetation diversity. De Vries et al. (2010) argue that expert-based models estimate plant diversity responses to environmental variables. Models developed for specific regions like the Netherlands (Wamelink et al. 2005) have shown promise, emphasizing the importance of measuring variables such as landform, soil acidity, and nutrient and water availability. Our research, alongside Jahani et al. (2020), found that soil organic matter and moisture are crucial factors influencing plant diversity after human activities.

In Lar National Park, tourist activities tend to compress soil and vegetation, making shrubs more sensitive to human activities than herbaceous plants (Whinam and Chilcott 2003). Soil conditions, such as moisture and nutrient availability, affect vegetation damage and ecosystem regeneration potential. Soils with higher moisture support greater plant diversity (Whinam and Chilcott 2003), which aligns with the MLP model's sensitivity analysis results. For example, a 25% increase in soil moisture (from 38% to 63%) could lead to an additional 4 plant species (11 to 15) in the habitat. Given that soil moisture in Lar National Park ranges from 25% to 80%, our model effectively assessed the impact of soil moisture on plant diversity.

Acknowledgements

We extend our gratitude to the Environment Department of Tehran for their involvement in the survey. Their support was instrumental in enhancing the quality of our results and contributing to the success of this work.

Abstract

Livestock excretions play a crucial role in nutrient cycling within pasture ecosystems. However, traditional field observation methods require significant human effort and time. In this study, we developed the Dung Detector (DD) model, which utilizes unmanned aerial vehicle (UAV) images and the You Only Look Once (YOLO) v5 object detection approach, to identify cattle dung in pastures. We have also evaluated the spatial distribution of cattle dung pats in these pastures. The DD model consists of five paddocks, namely Obihiro (OBH), Shintoku (STK), Minokamo (MNO), Miyota (MYT), and Yatsugatake (YGK). A custom dataset containing 1,504 images segmented from UAV orthomosaic images was used for training. The accuracy of the DD model was assessed by comparing it with ground truth data obtained from 2-3 quadrats (10 m × 10 m) in each paddock. Accuracy (F-score) of the DD model in each plot ranged from 0.432 to 0.861, with better results observed in paddocks characterized by simpler grass species and lower surface grass height (SSH). The spatial distribution of cattle dung pats detected by the DD model showed a heterogeneous distribution pattern within the plots due to differences in where grazing livestock stayed due to fences, shaded forests, and water troughs.

Introduction

Cattle dung in pastures constitutes a critical source of soil nutrients; however, it also significantly contributes to greenhouse gas (GHG) emissions, particularly methane (CH_4) and nitrous oxide (N_2O) (Cai and Akiyama, 2017; Lombardi et al. 2022). The application of nitrification inhibitors, such as dicyandiamide (DCD), has been proposed as a mitigation strategy for these emissions; nonetheless, the application process can be costly and labor-intensive when employed across extensive agricultural fields (Betteridge et al. 2010). Additionally, cattle foraging behavior results in an uneven distribution of dung, particularly in hilly grassland environments (Yoshitake et al. 2014). The real-time mapping of dung distribution could enable targeted application of DCD, thereby contributing to the reduction of GHG emissions.

Current methodologies for monitoring cattle defecation, including global navigation satellite system (GNSS)-based technologies, are encumbered by limitations in battery life and overall usability (Watanabe et al. 2019). Drones have emerged as a promising alternative for the detection of cattle dung, with investigations demonstrating their ability to identify fresh dung based on color and shape. However, challenges remain in detecting older dung, especially within heterogeneous pasture ecosystems where soil coloration may closely resemble that of dung (Yoshitoshi et al. 2015). Geographic object-based image analysis (OBIA) presents potential avenues for improvement; nonetheless, it is also constrained by factors such as site-specific dependency and limited versatility (Blaschke, 2010).

In response to these challenges, the present study employs a deep learning-based object detection methodology to enhance accuracy and adaptability. Among the various algorithms available, YOLO (You Only Look Once) is particularly notable for its efficiency and widespread application in agricultural contexts, including weed and cattle detection (Ahmad et al., 2021; Gallo et al., 2023). The "Dung Detector (DD)" model was developed utilizing YOLOv5, which was selected for its robust performance and adaptability. This model was trained on a custom dataset specifically tailored to drone imagery of cattle dung, thereby addressing the existing gap in available datasets.

Methods

The study was conducted in June-July, 2022 across five pastures in Japan: Obihiro (OBH), Shintoku (STK), Minokamo (MNO), Miyota (MYT), and Yatsugatake (YGK) (Figure 1; Kawamura et al. 2024). These locations include two permanent grazing paddocks (OBH, MNO) and three rotational grazing paddocks (STK, MYT, YGK), with sizes ranging from 0.59 ha (OBH) to 3.72 ha (STK). Terrain varied from flat (OBH, slope = 1.0°) to hilly (MYT, slope = 8.7°), with slopes calculated using 5-m mesh digital elevation models (DEM5A and DEM5B) published by the Geospatial Information Authority of Japan (https://fgd.gsi.go.jp/download/ref_dem.html).

Fig 1 Location of five target paddocks: (a) Obihiro (OBH), (b) Shintoku (c) Minokamo (MNO), (d) Miyota (MYT), and (e) Yatsugatake (YGK) (Kawamura et al. 2024). White letters at the bottom of the pictures are

the dominant grass species of the paddock and the survey dates. KB, Kentucky bluegrass (*Poa pratensis* L.); DC, *Digitaria cilaris* (Retz.) Koeler; OG, Orchard grass (*Dactylis glomerata* L.); PR, Perennial ryegrass (*Lolium perenne* L.); RC, Red clover (*Trifolium pretense* L.); TY, Timothy (*Phleum pretense* L.); WC, White clover (*Trifolim repens* L.); ZJ, Zoysia japonica Steud.

A Parrot Anafi drone was utilized for image capture. The flights were conducted in accordance with the mission parameters established by Pix4Dcapture, which specified an 85% forward overlap and a 75% side overlap at an altitude of 28 meters, resulting in a ground sampling distance of 0.95 cm. Ground control points (GCPs) and ground-truth data were collected using Real-Time Kinematic Global Navigation Satellite System (RTK-GNSS) technology. Two 10 × 10 meter quadrats within five paddocks (OBH, STK, MKB, MNO, MYT) were surveyed to validate the locations of dung.

Orthomosaic RGB images with a resolution of 1 cm were generated using Metashape Pro and subsequently partitioned into 640 × 640 pixel tiles for compatibility with the YOLO model. The images were saved in JPG format for the purpose of annotation and in GeoTIFF format for the extraction of dung location data.

A custom dataset consisting of 1,504 images was developed, allocating 80% of the data for training and 20% for validation. Image labelling was conducted using MakeSense, with two classes designated: dung and stones. The YOLOv5x model underwent training for 500 epochs employing an Nvidia RTX A4000 GPU. The model exhibiting the highest mean Average Precision (mAP) on the validation dataset was selected for subsequent testing.

Dung detection was conducted across four paddocks, with the exclusion of YGK due to the absence of ground-truth data. The assessment of detection accuracy was executed utilizing Precision, Recall, Overall Accuracy (OA), and F-score metrics, which were calculated based on the counts of true positives (TP), false positives (FP), and false negatives (FN). The F-score provided a comprehensive evaluation of model performance, with values approaching 1 indicative of superior accuracy.

Results

Using the DD model, cattle dung detection was conducted in five paddocks across Hokkaido (OBH, STK), Gifu (MNO), Nagano (MYT), and Yamanashi (YGK) prefectures (Figure 1). The detected dung counts were 666 (OBH), 2,429 (STK), 688 (MNO), 165 (MYT), and 3,716 (YGK), respectively. The model achieved high accuracy in OBH (F-score = 0.861) and STK (0.835), where the grass was short and simple in species composition. Dung color variations, from dark brown to white, were also detected effectively (Figure 2a). In contrast, in MNO and MYT, dense vegetation and taller grass (MYT: mean height 38.9 cm) resulted in lower recall (0.500, 0.276), as many dung pats were concealed under the grass despite precision exceeding 0.9.

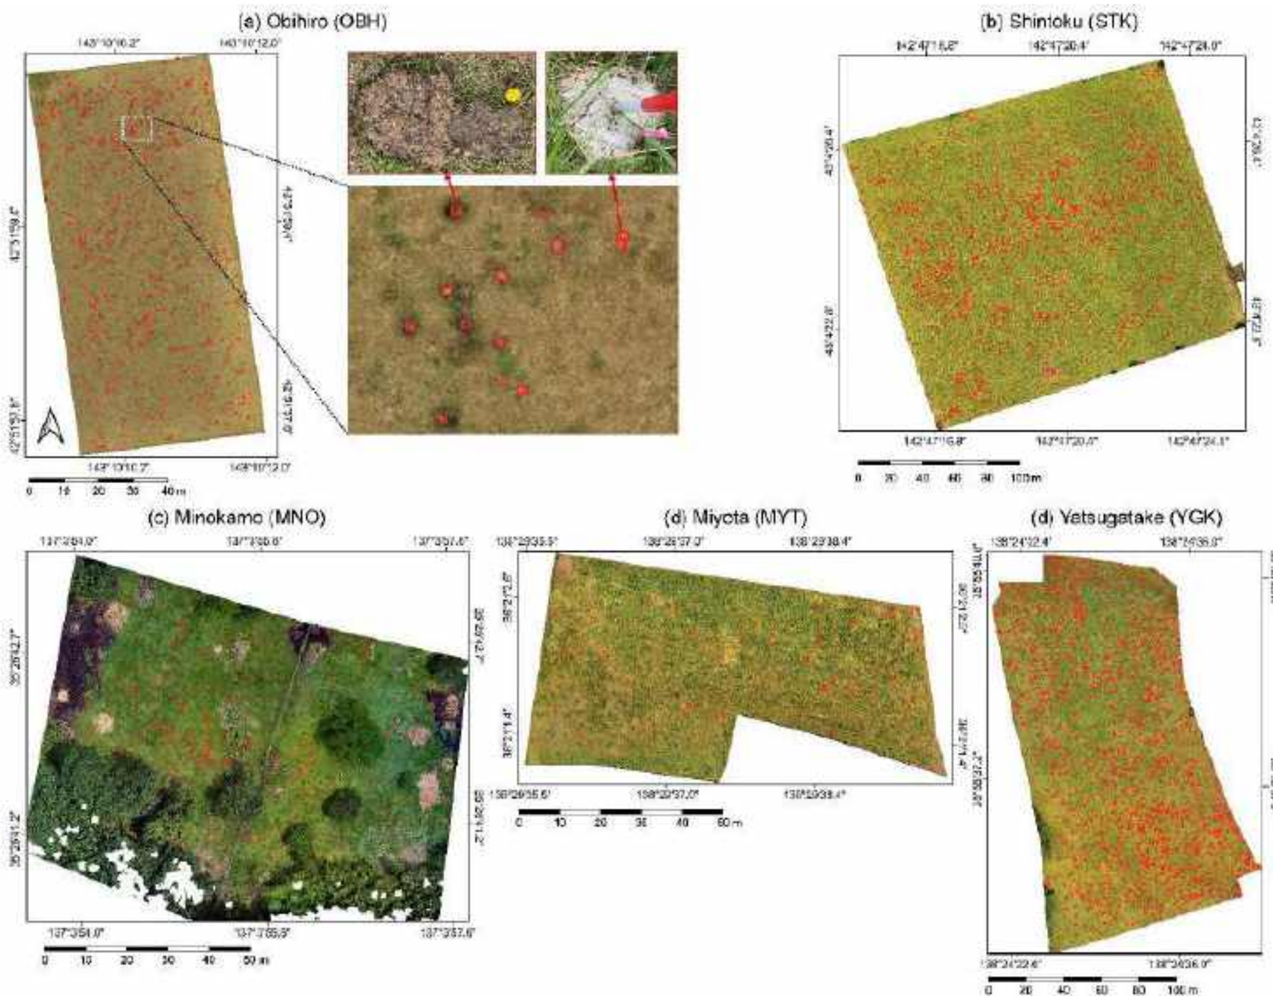

Fig 2 Spatial distribution of cattle dung pats detected from drone images using YOLOv5 in five paddocks (Kawamura et al. 2024).

Discussion

The application of deep learning (DL) for remotely sensed image data is expanding in grassland and livestock management (Muro et al., 2022); however, cattle dung datasets for grassland ecosystems remain underrepresented. This study developed the DD model using YOLOv5 and a custom dataset (1,504 images) to detect dung pats in drone images. The model identified between 666 and 3,716 dung pats per field, consistent with estimates of dung production (8–13 pats per day per cow). These results suggest that the detected dung pats were approximately 10 days old or less.

Dung detection accuracy was highest in short-grass pastures (OBH, STK; F-score = 0.861, 0.835) but exhibited lower performance in tall grass pastures (MYT; Recall = 0.281), where vegetation and terrain obscured dung in the drone images. The camera angle (80°) and the presence of invasive tall grasses, such as *Phalaris arundinacea*, likely contributed to the challenges in detection, indicating a need for methodological adjustments in future studies. Furthermore, updates to the detection models are necessary to enhance performance in complex environments.

In comparison to machine learning and Object-Based Image Analysis (OBIA) methods (Yoshitoshi et al. 2015), YOLOv5 demonstrated versatility across multiple paddocks, albeit with slightly lower accuracy. Enhancements can be achieved by updating the model with newer YOLO versions and incorporating expanded datasets, which could improve performance and applicability to a range of pasture types.

This pilot study highlights the potential of DL and drone technology for identifying the distribution of cattle dung, which can be beneficial for grazing management. However, several challenges persist: the model currently provides only the location and approximate size of dung (bounding boxes) without information regarding dung age or mass. Given that dung mass and age significantly influence nutrient cycling, grass recovery, and GHG emissions, future research should focus on evaluating dung decomposition processes while integrating seasonal and geographic variations (Cai et al., 2017; Saggar et al., 2015).

Readily available: rangelands information and learning tools from the rangelands partnership

Kuden, JL[1], Pfander, JL[2]

[1] University of Alaska, Consortium Library, 3211 Providence Dr, Anchorage, AK 99508, jlkuden@alaska.edu; [2] University of Arizona Libraries, 1510 E University Blvd, Tucson, AZ 85721, jpfander@arizona.edu

Key words: open access; information systems; land management tools; information resources and videos; knowledge sharing

Abstract
Actively collaborating with institutions and organizations in the U.S. and around the world, the Rangelands Partnership is committed to providing reliable science-based information resources through the Rangelands Gateway web portal (https://rangelandsgateway.org/). The Gateway brings together rangeland ecology content from the United States, Australia, Canada, Mexico, South Africa, and other countries in addition to organizations such as the United Nations Food and Agriculture Organization (FAO). The Partnership's vision is to support the information needs of multiple audiences including range managers, natural resource professionals, Extension specialists, educators, decision-makers, and students as well as to contribute to improving the health and sustainability of rangelands and the communities of people who depend on them by providing credible and useful information.

Introduction
The Rangelands Partnership (RP) is a unique collaboration, spanning several decades between range scientists, information technicians, and librarians. This interdisciplinary team of experts has created the Rangelands Gateway (RG) website which provides a wide variety of freely available information resources and tools, including articles, technical reports, videos, global resources, and more. The website brings together information on key topics such as large landscape conservation, human and economic dimensions of rangelands and maintaining and improving rangelands. The poster that accompanies this paper focuses particularly on foundational educational tools and resources such as glossaries and videos for anyone including those new to the concepts of rangeland ecology and management. There are quality materials available on RG for students, researchers, public and private land managers, and educators.

Methods
The multi-disciplinary group of range scientists, librarians and IT specialists in the RP accomplishes the work through regularly scheduled Zoom meetings, a RP listserv (an email group), the RP Newsletter and

an annual RP conference that rotates between RP member states with both in-person and Zoom attendance options.

Individual members are encouraged to provide troubleshooting input on the RG website. For example, in August 2023 a librarian noticed the search interface wasn't providing consistent and complete results. That started a journey of working with the technological specialist team at the University of Arizona, followed by testing done by librarians and range scientists, further modifications by the technical specialists, resulting in an improved search experience on the RG.

A particularly valuable and impactful method for accomplishing our goal of providing reliable science-based information resources through the RG has been the establishment of a Memorandum of Agreement (MOA) between the Society for Range Management (SRM), Elsevier, the University of Arizona (UA) Libraries, the UA College of Agriculture, Life & Environmental Sciences. The MOA allows the RP to provide open access to articles published in the Society of Range Management's (SRM) major publications, *Rangeland Ecology and Management* (REM) and *Rangelands* magazine. Full issues of *REM* and its predecessor *Journal of Range Management* are available from volume 1 (1948) up to five years from the present year. SRM's *Rangelands* issues are available from volume 1 (1979) up to two years from the present year. These two publications bring a wealth of peer-reviewed articles available through the RG.

In addition, throughout the existence of the Rangelands Partnership, RP members have actively pursued and received grant funding. This has allowed the Partnership to create and deliver much needed educational resources for multiple audiences through diverse platforms including videos, digital apps and decision-making tools, providing access to a complete reference website.

Results

The Rangelands Gateway (https://rangelandsgateway.org/) contains a Library of more than 23,612 records of articles, conference proceedings, reports, along with videos, maps and educational and decision support tools. It also includes backfiles (archived articles) of the Society for Range Management (SRM) journals, publications from the Australian Rangeland Society and the Grasslands Society of Southern Africa, and content from other organizations and about other countries.

More than 70 videos on various rangeland topics can be found on the YouTube channel (https://www.youtube.com/user/GlobalRangelands) highlighted on the Tools page in addition to distance education courses, career information and other resources. Visit the Topics section to view content such as Rangelands in the World, Large Landscape Conservation and others.

The Global section on the Gateway highlights organizations and initiatives around the world that the Partnership is engaged with, including the 2026 International Year of Rangelands and Pastoralists (IYRP) and regional IYRP groups share plans and resources for outreach and education in advance of 2026. Visit the Rangelands Gateway web portal to learn more about how the Rangelands Partnership is "working together for our global rangelands future" by increasing access to valuable information resources through technology, information systems and communication. These materials are open access and freely available to the world.

Conclusions

There are challenges faced by RP members. For example, finding time to do volunteer/service Partnership work such as taking leadership positions in the RP Executive Committee, keeping up with fixing errors in

RG records, keeping website pages refreshed and up-to-date and other important RP work when responsibilities of paying jobs take priority, is a significant and ongoing challenge.

In spite of these challenges, the RP remains committed to the vision statement: "A multi-disciplinary collaboration that creates and furnishes authoritative, reliable, and vetted rangeland ecology content for range managers, natural resource professionals, Extension educators, decision-makers, and students to support the health and sustainability of rangelands and the communities of people who depend on them."

The ongoing success of the Rangelands Partnership can be attributed to the powerful synergy of the collaboration of range scientists, librarians, and technological specialists. The combination of these professionals diligently working together has resulted in continued efforts towards web-based sharing of quality and scientifically valid rangelands information and learning tools.

Acknowledgements
The Western Education/Extension and Research Activity (WERA) under the auspices of The Western Association of Agricultural Experiment Station Directors started supporting the Rangelands Partnership in 2008 and has done so annually. Many members in the partnership have received various grants from the United State Department of Agriculture agencies. On the RG website there is a long list of Partners and Collaborators that have contributed time, expertise, information materials, and funds towards this effort.

Using historical photos to monitor long -term changes in South Australian rangelands

Lay, BG[1]; Maconochie, JM [2]

[1] Contract Botanist, Harrogate, S.A.; [2] Senior Rangeland Scientist, Pastoral Unit, Dept. of Environment and Water, Adelaide

Key words: Historical vegetation changes repeat photography.

Abstract

Using repeat photography, or retaking photos at a later date from the same or similar locality, is a technique often used to illustrate changes particularly inbuilt environments. In rangelands and other natural environments, the technique in a general sense is often used to illustrate changes in rangelands measured or monitored by other means. The concept of a photographic monitoring point, or photopoint, is derived from this simple concept, and is commonly used to describe photo-sites taken from a fixed point, either using posts, pegs or other markers, or by means of an accurately geo-positioned location.

The project seeks to find out what ecological changes in the South Australian Rangeland area can be revealed simply by accurately re-locating sites where the original photo was taken 50-100 years ago. The original photos were sourced mainly from the records of early pastoral inspectors and Pastoral Board members. A few were sourced from pastoralists, as well as other government officials.

An appraisal of changes evident from 103 photo-pairs this year reveal almost ubiquitous improvement in site condition, and vegetation cover. However some areas, particularly with sandy soils show significant increases in less palatable shrubs and bushes.

Introduction

The poster provides a summary of changes in vegetation, soils, and other aspects of pastoral landscapes revealed from the relocation and repeat photography taken of the 103 sites where historical photos were taken, dating back to early last century. A book entitled "Land, Lease and Lens" has been produced which includes all the changing photo-pairs relocated in 2024.

The project, completed by Bren and Elizabeth Lay in 2024, was originally developed in 1995 as a research project funded by the then Australian Natural Heritage Trust. At that time, the Pastoral Board was overseeing the first round of pastoral lease assessments under the *Pastoral Land Management and Conservation Act 1989*. That program involved the establishment of fixed ground-based photopoints set up in each paddock or land type on all properties held under pastoral lease tenure. These new sites generally had quantitative data including belt transects and plant species lists collected at the time of establishment or re-visit.

At the time of the first round of pastoral lease assessments, there was an expectation that these new photopoints would be regularly re-visited. The Board in the 1990's emphasised its desire to obtain the "Second point on the graph" as a general expression for its role in capturing any significant land condition trends at the site (and surrounding area) during this process.

The simple objective of this work was, therefore, to determine what information, at both a site, and regional level, can be gained from analysis of retakes of a suite of historical photos. This recognised that in most cases no data was gathered at the time the photos were first taken. However, for many sites, site data was gathered during retakes at the time the project was begun, in the 1995-2000 period. These sites will be shown as a series of three photos in the book, as in the series included here (fig 1-3).

Methods

Most of the photos gathered for this project and re-visited in 2024 were taken from published or unpublished historical texts, or from reports submitted to the Board by early pastoral inspectors or Board members.

Of particular note here is the photos taken by one of the Board's earliest Inspectors appointed in 1924; Mr Cecil Goode, who was the first person attached to the Board, who accurately recorded the location from where he took many of the photos in his inspection reports. These photos date from the early 1940's, and provided some of the more interesting photo-comparisons to come out of this study.

The methods used for this repeat photography project was similar to that of books or monographs published overseas, particularly in the United States of America, such as Hastings and Turner (1965).

The challenge: finding the sites.

We recognised that because there was generally minimal or no data attached to the original photos, then they would only be worth the effort to re-visit if there was a reasonable prospect that the location could be found, or that the scene in the photo could be matched with a reasonably degree of certainty.

Achieving this part of the project sounded straightforward, but turned out to be quite challenging for us. because:

- Paddock or property configurations had changed, with fencing not maintained or removed
- Tracks were no longer visible, or had overgrown or washed out.
- The original track alignment had sometimes been obliterated by bulldozed replacement tracks or roads
- Even where the site location was known or evident, it was sometimes physically impossible to drive to it, necessitating a walk or swim to the exact location.
- The location was found, but deemed unsuitable due to the original scene being occluded by tree or shrub growth in the foreground of the photo.
- Site data was not available to us, or to the lessee concerned.

Despite these challenges, some sites were found purely by perceptive observations of the station managers or the authors.

Results

Altogether 103 sites were re-photographed and a selection included in the book if they fitted this criterion *and* showed or contributed to an interesting story from an ecological or land condition perspective. The re-takes were completed in calendar year 2024. At least another 50 sites were searched for without success, or were abandoned/not included for the reasons listed above.

For each site, these successful or abortive attempts involved vehicle traverses of up to100km or more, and the large amount of off-track traverse resulted in the destruction of more than a dozen AT rated tyres.

Analysis of changes

For the purpose of comparing and analysing the changes evident in the photo-pairs or triples, the rangeland region was divided into six districts recognised by the S.A. Arid Lands Landscape Board. as these districts were defined, at least in part, by land type, it made sense to investigate whether or not there were any generalisations which could be made about changes evident in each district. In addition, if any vegetation type occurred more widely, the question was asked as to what significant trends were evident over these long time periods.

For this paper and to illustrate the process, trends evident from a typical three-photo series in the Northern Flinders Ranges are summarised as Figures1-3.

The generally barren landscapes in overgrazed areas and distinctive topographic features fortunately enabled accurate re-location of many sites, although tree and shrub growth in some cases precluded views of the mid and background areas.

Discussion [Conclusions/Implications]

When undertaking this project, we were guided in our approach by the many publications using this technique. A good discussion and bibliographic summary of work using repeat photography from an Australian rangelands perspective is Pickard (2002). He points out that there are relatively few comprehensive studies using this approach in this country. In South Australia, studies of changes over long time periods at Koonamore (Hall et. Al. (1964) provide some of the best insights as to the value of long-term repeat photography from fixed points.

It is from the USA that a number of studies such as this one provide the material on historical or ecological changes in a particular region or land type. Some of them have been produced as a book, often best described as a generalised account of landscape changes in a particular area or region. Progulske (1974,), and Gruell (2001) have provided insightful accounts over long time periods in coffee-table book format.

Conclusions

The question most often asked of this work is "Were there any consistent trends evident across the rangelands of South Australia over these long time periods?". Based on a careful comparison of changes evident in the 100 or so photo-pairs, it was clear that:

- More than 75% of sites had clearly improved in condition, based on commonly accepted criteria
- Many sites distant from stock watering points had dramatically improved due presumably to the reduction of rabbit populations since the release of the Calicivirus.
- A number of native trees have changed little over the 50-100 year time interval. Red mallee (*Eucalyptus socialis)*, coolabah (*E. microtheca*) and Flinders Ranges corkbark (*Hakea edniana*) are foremost among these.

- By contrast, common wattle species, such as mulga (*Acacia aneura*), western myall (*A. papyrocarpa*) and sandhill wattle (*A. ligulata*) have often not survived over these time periods, or have regenerated spectacularly where seasonal conditions have enabled this to occur.
- In the northern cattle country, changes in abundance and composition of short-lived herbaceous plants and grasses are far more evident than was the case at sites further south. This may have been due, at least in part, to the heavy summer rains received in some areas in early 2024.

Acknowledgements
We are indebted to the Pastoral Board of South Australia for its encouragement and financial support for this project. Many of the sites where an intermediate photo was taken in the 1990's were found and documented by rangeland officers John McDonald and Tonia Brown. Senior rangeland officer John (Max) Maconochie and Pastoral Unit manager Saravan Peacock provided the support needed for off-site operation as a contractor. The provision of GIS support enabled real-time navigation, - critically important in enabling many sites to be found and re-taken. Even so, we could not have completed the re-visits to so many sites, often in parts of properties where no road access remains, without the assistance of many property owners and/or managers.

1966

Figure 1: Dunbar Hut Warraweena Station, Flinders Ranges. A stock watering point about 1km west of here explains the degradation and gullying evident, compounded by uncontrolled goat and rabbit grazing pressure. The only vegetation on the range at rear are some remnant native cypress-pines.

1999

Figure 2 Dunbar Hut, Warraweena Station (now formalised as PP 6682). Dramatic improvement in land condition 33 years later, in part explained by the purchase of the lease by a conservation company, which also encourages the control of feral goats. Extensive regeneration of the pines is now evident, at rear, complemented by the recent growth of Lemon-scented grass following a good summer rainfall event that year.

2024

Figure 3 Dunbar Hut, Warraweena Station. (PP 6682)

The fence has now been removed for firewood, while the regeneration of pines continues on the range behind, together with various Wattle species. In the foreground dry seasonal conditions prevail with no annual growth

Development and implementation of a forage management platform in Uruguay ('iPasto').

Abstract

Introduction

Methods

iPasto is a digital platform for data management (Lombardo 2021). It is a web application that allows recording, calculating and visualizing information for improving pasture management at the paddock and farm scale. It links management and productivity data of grassland and paddocks (lots or grazing areas) of a farm. The data recorded in the farm (paddock or field monitoring) and data from remote sensing generate real-time rangeland performance information, which is stored in a database for further analysis. The platform is divided into 3 modules. The first module is basic information, where the user configures his farm with his grazing areas; the second module is pasture monitoring; and the third is grazing areas monitoring. The forage monitoring allows, through the use of remote sensing and an ecophysiological model adapted from Monteith (1972), to estimate and visualize information on the Net Aerial Primary Production (NAPP) at the paddock and farm scale for the various forage resources from 2000 to the present day. The main outputs of this module are: 1-NAPP (kg DM). The 'Paddock Monitoring' module allows updating the status of the paddocks, as well as displaying the following outputs or global forage performance indicators on the farm: 2-Grass Availability (GA) at a point in time (kg DM/ ha); 3-Meal Plate Index (MPI), an index which compares the forage or grass available with that required for optimal livestock performance (Duarte 2020), . The result is expressed in decimal,; an MPI value of 1 means that the available grazing area equals that needed, while lower or higher values show shortages or surpluses respectively. 4-Proportion of area available for grazing at different forage height (*i.e.* generated from the proportion of area at three height ranges); this variable has three indicators: proportion of area with forage height < 2.5 cm'(PGR-2.5), 2.5 to 5 cm(PGR2.5To5) and > 5 cm(PGR5).

iPasto is developed following a basic Client-Server architecture. The website is developed using the ReactJS framework, also in JavaScript. This unifies the use of a single language for both components of the application. The database is SQL and MySQL is used to implement it. Pipelines were developed to implement CI/CD to streamline the deployment/testing/put into production process. This software gives the possibility to capture information with the desired frequency and generate a database in real time. The implementation of iPasto accumulates more than 2 years of use from June 2021 to March 2023. After the work of dissemination and training in the use of the platform, its implementation begins with 25 farms which are members of the Grassland Management Project FPTA No. 356 (Pereira Machin 2020) executed by the Instituto Plan Agropecuario (IPA). This program is extended now to more than 400 producers associated with the institution. For the descriptive analysis of its main outputs, we used the 2021-2022 and 2022-2023 seasons for the group of initial establishments of the monitoring proposal.

Results
The iPasto platform is available for users registered in Instituto Plan Agropecuario. The results in Table 1. show that the grasslands aboveground net primary productivity (NAPP) was 4534 kg DM/ha. Grass Availability (GA) was 950 KgDM /ha. The Meal Plate Index (MPI) was 0.75 and the proportion of the ranch with forage height > 5 cm (PRG5) was 27%. Meat productivity (MP) was 109 kg/ha, NAPP required to produce one kg of meat (GMP) was 46 and Meat production efficiency by stock (MPES) was 165 Kg MP for US.

PRG5 (in Figure 1) indicted there are 3 groups (High, Medium and Low Systems). High systems (PRG5=60%): GA=1440, MPI=0.85 MP=153, GMP=30, Meat production by stock unit (MPES)=175, SU=1, mainly integrated by rotational grazing management and continuous grazing with resting. Medium systems (PRG5=22%): GA=886, MPI=0.72, MP=99, GMP=51, MPES=128, SU=0.84, mainly integrated by continuous grazing with breaks (grazing with rest periods, no grazing). Low systems (PRG5=5%): GA=642, MPI=0.71, MP=87, GMP=50, MPES=154, SU=0.6, correspond mainly to continuous grazing. Therefore, high systems have the best values for grass use efficiency (GMP and MPES), linked to improved values of GA, MPI, PRG5, MP and SU. In low and medium systems, MP and MPES are improved when MPI, GA and SU are improved and when a rotational grazing module is included in the continuous grazing. There is a positive trend in the MPES as MPI gets higher in March and June for all the ranches.

Table 1. Index averages 2021/2022 and 2022-2023

	2021-2022	2022-2023	AVERAGE
NAPP (KgMS/ha/year)	4901 [3290-6558]	4167 [2163-5226]	4534
GA (KgDM/ha)	1015 [336-3415]	885 [208-1951]	950
MPI [0 To 1.2]	0.79	0.70	0.75
SU (KgLive Weigh)	307	323	315
MP (Kg/ha/year)	113	105	109
GMP (KgDM/Kg of MP)	46	47	46.5
MPES (Kg/Stock Unit)	149	141	145

(NAPP: aboveground net primary productivity, GA: Grass Availability, MPI: Meal Plate Index, SU:Stock Animal Unit, MP: Meat productivity, GMP: ANPP required to produce one kg of meat MPES: Meat production efficiency by stock)

Discussion
iPasto is a tool that allows data capture and generates simple indicators that assist in the management of forage resources. The database is enriched daily, which offers the possibility of including artificial intelligence (AI) to develop automatic processes that improve accuracy in the estimation of existing and future indicators. It has the potential, through scaling up to the national level, to become a free platform with institutional backing and support to improve decision-making in adaptation processes and contribute to efficiency in the use of forage. High systems have the best values for grass use efficiency (GMP and MPES), linked to improved values of GA, MPI, PRG5, MP and SU. In low and medium systems, MP and MPES are improved when MPI, GA and SU are improved and when a rotational grazing module is included in the continuous grazing. There is a positive trend in the MPES as MPI gets higher in March and June for all the ranches.

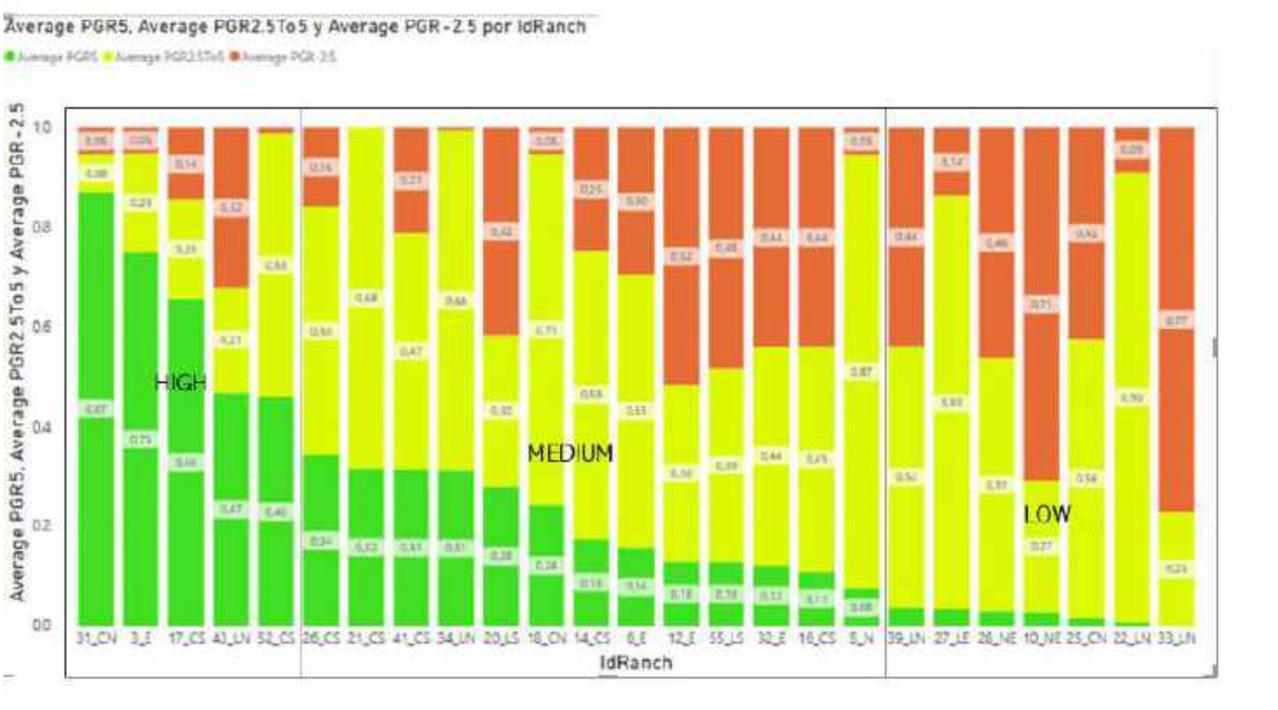

Figure 1. PGR5 evolution 2021/2022 and 2022/2023 by 25 ranches.

Regional Headquarters Palmira Campus Cali –Palmira, Colombia; [4] Caritas, Regional Office – Central Asia

Key words: Image processing; digital photography; rangeland assessment; geotagged photographs; community engagement.

Abstract

Monitoring rangeland vegetation is essential for sustainable land management, biodiversity conservation, and climate change mitigation. Traditional vegetation monitoring methods often require extensive fieldwork, which can be time-consuming and costly. Crowdsourcing, which leverages the collective power of a large number of volunteers, offers a promising alternative. This study examines the effectiveness of using crowdsourcing to collect geopositioned images for monitoring rangeland vegetation. By engaging herders and pastoralists with smartphones featuring built-in GPS capabilities, a substantial dataset of geotagged photographs from diverse rangelands was amassed. These images were transferred to a central repository when an internet connection was available, ensuring continuous data flow from even the most remote areas. Subsequently, the images were analysed using advanced image processing and machine learning techniques to assess vegetation and ground cover in near real time. Preliminary results indicate that our protocol can provide high spatial and temporal resolution imagery, which complements traditional monitoring methods by offering more immediate and detailed insights. These images also serve as ground truth for supervised classification of large-scale remote sensing satellite scenes. Additionally, this approach enables sampling of inaccessible remote areas while promoting community engagement and environmental awareness among pastoral communities. The necessary steps for implementation are discussed, along with examples from various locations. The findings highlight the potential of crowdsourcing as a cost-effective and scalable tool for rangeland monitoring and management, showcasing its ability to enhance both data quality and stakeholder participation.

Introduction

Vegetation canopy cover is a critical biophysical indicator for assessing rangeland condition. It protects the soil surface and influences key ecological processes such as rainfall infiltration, soil erosion reduction, soil respiration, sunlight interception, and wind erosion, thus supporting overall ecosystem functionality (Spaeth Jr, 2020; Park et al, 2024). Additionally, vegetation cover is a vital measure of rangeland health, closely correlated with climate conditions (Almalki et al, 2023). Its composition and structure, which directly impact rangeland productivity, are influenced by grazing practices and other human activities (Sanaei et al, 2018).

Assessing changes in vegetation cover is fundamental for understanding the interaction between environmental and climatic conditions, human activities, land-use practices, and natural ecosystems (D'adamo et al, 2021). Monitoring these changes over time provides valuable information that informs effective management planning and promotes sustainable resource utilization (Azarm et al, 2021). Data on vegetation cover changes are crucial for predicting future trends and establishing a long-term framework to enhance decision-making and resource management (Shi et al, 2022). Therefore, the availability of accurate, up-to-date information is essential for supporting effective monitoring, planning, and management efforts in rangeland ecosystems.

However, quantifying ecosystem parameters to track conditions and trends remains challenging, time-intensive, and costly, resulting in limited detailed records for many areas worldwide. To address these challenges, this paper presents a procedure for local scale monitoring that documents rangeland conditions in near real-time. By integrating crowdsourcing, geopositioned digital images, and advanced image processing software, we enable the rapid sampling and recording of vegetation, litter, and soil parameters. VegMeasure®, an image analysis tool developed to monitor vegetation cover over time (Louhaichi et al, 2001; Louhaichi and Hassan, 2018), serves as a component of this process. This approach offers a practical, efficient, and scalable solution for enhancing rangeland monitoring and management.

Methods

The VegMeasure® software offers an efficient and cost-effective solution for estimating rangeland vegetation parameters and conducting non-destructive monitoring. To facilitate data collection, three pastoralists were equipped with smartphones featuring GPS-enabled 16-megapixel digital cameras. Participants received training on proper image acquisition techniques before starting data collection.

Images were captured using a pole-mounted camera to maintain a consistent height, as recommended by Booth et al. (2004) (Fig. 1a). When a pole was unavailable, handheld images were taken at a comfortable height (Fig. 1b). The pastoralists were trained to hold the smartphones vertically to ensure accurate GPS georeferencing during image acquisition. Each pastoralist captured images across their respective rangeland locations, ensuring diverse coverage of vegetation and bare ground conditions. Captured images were uploaded to a designated repository once a Wi-Fi connection was available and were subsequently processed using VegMeasure® software. The software employed a supervised classification method, assigning each pixel in an image to a specific class type based on predefined categories, enabling the classification of different land cover types. While VegMeasure® can classify ground cover into multiple categories, including vegetation, bare ground, rocks, and litter (Louhaichi et al, 2018), this study utilized a simplified two-class system, focusing on vegetation cover and bare ground. Classification accuracy was assessed using the accuracy assessment tool in VegMeasure®, which computes an error matrix and derives the Kappa Index of Agreement to quantify classification reliability. Stratified random sampling was applied, selecting 180 points per class from 50% of the images to validate the accuracy of the classified outputs.

Fig. 1a: Technical staff from Sughd Province - Tajikistan using a pole for taking straight down images.

Fig. 1b: Pastoralist from Rasht valley in Northeastern Tajikistan, taking images using a smartphone.

Results

A total of 180 images, with 60 captured by each pastoralist (which accounted for approximately 70-75% of their total images) in the Rasht Valley, were analyzed after excluding those that were not vertically oriented or were affected by shadows to ensure the quality and consistency of the dataset. The analysis revealed notable differences in vegetation and bare ground cover across the areas managed by the three pastoralists. The first pastoralist's images showed an average vegetation cover of 60%, with values ranging from 50% to 65%, while bare ground accounted for the remaining 40%, ranging from 35% to 50%. The second pastoralist's images exhibited a significantly higher average vegetation cover of 70%, with a range of 59% to 81%, and a correspondingly lower bare ground cover of 30%, ranging from 19% to 40%. In comparison, the third pastoralist's images indicated an average vegetation cover of 53%, with bare ground making up 47%. The classification accuracy of the analysis was consistently high, ranging from 95-99% (Fig. 2 a, b).

Fig. 2a: Straight down image of Tajikistan grassland (before).

Fig. 2b: Processed image using VegMeasure software (after): plant cover 78.5%, bare ground 21.5%, classification accuracy: 98%

Discussion

The results demonstrate the potential of using readily available smartphone technology, paired with VegMeasure software, for efficient and cost-effective assessment of rangeland vegetation cover in the Rasht Valley of Tajikistan. The variation in vegetation cover across rangelands, where pastoralists graze their animals, highlights the spatial heterogeneity typical of rangelands, particularly in terms of plant cover. This variation emphasizes the need for localized monitoring and tailored management strategies (Bestelmeyer et al, 2019).

This approach offers a significant advantage over traditional methods, as it reduces the labour-intensive and time-consuming aspects of rangeland assessment (Yu and Guo 2021). Additionally, it allows for continuous monitoring over time, enabling the study of both current and past conditions (Hu et al, 2024). Each image captured includes GPS location data, providing a valuable tool for tracking changes in vegetation cover and informing management strategies However, changing weather conditions like snow and rain, uneven rangeland geography, maintaining the phone's level and angle, and issues with shadows and lighting were challenging for pastoralists taking photos.

Despite these challenges, the simplicity of image acquisition—requiring only basic training in proper image capture techniques—makes this approach easily accessible to local communities, empowering them to actively participate in monitoring their rangelands. Furthermore, this participatory approach fosters knowledge sharing and facilitates communication of rangeland conditions to local authorities, which is essential for effective decision-making and sustainable rangeland management.

Conclusions/Implications

Integrating geo-referenced images collected through community networks can play a pivotal role in the sustainable management and restoration of Tajikistan's rangelands and ecosystems. This approach not only has the potential to significantly reduce monitoring costs but also facilitates the generation of detailed datasets critical for tracking site changes and trends over time. It enables seasonal or annual revisits to monitored sites, providing insights into the spatial and temporal impacts of natural and human interventions. Moreover, it standardizes ground cover estimates across sites, overcoming the limitations of traditional visual assessments. Ultimately, this method supports both ecological restoration efforts and the empowerment of local communities.

Pastoralist piloted drone monitoring – drones as a tool not a toy

Marver, RM[1]; Singh, HS[2]

[1] Contour Environmental and Agricultural Consulting, Northcliffe Western Australia; [2] Contour Environmental and Agricultural Consulting, Perth Western Australia

Keywords: Drones; Livestock; Rangelands; Precision

Abstract

Landscape management is at the heart of what pastoralists do. Ultimately the viability and sustainability of pastoral businesses is based on how their landscape functions and responds to rainfall. Core to the concept of improving landscape function in a rainfall limited climate – Rainfall Use Efficiency. Management strategies that improve Rainfall Use Efficiency such as regenerative grazing and erosion control techniques can be implemented on any property but need to be done so in a targeted and informed way. The challenge in achieving good landscape management comes not only in knowing what to do but more importantly when to do it. This is particularly challenging given the variable climatic conditions and diverse landscape types experienced in the Pilbara.

Emerging Ag Technologies are providing tools and data that make managing the variability easier. Drone technology is a rapidly growing industry and is becoming increasingly accessible. Drones present an opportunity to gather information about your landscape in a repeatable, reliable and efficient way, and to use that information to make informed decisions about your landscape management.

With funding from the Southwest WA Drought Resilience and Innovation Adoption Hub, Contour Consulting has developed a new tool that is pastoralist-friendly and allows for more informed pasture assessment and calibration of your stocking decisions. The process is end-to-end, from establishing monitoring sites through to follow-up support, and is tailored to your property.

The tool provides quantitative pasture and landscape condition data through repeatable assessments that will give land managers direction and confidence to make proactive grazing management decisions. It also creates a database of evidence that could be used in documenting improved management as part of a carbon or natural capital project.

Introduction

Australian Rangelands span an impressive area of 6,300,000 km^2 area and represent a diverse array of vegetation types. Despite this diversification, they function as a cohesive natural ecosystem which is primarily utilised for grazing livestock (Wilson, 1988). Australian Rangelands are incredibly vast, requiring modern solutions for precision agriculture to monitor these areas effectively. Tracking the large-scale ecosystem changes is mandatory for the better landscape and livestock management. To monitor these areas, tools like drones play a crucial in the livestock production and management.

Drones have been proven to offer numerous advantages from the last 10 years as a part of precision agriculture (Zuo, 2021). The information gathered can assist the pastoralist to make quick decisions about whether to intervene to guarantee the best possible output at the end of the season. Digital, thermal, and multispectral cameras are the most often utilized types of cameras, and they are crucial in giving the necessary information on vegetation and livestock conditions (Aquilani, 2022).

Unmanned Aerial Vehicle (UAV) technology was used along with in person site assessments to develop a digital library of different sites on the Yerilla Station in the Goldfields region of Western Australia, to accelerate the process of decision-making regarding stocking numbers and pasture utilisation. On-ground photos, cattle condition assessments and remote sensing technology were integrated for better pasture management across different seasons. This Project was joint venture between Contour Consulting and the Southwest Drought Hub WA.

Methodology

Eight monitoring sites, each with 3 to 4 subsites (Figure 1), were selected for drone monitoring at Yerilla Station, 150 km northwest of Kalgoorlie Boulder in the goldfields region of Western Australia. Sites were selected using a combination of geospatial desktop analysis and in consultation with the station manager. Detailed information about the land system, pasture type, current pasture condition, occurrence of erosion and its extent/type, and important indicator species i.e. increaser and decreaser species were recorded during an initial on-ground visit to each of the sites. Rainfall data is being recorded by installing rain gauges on each of the sites. Subsites were selected in areas that had a higher probability of responsiveness to the changing seasonal conditions and management. Observations were made about the grazing extent, palatable species, micro-habitat areas and recruitment rate of desirable species. This data forms the basis for the land manager to be able to interpret and identify pasture condition changes through reassessment.

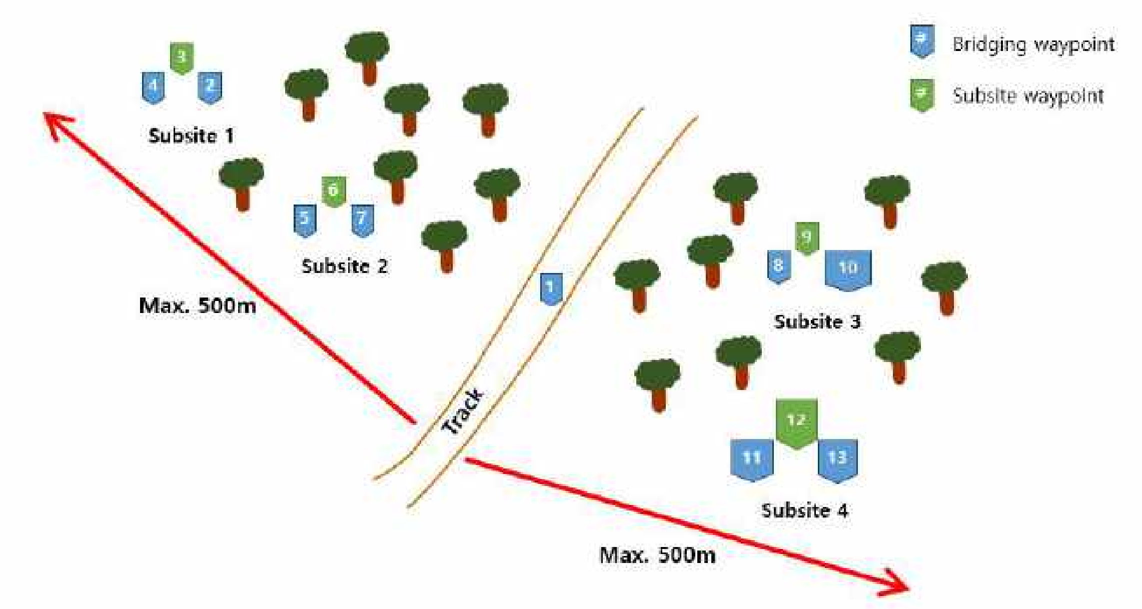

Figure 1: Setting up the monitoring site along with 4 different subsites

Autonomous flight waypoints were setup to capture an RGB photo of each subsite using the off-shelf drone technology and a drone programming app 'Litchi for DJI Drones' (Figure 2). Photos are taken at or above the canopy height to allow for monitoring of understorey species. Birdseye photos can be used to assess ground cover in grassland sites.

At Yerilla, photos of each subsite were captured monthly in a repeatable manner to build up a library for monitoring the growth of the palatable species, changes in the pasture and indicator species for grazing management decisions. A 'rolling rainfall to stocking rate' spreadsheet was developed to assist the station manager in monitoring rainfall and current stocking rates. Using the station's median rainfall data, this tool compares the current stocking rate to the suggested rate (Figure 3). This tracker offers useful information for making well-informed stocking decisions, such as whether to move stock into or out of an area based on pasture conditions and recent rainfall when paired with monthly photos. An assessment sheet is used as go-to-go record keeper for all the observations and action during assessment or re-assessment of a monitoring site. Information about desirable/undesirable species, rain gauge reading, temperature and any adjustment made to the stocking numbers are recorded to keep all the crucial details in check for better site evaluation process.

Figure 2: Flight path simulation of a monitoring site in the Litchi app for DJI drones.

Results

Using drones as a part of modern precision agriculture has made the process of decision-making more efficient and faster. Reassessment of sites takes approximately 8-10 minutes. The data collected through the monitoring system supports land managers to proactively manage grazing across their property. During dry seasons, feed requirements for stock can be budgeted with the assistance of drones as a part of pre-planning. To prevent overgrazing, the Yerilla station manager now employs this technology with confidence for prompt livestock movement. This economical approach has the potential to be widely used. In addition to helping the cattle industry achieve high welfare outcomes and production targets, it offers to improve rangeland conditions over the long term and manage rangelands for drought resistance. Pastoralists from all around WA, including those from the Pilbara, Kimberley, and Goldfields-Nullarbor regions, have expressed their interest in learning more about the package.

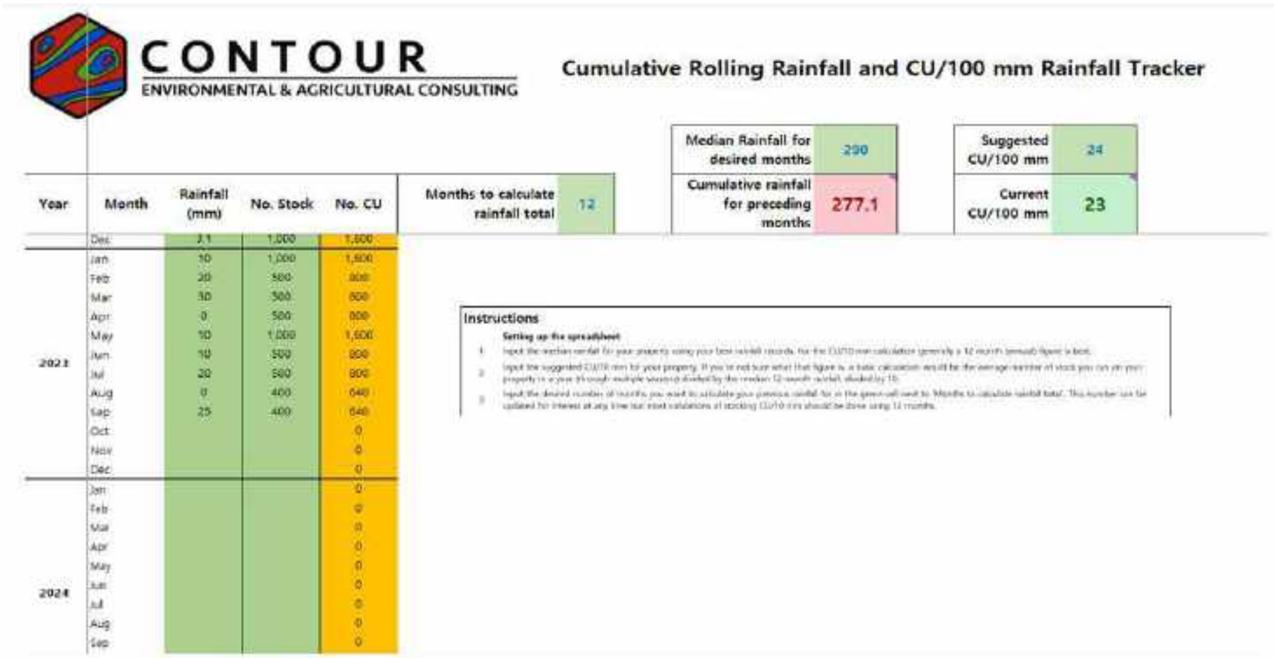

Figure 3: Cumulative Rolling Rainfall and Cattle Units/100 mm rainfall tracker

Conclusion

In conclusion, drones have revolutionized the precision agriculture methods and the way pastoralists manage their stock. UAVs assist pastoralists by keeping track of their livestock, monitoring the land's condition and identifying potential threats with a bird's eye view. The use of aerial imagery technology may help managers to not only increase productivity, but also enhance sustainability in the pastoral industry. The data-driven decisions have improved time management, which is a crucial factor for pastoralists. This modern precision agriculture tool can help to mitigate the risk associated with droughts or harsh weather conditions, ensuring the longevity of the rangeland operations and better management of the livestock. Ultimately, the adoption of UAVs represent an analytical thinking approach that aligns with the future of Australian Rangelands, making the way for a more productive pastoral sector.

Acknowledgements

We extend our gratitude to the Growers Group Alliance (GGA) for the funding of the Yerilla Station Drone Monitoring Project, an essential initiative under the South West Drought Hub WA. We would also like thank the station manager of Yerilla Station for their willingness to participate in the Yerilla Station Drone Monitoring Project.

Key words: Back Propagation Neural Network; Support Vector Machines; Keras image classification model; radial basis function

Abstract

A robust and accurate image classification model is essential for the development of a smartphone application to help farmers identify forages from weeds. This study focused on developing and comparing three models: Keras-based deep learning, Support Vector Machine (SVM), and Back Propagation Neural Network (BPNN). A total of 1500 images of alfalfa (*Medicago sativa*), sericea lespedeza (*Lespedeza cuneata*), and weeds were used. The Keras model was tested with varying image sizes, batch sizes, and epochs. The highest performance was achieved with an image size of 128, a batch size of 8, and 100 epochs, yielding accuracy, precision, recall, and F1 scores of 99.01%, but with the highest training time of 44.25 seconds. Alternatively, using a smaller image size of 32 and a batch size of 32 with 50 epochs resulted in a lower accuracy of 98.38%, but significantly reduced training time to 9.61 seconds. The SVM model, with a Radial Basis Function (RBF) kernel, had excellent performance metrics, achieving an accuracy, precision, recall, and F1 score of 99.02%, with an exceptionally low training time of 0.059 seconds and a testing time of 0.01 seconds. This indicates the SVM's efficiency and suitability for rapid classification tasks. The BPNN model, tested with an image size of 128 and a neuron structure of over 200 iterations, achieved an accuracy of 98.36%, with a training time of 2.17 seconds and a minimal testing time of 0.0017 seconds, also showing efficient computational performance. The SVM model is recommended for the smartphone application due to its high accuracy, precision, recall, and F1 score, with its minimal computational requirements, making

it both robust and efficient. This model's attributes align well with the practical needs of farmers for quick and reliable forage identification under field conditions.

Introduction

An effective and precise image classification model is essential for assisting farmers in differentiating forages from field weeds (Islam et al., 2021). In agricultural systems, precise identification of forages is crucial for optimizing livestock feed quality, enhancing farm output, and reducing losses due to poor resource mismanagement (Monteiro et al., 2021). Conventional identification methods are frequently laborious, subjective, and reliant on specialist knowledge, underscoring the necessity for automated solutions capable of operating effectively in practical environments, such as agricultural fields and pastures (Boruah et al., 2024).

Smartphone applications with sophisticated picture classification features can provide an effective solution for farmers by facilitating the swift and accurate identification of forages and weeds (Siddique et al., 2024). The effectiveness of these applications depends on the creation of classification models that achieve a compromise between high accuracy and computational efficiency, especially considering the processing limitations of mobile devices (Zhang et al., 2019). Recent breakthroughs in machine learning, encompassing deep learning, and traditional techniques, like Support Vector Machines (SVM) and neural networks, offer intriguing opportunities for developing such tools (Zhang et al., 2019; Siddique et al., 2024).

This research highlights the urgent necessity for novel and accessible solutions for forage identification through the examination of advanced machine learning techniques. It seeks to address shortcomings in existing agricultural methods by offering a solid technology framework for precision farming instruments customized to the practical needs of farmers through utilization of machine learning approaches to determine the ideal model configuration achieving both high performance and computational efficiency. The study aim was to evaluate these models on their possible incorporation into a smartphone application for agricultural purposes, focusing on their capacity to process field data reliably and efficiently.

Methods

This study utilized a systematic approach to develop and evaluate image classification models for differentiating alfalfa and sericea lespedeza forage plants among field weeds. The dataset comprised images organized into three distinct classes. Images were preprocessed by resizing them to uniform dimensions, normalizing pixel values to a range of 0-1, and calculating fractal dimensions for enhanced feature extraction. Additional preprocessing included data augmentation techniques, such as rotation, translation, and zooming, implemented using the TensorFlow ImageDataGenerator.

Three primary modeling approaches were investigated: traditional machine learning models, a custom Keras-based deep learning model, and pre-trained deep learning architectures. Traditional models, including Support Vector Machines (SVM) and Back Propagation Neural Networks (BPNN), were trained on features extracted from the preprocessed images. Dimensionality reduction for these models was performed using Principal Component Analysis (PCA) to reduce computational complexity. The SVM models were tuned for different kernels (linear, RBF, and polynomial) and penalty parameters (C), while BPNN models were optimized for hidden layer configurations and maximum iterations. A custom Keras-based deep learning model was implemented with multiple dense layers, batch normalization, and dropout for regularization. The model was trained using the Adam optimizer and sparse categorical cross-entropy loss function. Hyperparameter tuning involved experimenting with batch sizes (8, 16), epochs (25, 50), and input image sizes (75x75, 512x512). Early stopping and learning rate reduction callbacks were employed to avoid overfitting and enhance convergence. The image data set was split into a 70:20:10 ratio as training, testing, and validation sets, respectively, for each model tested.

Performance metrics, including accuracy, precision, recall, F1-score, training time, and testing time, were recorded for all models. Hyperparameter tuning was conducted using grid search and cross-validation for SVM and other traditional models. An ensemble model combining SVM and BPNN was developed to leverage the strengths of individual classifiers. Comparative analyses were conducted to identify the best-performing configurations, and results were visualized through confusion matrices and performance plots.

Results

The results highlight the performance evaluation of three classification models—Keras-based deep learning, SVM, and BPNN—for forage identification among field plant weeds. A total of 1500 images were used to develop and test these models, with detailed performance metrics and computational requirements assessed.

The Keras model demonstrated high flexibility in parameter tuning, with image size, batch size, and epochs significantly impacting performance. The optimal configuration, using an image size of 128, a batch size of 8, and 100 epochs, yielded an accuracy of 99.01%, precision of 99.01%, recall of 99.01%, and an F1 score of 99.01%. However, this configuration incurred the highest computational cost, with a training time of 44.25 seconds. In contrast, a smaller image size of 32, batch size of 32, and 50 epochs achieved slightly reduced accuracy (98.38%), but considerably decreased the training time to 9.61 seconds. These results underline the trade-off between model accuracy and computational efficiency.

The SVM model, employing a Radial Basis Function (RBF) kernel, emerged as the most computationally efficient among the three models. It achieved accuracy, precision, recall, and F1 scores of 99.02%, with a remarkably low training time of 0.059 seconds and a testing time of just 0.01 seconds. These metrics demonstrate the SVM model's capability for rapid and accurate classification, making it highly suitable for applications requiring minimal computational resources.

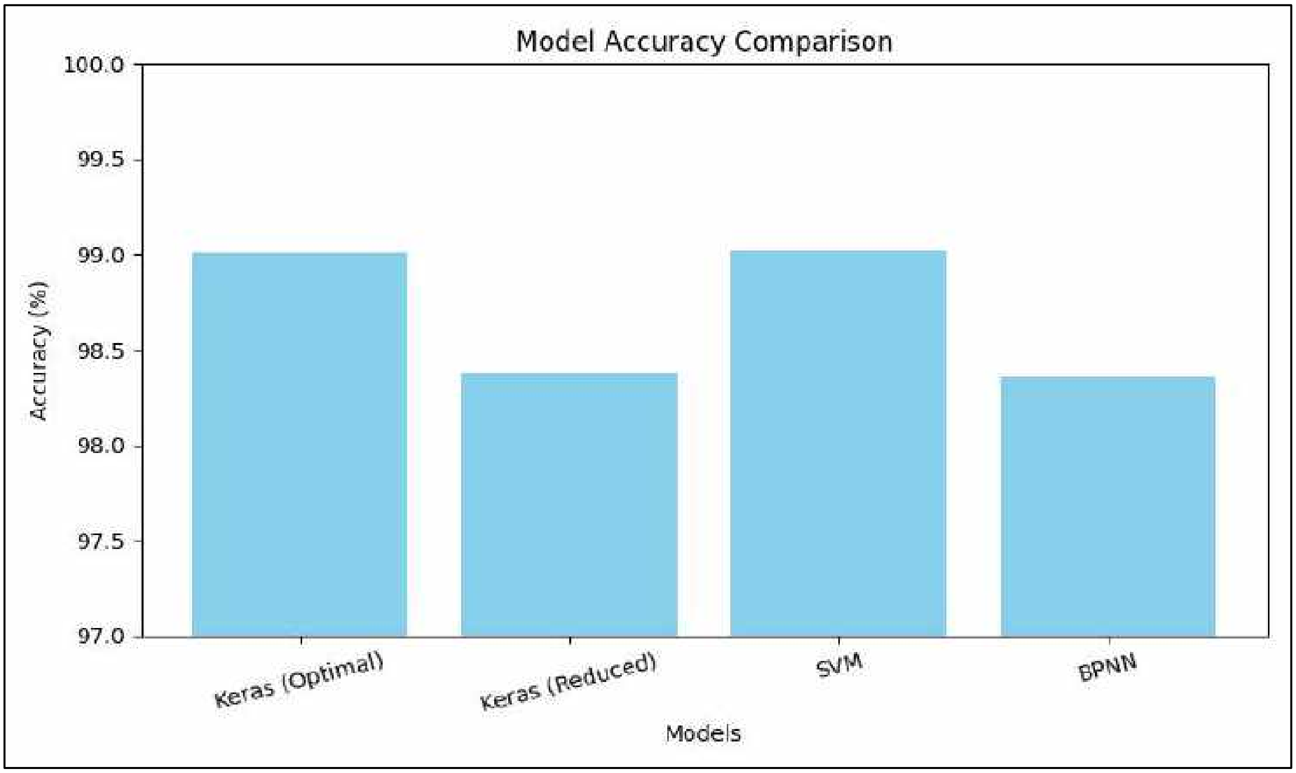

Figure 1. Graphical representation of different models for the accuracy in identification of different forage species.

The BPNN model, tested with an image size of 128 and a neuron structure across 200 iterations, achieved an accuracy of 98.36%. While its performance was slightly lower than the Keras and SVM models, it demonstrated excellent computational efficiency, with a training time of 2.17 seconds and a testing time of only 0.0017 seconds. This makes it a viable option when computational constraints are a priority.

Discussion

This study demonstrates the use of image classification in agriculture by building and assessing three machine learning models specifically designed for forage identification among field weeds. The results underscore the advantages and compromises of each model, offering an in-depth examination to inform their practical use.

The Keras-based deep learning model exhibited an accuracy of 99.01% and resilience under optimum conditions. Nonetheless, its substantial processing requirements, evidenced by a training duration of 44.25 seconds, may restrict its applicability in resource-limited settings, such as smartphones. Modifications to image and batch sizes demonstrated the model's flexibility, resulting in a small decrease in accuracy to 98.38% alongside a considerably reduced training duration of 9.61 seconds. This scalability emphasizes the adaptability of deep learning, while also revealing its reliance on accessible computer resources.

The SVM model, utilizing a RBF kernel, proved to be the most effective and feasible choice, attaining the highest accuracy (99.02%) and precision metrics, alongside extremely low computing demands. The training duration of 0.059 seconds and testing duration of 0.01 seconds render it very appropriate for real-time applications. These results corroborate previous studies highlighting the SVM's resilience and computational efficacy in managing smaller datasets and non-linear classification challenges (Khawaja et al., 2024; Siddique et al., 2024). The efficiency of the SVM model renders it an exemplary choice for the proposed smartphone application, providing farmers with a swift and dependable diagnostic instrument.

The Back Propagation Neural Network (BPNN) demonstrated exceptional performance, with an accuracy of 98.36% with low training and testing durations of 2.17 seconds and 0.0017 seconds, respectively. Its computational economy renders it suitable for situations necessitating swift processing; nonetheless, its somewhat diminished accuracy indicates it is suboptimal for high-precision jobs in comparison to SVM and Keras models. These findings validate earlier research that recognized BPNN as an efficient lightweight alternative for limited contexts (Siddique et al., 2024).

This study's main contribution is the construction and comparative analysis of machine learning models for a smartphone application designed for forage identification. The SVM model excels as the most pragmatic option because of its excellent accuracy and computational economy. This approach corresponds with the practical limitations faced by farmers, who necessitate swift, dependable, and resource-efficient solutions for agricultural production challenges. This research's ramifications also transcend forage detection, demonstrating the potential of incorporating machine learning into agricultural tools to improve production and decision-making.

Subsequent research should investigate the scalability of these models for larger and more heterogeneous datasets, along with their applicability to multi-class classification problems. Moreover, incorporating the SVM model into user-friendly smartphone interfaces could augment its practical utility, facilitating the adoption of smart farming technology. This study establishes the foundation for resource-efficient, AI-driven agricultural solutions, connecting advanced technology with practical field application.

Key words: browse; Succulent Karoo; regression analysis

Abstract

In the winter rainfall region of South Africa, browse, such as shrubs and dwarf shrubs, is vital fodder for animals during the dry season. However, understanding how much fodder these shrubs can provide sustainably is limited. Existing methods for measuring browse production are insufficient for shrubs in this region. This study focused on *Roepera morgsana*, a common but less palatable shrub in the Succulent Karoo biome. The objectives were to find the minimum measurements needed to estimate canopy volume (CVol) and its correlation with leaf dry matter (LDM). The study was conducted at Nortier Research Farm near Lambert's Bay, selecting 25 healthy, non-browsed plants. Seven measurements, including total height and canopy diameter were taken before harvesting. After harvesting, plant material was divided into edible and non-edible parts, dried, and weighed. CVol was determined using various methods, and Pearson's correlation was used to find the best formula to describe LDM. Results showed that CVol based on three measurements (total height and canopy diameter) using Penderis' formula provided the best estimation of LDM ($p < 0.0001$). An exponential regression model best predicted LDM from CVol ($p < 0.0001$), offering a reliable non-destructive method for estimating browse availability from *R. morgsana*. This research contributes to better understanding the browse production of shrubs in winter rainfall regions, providing land managers with a valuable tool for veld management. Moreover, it lays the groundwork for developing similar models for other shrub species, enhancing the sustainability of fodder resources for browsing animals in these regions.

Introduction

The Succulent Karoo and Fynbos Biomes along the west coast of South Africa, with its mediterranean climate with warm dry summers and cool wet winters, are both recognized as biodiversity hotspots with more than 6000 recorded plant species of which many are endemic (Mittermeier et al. 2011; Mucina and Rutherford 2006). The main land use along the west coast is extensive farming, with livestock and to a smaller degree game species. The sustainable utilisation of this natural resource is thus very important. Browse, such as shrubs and dwarf shrubs, is vital fodder for animals during the dry season, as it is the main perennial growth form utilised as fodder in this area (Nenzhelele et al. 2020). However, understanding how much fodder these shrubs can provide sustainably is limited. Non-destructive methods have previously been developed to determine the browse production of savanna trees and some shrubs (Penderis 2012; Smit 2014) and dwarf shrubs in the Nama Karoo (Malan 2015; Smit and Janse van Rensburg 2021), but no techniques exist for shrubs in the winter rainfall region. Smit (1989, 2014) and Penderis (2012) found a relation between canopy volume of the trees and shrubs and their leaf dry mass, while Smit and Janse van Rensburg (2021) found that canopy diameter and the leaf dry mass of a dwarf shrub was highly correlated.

This study focused on *Roepera morgsana,* a less palatable shrub species that is common along the West Coast and other parts of the Succulent Karoo. This species sheds most of its leaves early in the dry season but is among the first to produce new, palatable growth. It grows up to 1.5 m high, is multi-branched and has mesophyllous, slightly fleshy leaves (Le Roux 2015).

The objectives of this research were to determine the least number of measurements necessary to calculate canopy volume (CVol) with the best fit to leaf dry matter (LDM), and to determine the relationship between CVol and LDM and develop a regression model that best predicts LDM.

Methods

Study site

The study was conducted at Nortier Research Farm (32.0345° S; 18.3324° E) situated in the West Strandveld bioregion and Lambert's Bay Strandveld (FS1) vegetation type with many elements of both the Succulent Karoo and Fynbos biome (Mucina and Rutherford 2006). The long-term average annual rainfall is 200 mm with 64% received during late autumn and winter.

Data collection

Twenty-five healthy, non-browsed *R. morgsana* plants were randomly selected at the end of the peak growing season in early October. Seven measurements of each plant were taken before harvesting, namely total height (HT), height at maximum canopy diameter (HM), height of first leaves or potential leaf-bearing stems (HL), maximum canopy diameter (D; average of two perpendicular measurements) and base diameter of foliage at height of first foliage or potential leaf-bearing branches (B; average of two perpendicular measurements). After the measurements were taken the plants were cut down at ground level, and plant material was divided between edible (leaves, and twigs < 2 mm in diameter) and non-edible (stems > 2 mm diameter) parts per individual, dried to a constant mass at 70 °C and weighed. Canopy volume (CVol) was determined according to the BECVOL method (Smit 2014), Penderis' method (Penderis 2012) and basic ellipsoid and cylinder volume formulae.

Data analysis

Pearson's correlation was used to determine the volume formulae that best describe leaf dry matter (LDM). Three regression models, namely linear ($Y = a + bX$), exponential ($Y = a*e^{b(\ln X)}$) and multiplicative ($\ln Y = \ln a + b(\ln X)$), where Y = LDM (kg) and X = CVol (m^3), were tested to determine which volume formulae predict the LDM the best. The linear regressions were performed with XLSTAT (Addinsoft 2023), while the non-linear regression procedure (PROC NLIN) of SAS software (version 9.4; SAS Institute Inc, Cary, USA) was used to fit exponential functions to the data. The natural logarithmic values of CVol were used in the exponential and multiplicative regression models to change the line from convex to concave to get a better fit of the model (Smit 2014).

Results

Pearson's correlation matrix showed that CVol with three measurements (HT and D) using Penderis' formula was the best explanatory variable to describe leaf dry matter ($r = 0.933$; $p < 0.0001$) compared to the other measured shrub dimensions.

All the data points for each model of the three regression models fall within the 95% confidence intervals of the observed data and has very high coefficients of determination values ($r^2 > 0.87$) (Fig. 1). The exponential regression model ($Y = 0.678*\exp^{0.663(\ln X)}$) gave the best prediction of LDM ($r = 0.957$; $p <$ 0.0001; RMSE = 0.163; AIC = -86.688) compared to the linear and multiplicative regression models (Table 1). The square root of variance of residuals (RMSE) is a good measure of how accurately the model predicts the response, while Akaike information criterion (AIC) is used to compare different possible models and determine which one is the best fit for the data. The lower these values are the better the fit of the model (Archontoulis and Miguez 2015).

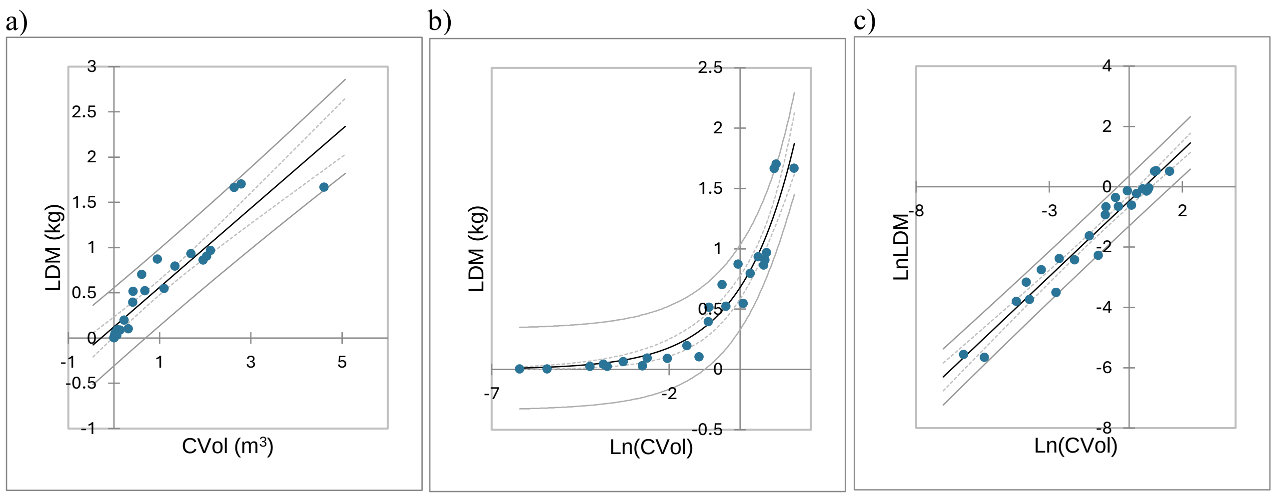

Figure 1: Three different regression analyses (a = linear; b = exponential; c = multiplicative) of the relationship between CVol (m^3) and the LDM (kg) for *Roepera morgsana* following Penderis' formula. The natural logarithm conversion of CVol were used for the Exponential and Multiplicative regression analyses. (Model; --- Confidence interval (mean 95%); Confidence interval (observed 95%))

Table 1 Results of the regression analyses of the relationship between CVol (m^3) and LDM (kg) of *Roepera morgsana* following Penderis' formula.

Regression model	***n***	***r***	***R²***	***p***	**a**	**b**	**RMSE**	**AIC**
Linear	25	0.933	0.870	< 0.0001	0.125	0.437	0.202	-78.051
Exponential	25	0.957	0.915	< 0.0001	0.6799	0.6633	0.163	-86.688
Multiplicative	25	0.977	0.955	< 0.0001	-0.470	0.836	0.391	-45.081

Discussion

Smit (2014) used seven measurements to determine the canopy volume of trees, Penderis (2012) found similar results with only six measurements. Smit and van Rensburg (2021) used only three measurements (HT and D) to find highly significant correlations between CVol and LDM of dwarf shrubs in the Nama

Karoo. *Roepera morgsana* has a similar shape to dwarf shrubs, although it is a much larger plant, and therefore a highly significant correlation between CVol and LDM was found with the same three measurements. Fewer measurements will result in less field work and make the model more attractive for use by land managers, and at the same time ensure that the predictive quality of the model is not sacrificed (Penderis 2012).

The exponential regression model provides a reliable non-destructive method for estimating the browse availability from *R. morgsana*. Available browse is that plant material of a shrub that is potentially edible for browsers based on the height above ground level to which the browsing animals can reach (Penderis 2012). Smit (1989) and Penderis (2012) developed different models, using their measurements for canopy volume, to determine the available browse at the different feeding levels. At 1.5 m high parts of *R. morgsana* is out of reach for sheep, the most common livestock along the west coast, that only browse up to 1.0 m high (Du Plessis et al. 2004). Using Penderis' formula for canopy volume in the regression model allows one to determine the available browse of *R. morgsana* at a specific height above ground level. Knowing the production potential of the vegetation can contribute to the success of sustainable extensive farming with livestock and wildlife (Penderis 2012; Smit 2014).

Conclusion and Implications

This research contributes to better understanding the browse production of shrubs in winter rainfall regions, providing land managers with a valuable tool for range management. Moreover, it lays the groundwork for developing similar models for other shrub species, enhancing the sustainability of fodder resources for browsing animals in these regions.

Sustainable management to reduce grasslands grazing pressure and improve household income in northern China

Yuping Rong[1]

[1]College of Grassland Science and Technology, China Agricultural University, Beijing China 100193

Key words: Farm optimized model; household production; lambing time; pen feeding; seasonal grazing.

ABSTRACT:
Analyses of the status of current livestock production and alternative management practices for livestock production can help farmers improve their farming systems based on their particular local resources and markets. The farm surveys and parameterization of the models were developed by scientists and farmers working together to evaluate the effects of finances, grassland management, animal management and changes in farm infrastructure. Our study aimed to utilize bioeconomic models to optimize farm and livestock production systems in the agro-pastoral area in northern China. These analyses will hopefully lead to improved incomes, provide workable options for farmers and policy makers to restore grasslands and result in sustainable utilization of China's grassland resources.

To examine possible ways to sustainably manage grassland in the agro-pastoral areas, a formal survey of sheep farmers was conducted, and data from experimental trials were obtained in Hebei Province of northern China. The model of farm management analyzed annual feed supply and demand and showed that the gap in the annual feed supply and demand could be reduced by using improved sheep breeds for meat production instead of current breeds. Economic analysis showed that maximal profits could be achieved by using a combination of seasonal grazing at a grazing intensity of 5.4–6 sheep ha^{-1} and pen feeding. In addition, changing lambing time to November would reduce grazing pressure during the summer, which will be beneficial for grassland restoration and enhanced ecosystem services.

By obtaining accurate on-farm information from pastoralists and using these data to parameterize two models, realistic changes in management strategies were identified that could increase farm income and reduce grassland grazing pressure. This activity increased public awareness of optimized farm management tools and provided a sound basis for identifying management alternatives for the sustainable management of grassland resources.

Introduction

Traditional livestock management practices in northern China are often based on survival through the year rather than producing goods for a market and running the farm as a business. What happens on these grasslands has important implications for millions of people in this region of China, and also safeguards the northern and the southeast cropland region of China. Analyses of the status of current livestock production and alternative management practices for livestock production can help farmers improve their farming systems based on their particular local resources and markets (Takahashi et al. 2011; Komarek et al. 2012; Zheng et al. 2013). Model analysis of farm production provides a valuable tool for both government officials and farmers to optimize natural resource use for livestock production. Model solutions have been used to try and guide farmers to increase market access and develop quality standards, thereby making livestock production more profitable Parsons et al. 2011; Komarek et al. 2012; Zheng et al. 2013). The objective of our study was to utilize bioeconomic models to optimize farm and livestock production systems in the agro-pastoral area of Fengning County, Hebei Province in northern China. The farming analysis model was developed by scientists and farmers working together in the northern grassland area of China to evaluate the effects of finance, grassland and animal management and farm infrastructural changes (Kemp et al. 2011). The objective of our study was to utilize bioeconomic models to optimize farm and livestock production systems in the agro-pastoral area of Fengning County, Hebei Province in northern China. These analyses will hopefully lead to improved incomes, provide workable options for farmers and policy makers to restore grasslands and result in sustainable utilization of China's grassland resources.

Methods

Data to parameterize the models were obtained from various sources, including farm surveys, published information, expert opinions and field trials (Ma et al. 2014). Several functional relationships between various biological parameters and either grassland condition or livestock condition were derived using experimental trials in the local area (Figure 1).

Data collected from the farm surveys and field trials were used to parameterize two models: StageONE Feed-Balance Analyser Model and StageTWO Optimising Model (Takahashi et al. 2011). The model uses metabolisable energy to link feed supply, demand and utilization. Both models derive net farm livestock financial returns for the starting conditions using biophysical and financial data.

Results

Current sheep production system in Fengning County

In the southeast portion of the Mongolian Plateau, Hebei fine-wool sheep and small-tail sheep crossed with Mongolian sheep are the dominant livestock. The typical farm averages 5 to 8 ha of land for fodder (typically maize silage, oats, wheat and potatoes), and about 700 ha of grassland is communally used by the village. Lambs are born from January to March and sold at about 8 to 12 months of age, according to the herder's need and market price. Grassland is continuously grazed at a stocking rate of 4.0 sheep ha^{-1} throughout the year, resulting in very high grazing pressures. Though a few small household farmers feed sheep during winter, energy and nutrient deficiency are typical from late-September to May because of poor forage nutrition and animal management (Figure 2a).

Figure 1 Study location of Fengning County, Hebei Province in northern China.

Options for farm improvement using different sheep breeds

In recent years, most farmers switched their focus to meat production due to the favorable mutton market. Farmers prefer small-tail sheep to other varieties because of the high birth rate, though this variety is not good for meat production. Given the poor nutrition of animals during winter and the high cost of purchased fodder, one alternative strategy is to use sheep varieties with good meat production. Some local farmers have crossed local ewes such as small-tail sheep with German Merino rams or Dubo rams for improved meat production. These crosses can increase live-weight gain with grazing during the summer and pen feeding in winter. Data from these new sheep breeds and the pen feeding trial were used to re-run the StageONE Model. The model results showed that the energy gap between maintenance and actual feed intake was narrowed (Figure 2b).

Options for farm improvement by changing lambing time

Results from the StageONE Model showed that lambing in January through March resulted in a sub-maintenance level of energy intake for ewes during most of the year (Figure 3a). Lambing in Jan. would be predicted to result in a major feed deficit from January through April (60% of maintenance). April lambing (Figure 3b) was closer to the maintenance level during November to February, but resulted in a large feed deficit during March to June (50% of maintenance). Lambing in June (Figure 3c) enabled an improved feed equivalent during winter and spring; however, intake did not meet maintenance levels during summer grazing in June and July. Lambing in November (Figure 3d) allowed intake to reach maintenance levels for nearly the entire year. This strategy might be further improved by possibly selling lambs and cull animals earlier (3 to 4 months of age) and by providing good nutrition in feeding pens. By lambing in November, pregnant ewes would have a greater probability of accessing higher quality forage during the summer, resulting in a higher lamb birth weight.

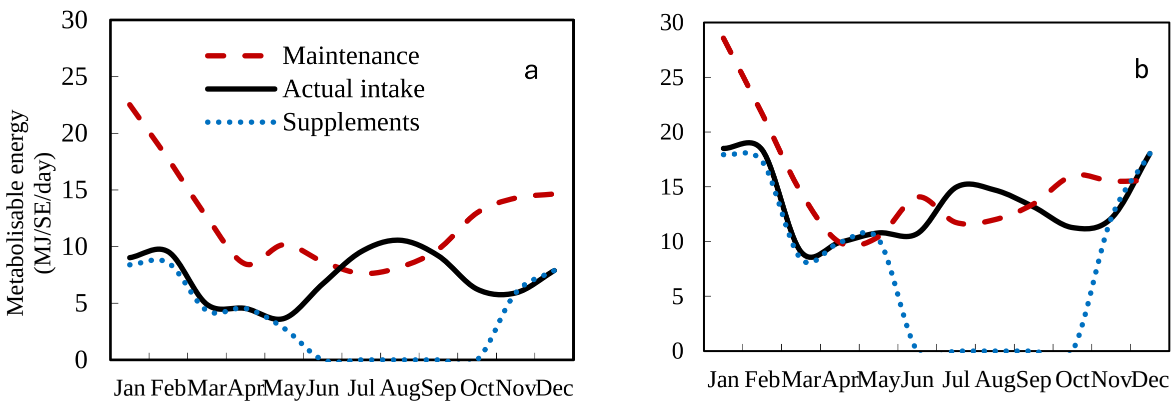

Figure 2 Metabolisable energy (ME) requirement, total ME intake and ME from supplements at the same live-weight per sheep equivalent for a typical farm in Fengning County, Hebei Province: a) current farm production and b) farm production using an improved sheep breed. (Note: Total ME intake is the intake of forage plus supplements. Ewes lambing in January).

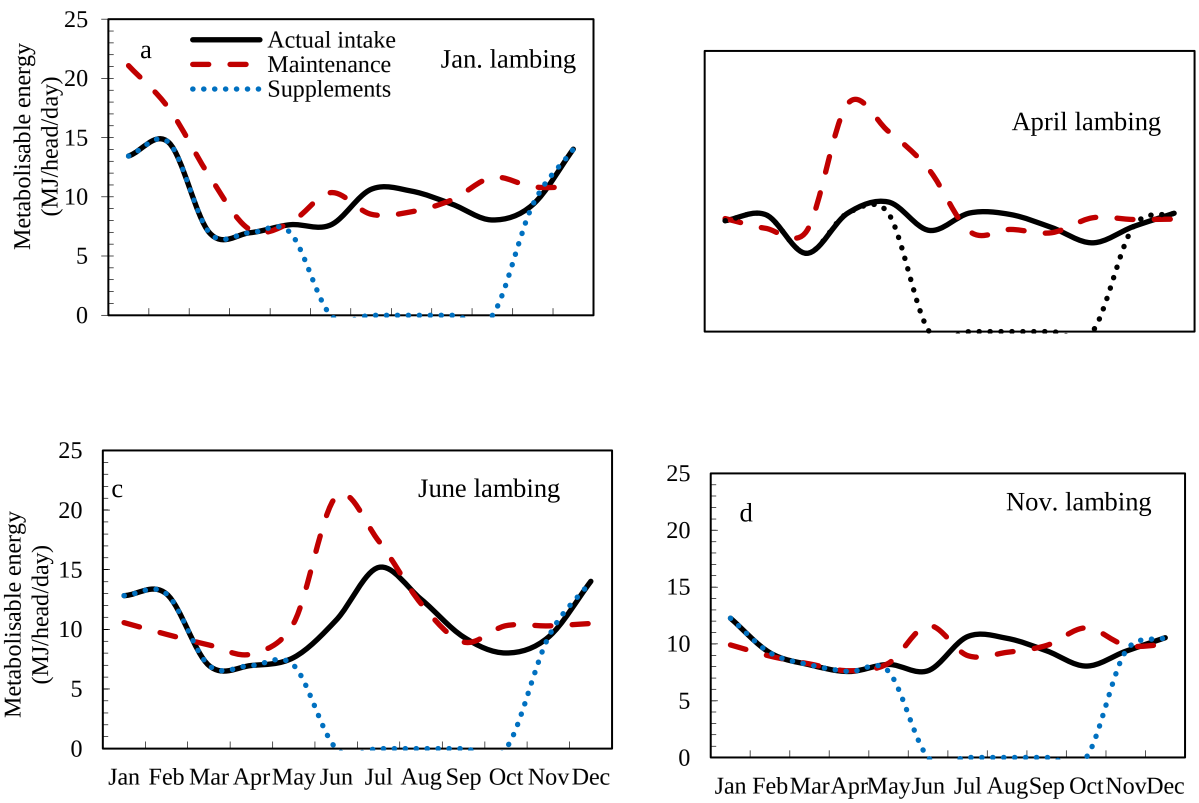

Figure 3 The effect of lambing time on feed energy balance for ewes in Fengning County, Hebei Province for: a) lambing in January (typical practice), b) lambing in April, c) lambing in June and d) lambing in November. With pen feeding from 15 Oct. to 15 June, feeding oat hay at 0.2 kg/day/head, alfalfa hay at 0.5 kg/day/head, maize grain at 0.1 kg/day/head, and other protein sources at 0.1 kg/day/head (ME = metabolisable energy).

Discussion

A key issue for managing livestock is maintaining a balance between livestock feed requirement and livestock feed availability (Darnhofer et al. 2010; Ma et al. 2014). Efforts to achieve this balance typically focus on increasing the forage and feed available to livestock and improved livestock performance through breeding (Herrero et al. 2009). Based on our local farm survey and the application of *StageONE* and *StageTWO* Models, we identified several strategies that may be beneficial for improving sheep management in northern China.

Analyses of the current livestock production status and alternative production management strategies through on-farm surveys and the application of model analysis showed the following changes should be made to the current farming system: 1) grasslands should only be grazed during the growing season, 2) pen feeding should be done during the non-growing season and 3) lambing time should be changed. These changes would better match local resources and lamb markets. The farm surveys and parameterization of the models were developed by scientists and farmers working together to evaluate the effects of finances, grassland management, animal management and changes in farm infrastructure. By obtaining accurate on-farm information from pastoralists and using these data to parameterize two models, realistic changes in management strategies were identified to increase farm income and reduce grassland grazing pressure. This activity increased public awareness of optimized farm management tools and provided a sound basis for identifying management alternatives for the sustainable management of grassland resources. Hopefully this process can be applied in other regions of China to more sustainably manage China's vital grassland ecosystems and improve the livelihood of pastoralists.

Soil microbial community and functionality in response to degradation in alpine grassland: a meta-analysis

Key words: grassland degradation; microbial diversity; microbial adaptation; nitrogen cycling

Abstract

Alpine grasslands have undergone severe degradation over the past half century. Investigating the changes in soil microbial communities is crucial for developing effective restoration strategies in degraded grassland. In this study, we synthesize data from 36 studies worldwide and show that soil microbial alpha and beta diversity did not show significant response to grassland degradation. However, we found increases in the relative abundance of bacteria related to adaptation to extreme environments, e.g., *Gemmatimonadetes*, but decreases in the relative abundance of sensitive fungi taxa (e.g., *Basidiomycota*) following degradation. Additionally, we observed a decline in soil functions related to nitrogen decomposition and fixation under heavy degradation. Overall, these findings advance our understanding of the impact of grassland degradation on soil microbial communities and their functions across a large scale. This study highlights the importance of restoring soil microbial communities in degraded grasslands to sustain soil function. Future research should develop suitable practices associated with microbial inoculation or regulation to facilitate grassland restoration.

Introduction

Alpine grasslands are experiencing serious degradation due to the dual impacts of climate change and human activities. Soil microbial communities are of great importance for ecosystem functions, for instance, nutrient cycling. Usually, significant changes in soil microbial diversity and community structure will occur following degradation in temperate grassland. However, previous studies did not observe directional changes in soil microbial community composition in alpine grassland. For example, a previous study suggest that there was a decrease in bacterial richness after degradation (Wang *et al.*, 2021), while another study found bacterial richness did not show significant response to degradation, and the response of fungal richness varied by site (Che *et al.*, 2019). Given that the variance in microbial diversity and community composition induced by grassland degradation can dramatically suppress ecosystem functions (Breidenbach *et al.*, 2022), there is an urgent need to uncover the general response of soil microbes to degradation at a global scale when restoring degraded grasslands. We aimed to systematically assess the response of microbial communities to degradation in alpine grassland through Meta-analysis. This study will provide a scientific basis for formulating ecological protection and restoration strategies.

Methods

Data collection

We searched Web of Science (WoS, http://apps.webof knowledge.com/) in January 2024, with the following topic search ((grassland OR alpine) AND (micro* OR bacteria OR fungi OR AMF OR arbuscular mycorrhiza* fung* OR AM fung* OR AM symbiosis) AND (degrad* OR degenerat* OR deteriorat* OR deplet* OR restor* OR recover* OR reestablish* OR rehabilitat* OR renew*)). This search yielded more than 14,000 records. To avoid bias, the following criteria were used to screen studies: (1) The study was conducted on alpine grasslands and clearly described whether the studied grasslands were degraded or not. (2) Microbial community structure was determined using high-throughput sequencing, and at least calculated one soil microbial community metric, including alpha diversity (e.g., Chao1 or Simpson), beta diversity, and community structure was reported. (3) The study site was old-growth grassland rather than artificial grassland. (4) Sampling was conducted during the peak growing season. (5) Experiments with factors, such as N deposition, warming, drought, etc., were excluded. (6) Only field studies were selected, and laboratory incubation studies were not included. Finally, a total of 36 publications were remained for meta-analysis. For each study, we extracted means, sample size and standard deviation (SD) or standard error (SE) or 95% confidence interval (CI) if reported. If results were presented graphically, the software WebPlotDigitizer 4.6 (https://automeris.io/WebPlotDigitizer/) was used to digitize the data. Given that the levels of degradation likely affect the results, we captured the levels of degradation for each study. The degraded grasslands were considered to be lightly degraded if vegetation cover has decreased by more than 30%, and heavily degraded grasslands were those with a decrease of more than 50% in vegetation cover, compared to undegraded grasslands.

Calculation of the individual response ratios (RRs)

We used the natural logarithm-transformed (ln) RR to calculate the response of variables for each case study:

$$RR = ln\frac{Xt}{Xc} \qquad (1)$$

where $\bar{X}_t$ and $\bar{X}_c$ are the means of the concerned variable in the degraded and undegraded grasslands, respectively.

Its variance (v) were calculated as:

$$v = \frac{SDt^2}{Xt^2} + \frac{SDc^2}{Xc^2} \qquad (2)$$

where SD_t and SD_c are the standard deviations of the variable in the degraded and undegraded grasslands, respectively.

Calculation of the overall RR

All statistical analyses were performed in R (R Devel opment Core Team, 2024) using the R package *metafor* (Wolfgang Viechtbauer, 2010). The mixed-effect model was used to calculate the overall RR and the corresponding 95% confidence intervals of target variables. This model was also used to compare the RRs of variables between the light and heavy degradation by the omnibus test (QM). If the 95% confidence intervals for one RR overlapped with zero, then it was considered as an insignificant response to grassland degradation.

Results

Grassland degradation did not alter microbial diversity but reduced microbial function.

Grassland degradation did not affect alpha diversity (Chao1 and Simpson) and beta diversity of bacteria and fungi, but significantly changed community structure (Fig 1a). For instance, grassland degradation increased *Gemmatimonadetes*, while decreased *Basidiomycota* (Fig 1b). Grassland degradation had no effects on microbe biomass, enzyme activities of carbon (C) and nitrogen (N) decomposition. Grassland degradation did not affect the abundance of denitrification and nitrification genes, but decreased gene abundance related to nitrogen fixation (Fig 1c).

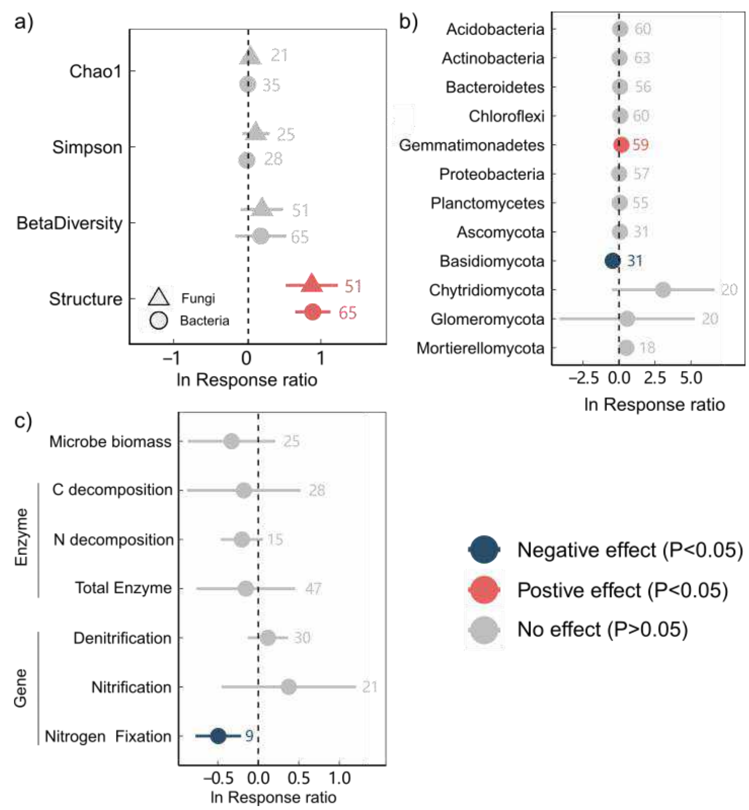

Fig. 1 Response ratios of soil microbial diversity (a), microbial community composition (b) and microbial function (c). Points are weighted means of RRs with 95% confidence intervals. The numbers on the right side of confidence intervals represent sample sizes. Positive mean values indicate increased variables induced by degraded grassland (red dots), while negative mean values indicate decreased variables induced by degraded grassland (blue dots). The intersection of confidence intervals and zero line indicates that there is no significant difference between the degraded and undegraded grassland (grey dots).

The RRs were significantly affected by the levels of degradation (Fig 2). As the levels of grassland degradation increased, we observed stronger RRs of enzyme activities (Fig 2a) and genes related to N cycling (Fig 2b). The overall and light degradation did not significantly affect C decomposition and N decomposition enzyme activities. However, when grasslands experienced heavily degradation, there were dramatic decreases in C and N decomposition enzyme activities (Fig 2a).

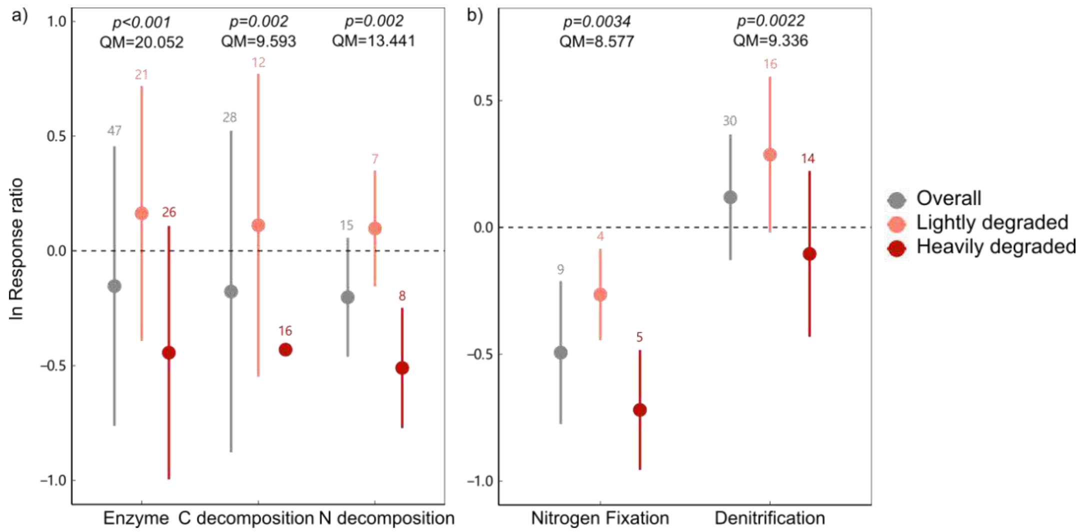

Fig. 2 Response ratios of soil enzyme activities (a) and functional genes (b) across grassland degradation levels. Points are weighted means of RRs with 95% confidence intervals. The numbers on the right side of confidence intervals represent sample sizes. Positive mean values indicate increased variables induced by degraded grassland (red dots), while negative mean values indicate decreased variables induced by degraded grassland (blue dots). The intersection of confidence intervals and zero line indicates that there is no significant difference between the degraded and undegraded grassland (grey dots).

Discussion

Grassland degradation altered soil microbial community structure. Degraded grasslands had lower soil nutrient content and poorer physical soil properties, such as reduced soil organic carbon content and lower aggregate stability, compared to undegraded grasslands (Li *et al.*, 2021; Luo *et al.*, 2023). These changes may explain the increase in the relative abundance of *Gemmatimonadetes*, which can adapt to extreme environments, and the decrease in *Basidiomycota*, which are particularly sensitive to environmental disturbances. Grassland degradation did not significantly affect microbial diversity. Microbial communities can sustain biodiversity through species turnover. For instance, following grassland degradation, certain microbial taxa, such as drought-tolerant bacteria, can replace less resilient species, thus preserving overall species diversity within the community (Liu *et al.*, 2023).

Grassland degradation decreased nitrogen fixation genes. The abundance of efficient nitrogen-fixing bacteria, such as *Rhizobium* spp., decreased, while microorganisms with lower nitrogen-fixing efficiency became more dominant following grassland degradation (Zhang *et al.*, 2022). Heavy degradation suppressed C and N cycling indicated by a decrease in C and N decomposition genes. Key microbial groups, such as efficient N-fixing bacteria and decomposers, diminished and cannot be replaced by other microorganisms, leading to a decline in critical soil ecological functions, such as organic matter decomposition and nitrogen cycling (Breidenbach *et al.*, 2022). This suggest that practices stimulating C and N cycling or increasing nutrient content should be developed in further studies. Light degradation did not significantly affect other functions of soil microbes, suggesting that these functions may be redundant (Louca *et al.*, 2018).

Grassland degradation shifted soil microbial community composition, increasing stress-tolerant taxa while decreasing those that are sensitive. Additionally, heavy degradation weakened soil functions, suggesting the loss of functional redundancy. These findings highlight the importance of managing microbial communities in grassland restoration. Future restoration efforts should prioritize the recovery of microbial community and functional redundancy. Moreover, the severity of grassland degradation influenced the maintenance of soil functions, highlighting the importance of early intervention and effective land management to prevent irreversible loss of microbial functions.

Using gypsum to ameliorate a highly-saline, scalded claypan

Andersson, KO[1]; Clarendon, S[1,2]; Humbert, G[3]; Conder, J[3]; Schneider, D[4]; Strong, C[5]; MacDonald, SE[1]

[1]NSW Department of Primary Industries and Regional Development, NSW Australia, [2]Department of Primary Industries and Regional Development WA, Australia, [3]Gurrawarra, Bourke, NSW, Australia, [4]University of New England, Armidale, NSW, Australia, [5]Australian National University, Acton, ACT, Australia.

Key words: scald amelioration; gypsum; sodicity

Abstract

Scalds are common on degraded soils in the rangelands of western NSW. Scalds restrict plant growth and biological activity. Scalds form due to dispersive (sodic) sealing surfaces and high salinity. Sodic soils can be stabilised by the addition of gypsum which flocculates the soil in the short term and decreases the propensity to disperse in the medium to longer term while facilitating leaching of problematic chloride salts. This study examined the use of gypsum to remediate a scald that was sodic (exchangeable sodium percentage (ESP) >10%) and had high salinity (electrical conductivity (ECe) ~45 dS/m) to at least 60 cm soil depth. Mechanical disturbance (ripping with a single mouldboard plough) previously trialled resulted in only minimal establishment of halophytes with shallow roots but with no survival. A replicated trial was established to examine the response of soil and pasture to four rates of gypsum: nil (Control), 1 t/ha (Low), 2.5 t/ha (Moderate), and 6.5 t/ha (High). The design allowed remote monitoring via Sentinel imagery.

After 12 months there was greater volunteer plant establishment and decreased surface salinity (to ~5 dS/m) in the High treatment areas. Satellite imagery indicated greater cover of green vegetation (NDVI) during the growing season, but only in the High treatments. While the timing of rainfall and leaching of salts will influence the persistence of the improvements, the results so far show the amelioration of an extreme scald with appropriate techniques.

Introduction

Scalded soils present problematic conditions for water infiltration and for plant establishment and growth. Scalds are areas that have lost their topsoil, leaving a clay subsoil as the new surface layer which is commonly hard, saline or sodic. Scalded country is common on alluvial and residual soils in the rangelands of western NSW and in dry regions globally. Researchers since the 1940s have demonstrated remediation of scalded land in the NSW rangelands by natural regeneration, and intervention by ripping, ponding, and managing grazing pressure. Successful remediation is the restoration of functioning soils and productive systems. Because salinity is a common feature of soils in dry areas and is close to the surface on scalded sites, flushing salts deeper into the profile is key to scald remediation.

Gypsum applied to dispersive soils can act to flocculate the soil surface in the near term while infiltration leaches undesirable salts deeper. In the longer term, calcium in the gypsum can exchange with sodium on clay surfaces to decrease their propensity to disperse. When vegetation establishes, infiltration can be enhanced and wicking of salts to the surface decreased; all these processes reinforce the amelioration of the scald.

The objective of this study was to assess remediation of a scald on an alluvial soil in north-west NSW, using different rates of gypsum, and to compare the soil conditions between the treated site and a nearby area that is recovering naturally.

Methods

The trial was located on 'Gurrawarra', approximately 80 km north-east of Bourke, NSW Australia (29º46'41"S, 146º23'19") on a scald situated on an alluvial meander plain west of the current Culgoa River. The climate is semi-arid, with an average annual rainfall of 370 mm, with a summer dominant rainfall pattern. Preliminary assessment of the scald identified high salinity, a dispersive surface and highly aggregated subsurface. The scald has persisted despite previous mechanical disturbance (ripping with a single mouldboard plough). The site was devoid of vegetation except for some small dead halophytes present in the old rip lines.

The application of gypsum was chosen because the landowners had noted the long-term (>10 years) effect of established vegetation at isolated spots where gypsum tailings had been dumped on the property. Prior to the application of the gypsum, soils were analysed at 0-10 cm, 10-20 cm, 20-30 cm and 30-60 cm for salinity (Shaw, 1999) and sodicity profiles (electrical conductivity, soluble chloride, exchangeable sodium percentage). Exchangeable cations were measured by the Tucker method with pre-wash to minimise any artefact of soluble salts or dissolution of sparingly soluble salts (15C1, Rayment and Lyons, 2011). Satellite data to calculate NDVI (normalised difference vegetation index; no units) for each plot was downloaded from the Sentinel portal (Copernicus; https://sentinel.esa.int/web/sentinel/home) from the first available date (2-11-2016) to November 2024. Laboratory analyses of samples collected in July 2023 from inside and outside the old gypsum dump and a separate self-ameliorating scald were also made for comparison with the trial.

The trial was established in July 2023. Three replicates of four treatments (including a Control) were established in 50 x 50 m plots. Gypsum was spread evenly at rates to reflect the approximate amount of gypsum dissolved through 10 cm at field capacity (1 t/ha, Low), a standard rate to allow for some leaching (2.5 t/ha, Moderate), and a rate to allow additional time for leaching and adequate for replacement of Na with Ca on the clay exchange sites (6.5 t/ha, High; Loveday 1976). The soil surface was tilled to approximately 10 cm after spreading to minimise wind drift. Banks were mounded around the site to minimise run-on.

Soil sampling and assessment of vegetation cover was undertaken in July 2024. 20 soil samples in each plot were composited at depths 0-5, 5-10, 10-20, 20-30cm for the same laboratory analysis as the 2023 samples. Additional samples were collected from the general plot area and the pre-existing rip lines (Control and High plots only), and under patches of newly established vegetation (High plots only) to assess effects of ripping and vegetation. Ground cover (percent cover of plant, litter, cryptogam, coarse woody debris, dung, rock or bare ground) was monitored in twenty 0.5 x 0.5 m quadrats located along four transects in each plot. Standard errors (se) were calculated for each measure.

Results

No differences in soil properties between treatment plots were found in the initial measurements. Drought conditions persisted following establishment of the trial until early 2024 after which 300 mm fell through the winter and spring. A visible response of improved infiltration in the High treatment compared to surface ponding in other plots was borne out with increased vegetation cover in July 2024. Vegetation cover did not differ significantly between the Control, Low and Medium treatments (averaging 4.2-7.2%) but was higher on the High gypsum treatment (average 18.0%, Figure 1). Despite the response of vegetation to the High rate of gypsum, there was no significant difference between the treatments in salinity down the soil profile (Figure 2). However, there was an overall decrease in salinity at the surface, and translocation to below 20 cm, compared to 2023 following good rainfall (Figure 2). The soil under vegetation in the High plots had lower salinity through to 20 cm depth than the bare Control and the bare patches within the High plots (Figure 3). The existing rip lines also affected salinity: within the High plots the salinity in the rip lines was lower than the bare areas in the 0-5 cm and 20-30 cm increments; and in the Control plots the salinity was lower in the Rip lines than away from the rip lines through the to 20 cm. After just one year there was no change in sodicity with any rate of gypsum (data not shown).

The salinity levels of the upper profile in the gypsum dump and under vegetation of the self-ameliorating area were low, while outside the dump the salinity was high and in bare areas of the self-ameliorating area the salinity was half that of the trial site. The sodicity inside the gypsum dump was lower compared to outside (5% and 15%, respectively, data not shown).

The relatively good 2024 season was reflected in the greater NDVI in the Control, Low and Moderate plots compared to the period preceding the trial (Figure 4). The apparent increase in NDVI immediately following installation was likely due to the surface disturbance. The greater plant cover observed in the High treatment compared to the other plots was consistent with the NDVI (up to 0.21), while there was no difference in NDVI between the Control, Low and Moderate plots.

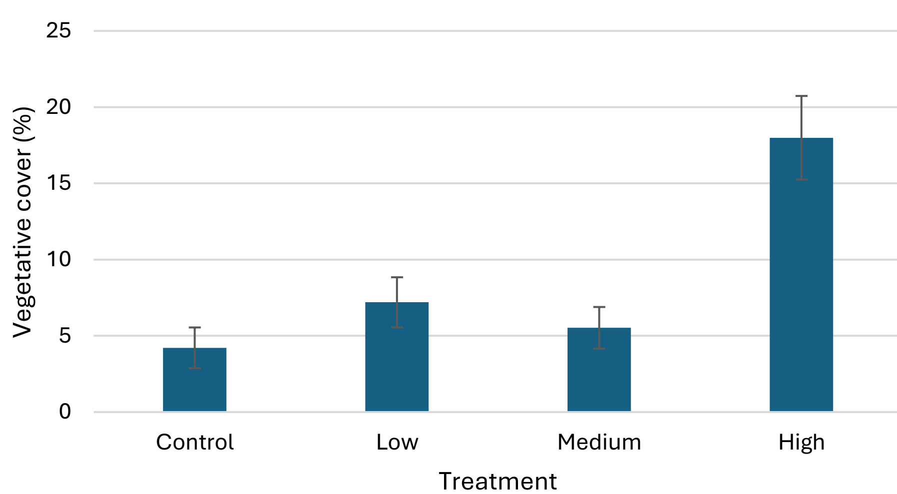

Figure 1. Average vegetative (plant + litter) cover within the different gypsum treatment plots in July 2024 (+/- 1 se).

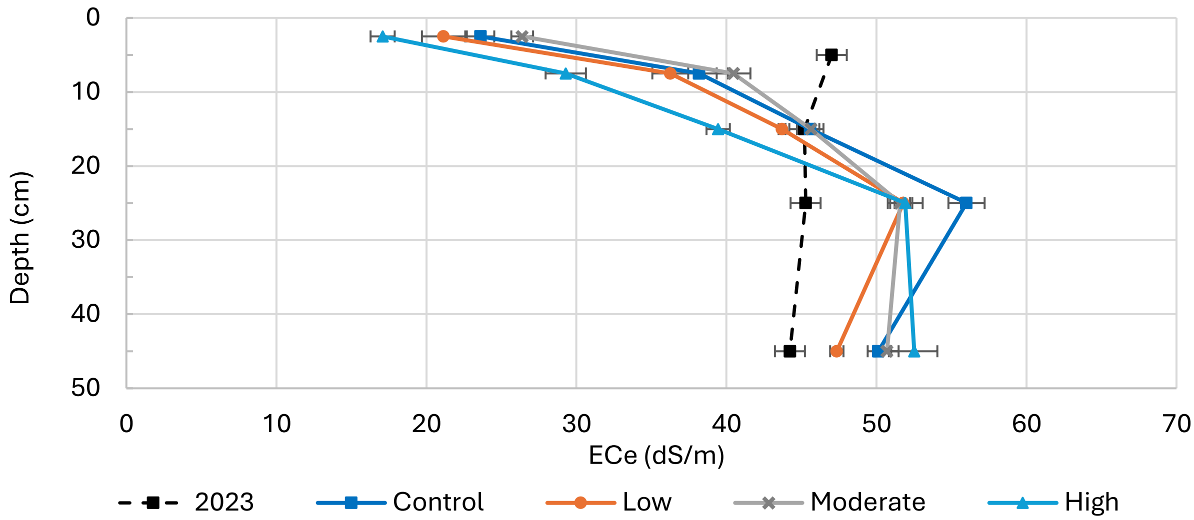

Figure 2. Average salinity (electrical conductivity, ECe) down the soil profile of the Control and Low, Moderate and High gypsum application plots in July 2024 and the site average in July 2023 (+/- 1 se).

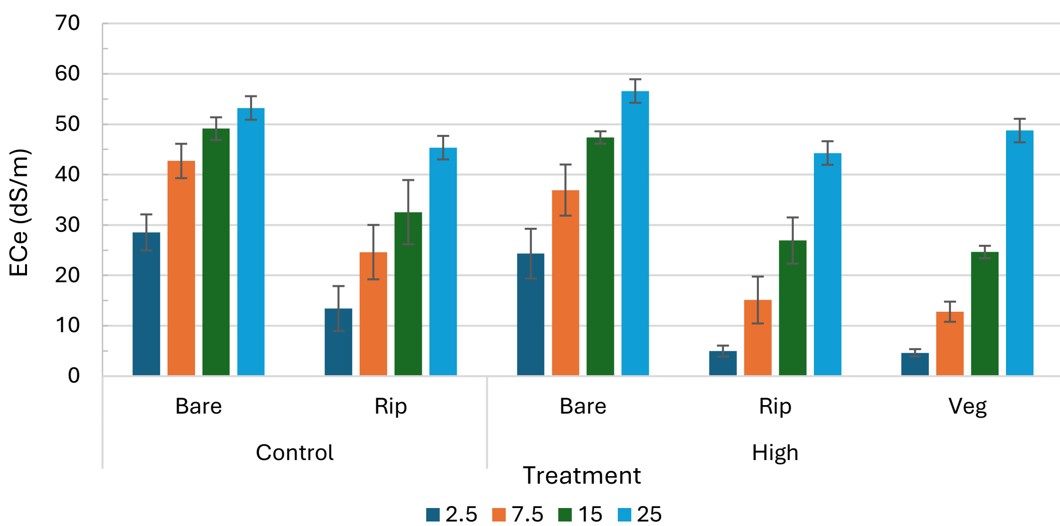

Figure 3. Salinity (electrical conductivity, ECe) within the Control and High treatments in July 2024 (+/- 1 se). Insufficient (~no) vegetation was present for sampling outside of rip lines in control plots.

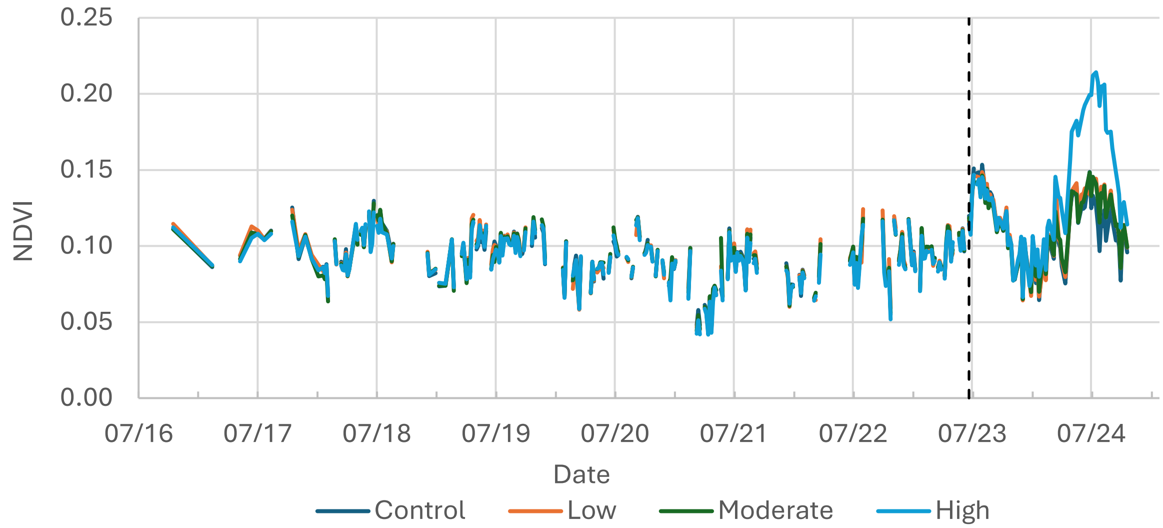

Figure 4. Remotely sensed NDVI over time at the gypsum demonstration site by treatment (vertical dashed line indicated date in installation).

Discussion

The overall response of both soil and vegetation to the gypsum application and earlier ripping on the scald has been an improvement in soil properties and a subsequent increase in plant establishment. The earlier ripping appeared to allow better infiltration and flushing of salts. However, these rip lines are narrow (~30 cm), and particularly in the Control areas the vegetation is still sparse. By comparison, the effect of the gypsum was promising but only at the High rate. While patchy, establishment of substantial patches of vegetation beyond the rip lines in vegetation the High treatment is likely to more effectively leach salts (Jones 1967). While senesced at the time of reporting (late spring 2024), the surface cover remains and serves to enhance infiltration.

The long-term success of the amelioration will depend on the persistence of the changes in the coming season and through drier periods. Persistent vegetation cover (even if senesced) would minimise wicking and re-occurrence of surface salinity, while ongoing exchange of Na for Ca would improve the inherent dispersibility. The marked change in salinity between 2023 and 2024, and between the treatments in 2024 compared to no significant change in sodicity indicates how much more dynamic fluctuations in salinity are compared to exchange processes. By comparison, the decrease in sodicity at the gypsum dump has occurred over 10 years at an unknown rate but likely very high rate of gypsum (Loveday 1976). Rather, landscape characteristics and the extent of the limiting factors guide the appropriate remediation technique and suitable rate of gypsum application. As is well understood (e.g. Jones 1967, Eldridge 1988), it is the leaching of salts that is often key to improving the rootzone for plant establishment and initiating positive feedback, and subsequent management and conditions determine the ongoing success of scald amelioration.

Soil testing to support decision making in the rangelands

Andersson, KO[1]; Orgill, SE[2]; Strong, C[3]

[1]NSW Department of Primary Industries and Regional Development, NSW, Australia, [2]Select Carbon, 275 George St, Brisbane QLD 4000 Australia, [3]Australian National University, Acton, ACT, 2601, Australia

Key words: acidity; salinity; phosphorus deficiency; organic carbon

Abstract

Soil testing is not typically conducted in extensive and low input rangelands systems. To assess the usefulness of quantifying soil properties, we benchmarked selected soil physicochemical properties with producers from 33 properties in the semi-arid rangelands of NSW, Australia. Producers selected sampling locations of different soil types and landscape positions to compare attributes of the upper rootzone (10 cm increments to 30 cm) for pH, salinity, exchangeable cations, sulphur (S), phosphorus (P), and soil organic carbon (SOC).

Laboratory analyses typically showed an increasing soil pH with depth to alkaline levels on alluvial soils. The pH of non-alluvial soils (aeolian and bedrock-derived soils) was evenly distributed from moderately acidic to moderately alkaline, though some areas were identified with acidity constraints. Soil salinity was generally low, but some targeted sites had soil salinity levels comparable to sea water. Sodic soils were found in many areas. Low SOC was associated with high salinity and sodicity. Soil P was high in some areas, particularly the alkaline alluvial soils, though on some non-alluvial soils P was low enough to limit livestock productivity.

Benchmarking soil properties proved a strategic tool for rangeland producers to identify constraints not previously quantified and assess management options. Some targeted ameliorants or supplements may lead to improved productivity and returns on investment. The results provide a basis for further investigation to address any constraints and variable productivity.

Introduction

Chemical, physical and biological properties influence the inherent productivity of soils, though soil testing is not typically conducted in extensive and low input rangeland systems. Management in rangelands is complicated by a typically variable climate, often compounded by historic degradation which sees producers managing landscapes in various stages of soil stabilisation and recovery. This management requires attention to soil health, identified by farmers in NSW semi-arid rangelands as a priority for their production systems.

The objective of this paper was to identify potential constraints to production in NSW rangelands from targeted soil sampling on 33 properties in the semi-arid rangelands of NSW, Australia.

Methods
Producers were trained in soil sampling for laboratory testing in 2023. Samples were collected from up to four sites each, enabling comparison between sites. Training in the use of the soil kits was undertaken through regional workshops and discussion with the project team. At each site, samples were composited at depths 0-10, 10-20 and 20-30 cm for laboratory testing. Laboratory testing of samples to characterise the upper rootzone increments included pH in water (pHw) and $CaCl_2$ (pHCa), electrical conductivity (EC), exchangeable cations, soil organic carbon (SOC) by dry combustion, P by Colwell and BSES, and S (KCl40). Chloride (Cl) was measured on selected samples for salinity (Shaw 1999) and effective EC was estimated according to Shaw (1999) for samples with EC>0.3 dS/m or by Slavich and Peterson (1993). Exchangeable cations were measured according to pH and EC (15C1 for samples with pHw>7.3 and EC>0.3, or 15E1; all procedures as per Rayment and Lyons 2011). Results were grouped into samples taken from alluvial or non-alluvial sites.

Results
Acidity, salinity, sodicity and organic carbon
Across all sites, the pH of the 0-10 cm samples ranged from slightly acidic to slightly alkaline (Figure 1), generally increasing with depth. The difference between pHw and pHCa varied with EC, from zero (highest EC) to two units (lowest EC). Approximately 5% of samples had pHCa less than 4.8 (minimum 4.1).

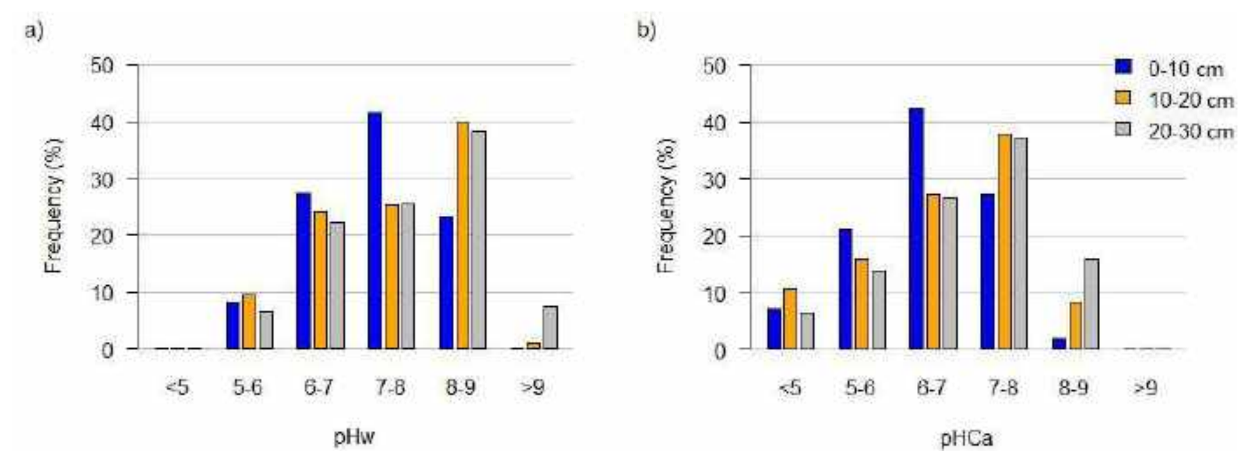

Figure 1. Frequency distribution of soil a) pHw and b) pHCa by depth for all samples.

Salinity was generally low in the samples collected from the upper 30 cm at each site (Figure 2). High salinity was more common in alluvial areas than the non-alluvial areas. 14% of sites sampled were areas of low productivity areas or scalds where the salinity was above 8 dS/m, and as high as the mid-fifties dS/m.

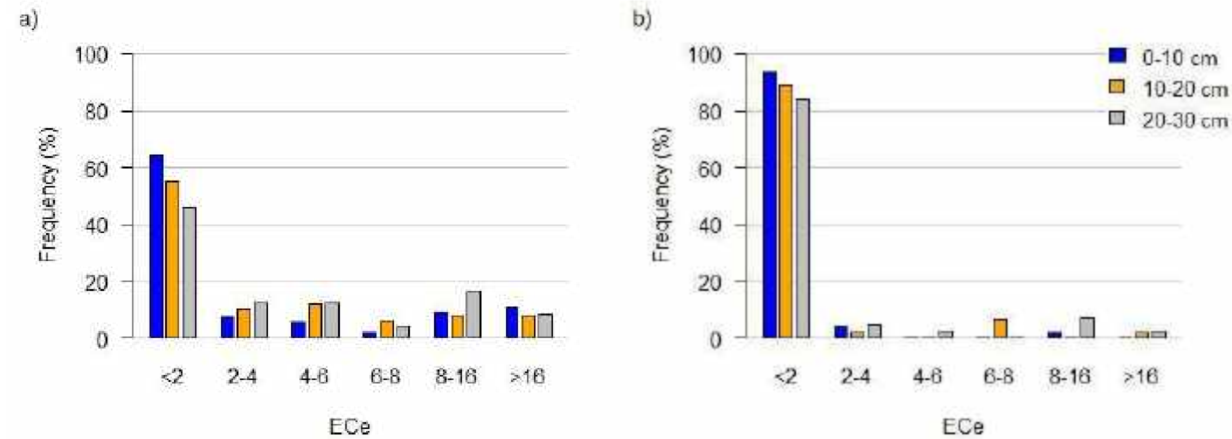

Figure 2. Salinity (electrical conductivity, ECe (dS/m) by depth in a) alluvial and b) non-alluvial areas.

Sodicity (ESP> 6%) was more common on the alluvial soils than the non-alluvial soils. There was a pattern of lower SOC in samples of increasing salinity and sodicity (Figure 3).

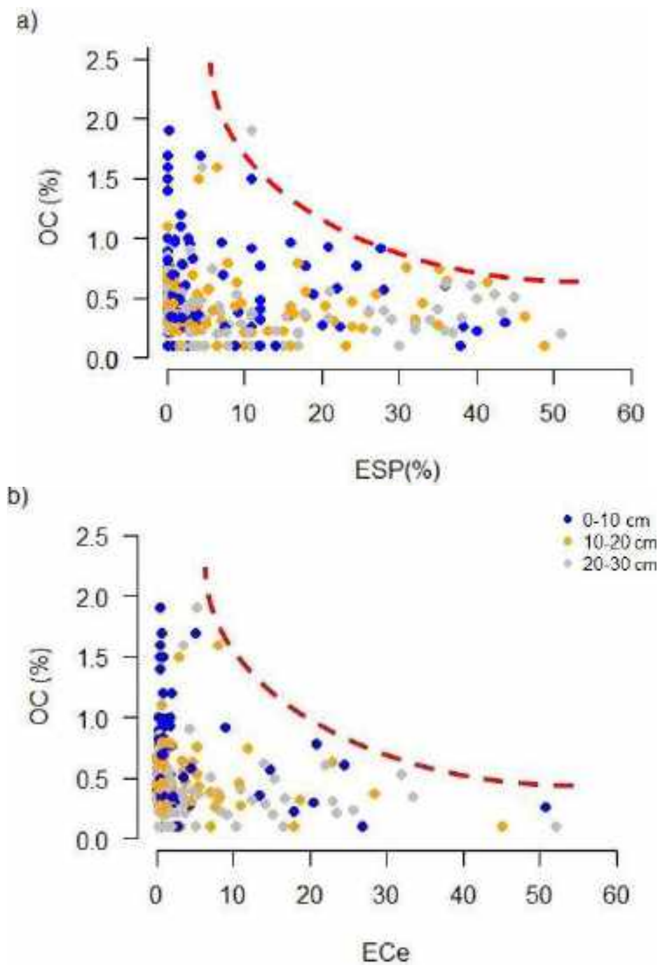

Figure 3. Relationship between soil organic carbon and a) ESP and b) salinity, by depth for all samples.

Fertility

The Colwell-P results ranged from below the laboratory's limit of reporting (LOR; <2 mg/kg) to 160 mg/kg (Figure 4). Colwell-P was higher in the surface than the deeper increments, and the non-alluvial soils had lower Colwell-P than the alluvial sites. In the non-alluvial areas 33% of 0-10 cm samples had Colwell-P <5 mg/kg, and a further 15% <8 mg/kg. At acidic to neutral pH levels the ratio of BSES-P:Colwell-P was between 1:1 and 4:1 (Figure 5), but at pHw >7.5 the ratio increased over 5:1 and up to 24:1 in 34% of 82 samples.

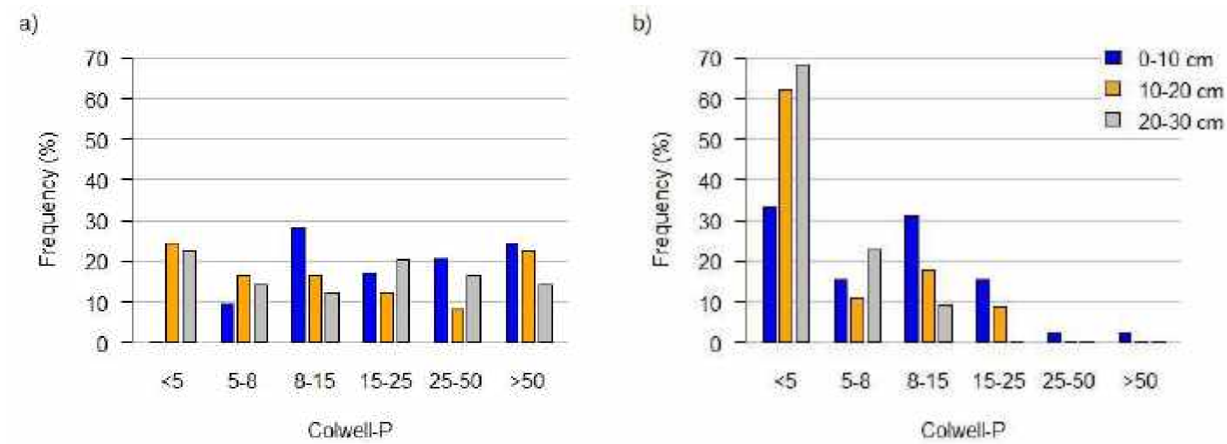

Figure 4. Frequency distribution of Colwell-P (mg/kg) by depth from a) alluvial and b) non-alluvial sites.

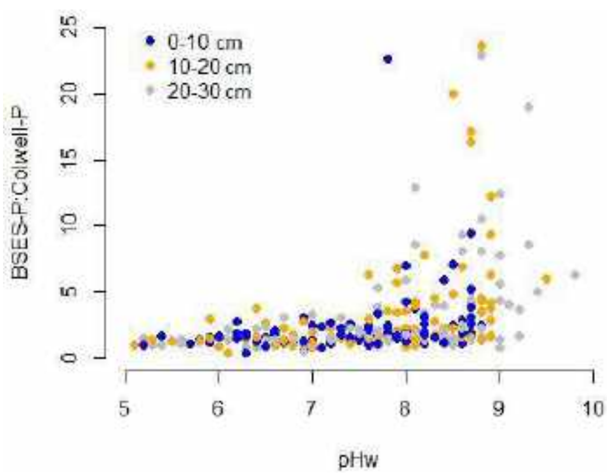

Figure 5. The ratio of BSES-P:Colwell-P v pHw by depth for all samples.

Sulphur levels were low (<5 mg/kg) at 42% of alluvial sites and 82% of non-alluvial sites (Figure 6). At the non-alluvial sites there was generally no substantial store at depth (92% had <10 mg/kg and 72% <5 mg/kg). By comparison, half the alluvial sites with low surface S had >20 mg/kg in the lower depth increments.

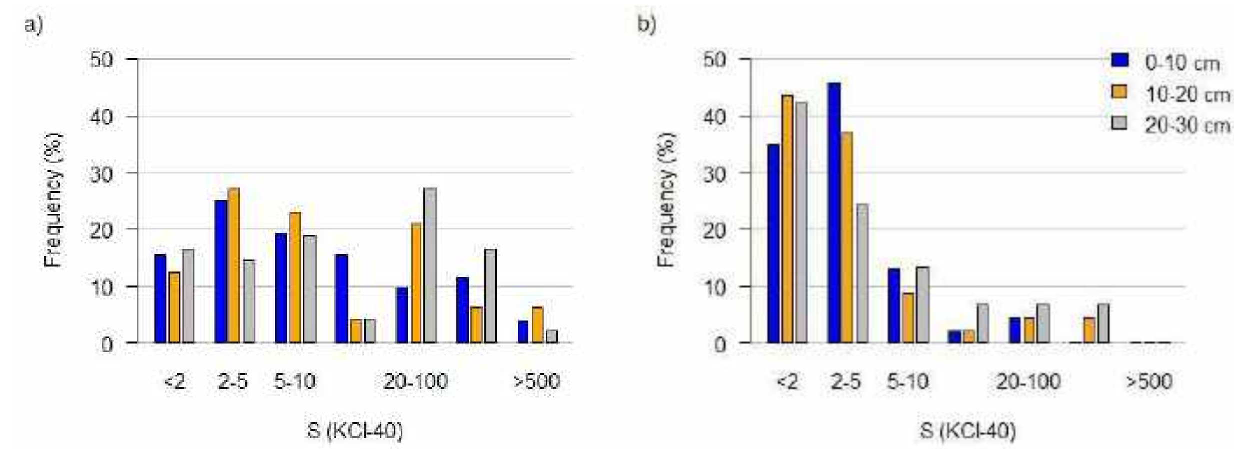

Figure 6. Frequency distribution of sulphur (mg/kg) by depth from a) alluvial and b) non-alluvial sites.

Discussion

Soil testing is rarely undertaken in the low input, extensive nature of livestock production in the semi-arid rangelands of southern Australia despite soil erosion, sodicity, surface sealing and salinity commonly causing constraints to production. Due to low rainfall, the soils are generally less leached and therefore can have higher pH, salinity, and fertility than high rainfall regions. Conversely, organic matter levels are generally low, which accentuates a range of soil structural and nutrient cycling problems.

This survey highlights the influence that attributes such as geomorphology have on soil properties. For example, soil alkalinity can induce nutrient deficiencies, while acidity found in some non-alluvial soils can restrict root growth and seedling establishment through nutrient imbalances and aluminium toxicity. The difference between pHw and pHCa fundamentally reflects the ions in solution (Slattery et al. 1999), and the most saline soils had the closest values. Salinity was a consistent feature of scalded areas, and in marginal areas was observed to vary within metres from high levels on bare ground and low levels under plant cover. Salinity >10 dS/m was common at such sites, and some cases approached double the concentration of seawater.

Low sodicity of the non-alluvial sites was expected as the region (Cobar pediplain, NSW Australia) has little sodicity, while sodium accumulation is common in western alluvial systems (Isbell et al 1997). Sodicity limits infiltration and root growth, and salinity limits moisture availability to plants. The low SOC with high sodicity and salinity may reflect a restriction to plant growth and accumulation of organic matter. Understanding these patterns highlights the importance of maintaining or building soil organic matter to buffer the impacts of salinity and improve soil structure, and can inform producers of appropriate management options.

Phosphorus was low on many non-alluvial areas characterised by mulga (*Acacia aneura*) and ironbark (*Eucalyptus crebra*) (Jackson et al. 2012). If forage on areas of higher P is not accessible to livestock their nutrition may be deficient (Schatz et al. 2023), even if at sub-clinical levels. Conversely, the ‘reserve’ of acid-soluble P at high pH represents a bank of fertility for plants that can acidify their rhizosphere (Dinkelaker et al. 1989).

Collecting soil samples from areas of interest allowed participants to link soil properties with production – high or low. This project encouraged producers to monitor soil data to support their decision making. Our recommendation was to pick key areas that are meaningful for monitoring of soil properties every 3 to 5 years to better understand major climate drivers and longer-term land management improvements and impacts.

Acknowledgements
We acknowledge the producers who participated with the sampling. The Rangelands Network for Soil Knowledge project was supported by Western Local Land Services through funding from the Australian Government's National Landcare Program, and Meat and Livestock Australia (project L.ADP.2019).

Preserving and enhancing soil health in the rangelands of Uganda

Nakachwa, NF[1]; Senkosi, K[2]

[1]Norifarm Industries Uganda Limited, Kapeeka Industrial Park, P. O. Box 148221 Kampala, Uganda, faynor34@gmail.com; [2]Kampala Capital City Authority, ksenkosi@kcca.co.ug

Key words: Rangeland; Rangeland health; Ecological site; Landscape attributes

Abstract

Rangelands in Uganda covers an area of 84.000Km2 which is about 44% of the country's land mass. Commonly known as the Cattle Corridor, it stretches from the south through the central region to the northeastern part of Uganda and supports pastoral and agropastoral communities.

Food insecurity in Uganda has been considered an outcome of low agricultural productivity which is attributed to the gradual decline in soil fertility originating primarily from anthropogenic causes including continuous tillage and mono-cropping as well as reduced agricultural inputs.

In our study, we highlight 2 smart agricultural technologies as alternative solutions to low soil fertility:

Organic fertilizers tend to be costly to farmers without integrated agricultural systems but some of their benefits include: preservation of soil by minimizing negative effects on the environment, exhibiting stability and resilience to a changing climate, having a beneficial effect of increasing organic matter and soil fauna and improving soil quality.

Vermicomposting is a technology that utilizes different species of earthworms coupled with microorganisms to mechanically digest the organic matter thereby enhancing mineralization. However, there is a need to apply the organic waste as the raw material to be digested; therefore, interplay of organic waste and the vermicomposting organisms is needed to achieve the mineralization.

Introduction

Rangelands in Uganda covers an area of 84.000Km2 which is about 44% of the country's land mass. Commonly known as the Cattle Corridor, they stretch from the south through the central region to the northeastern part of Uganda and support pastoral and agropastoral communities.

Food insecurity in Uganda has been considered an outcome of low agricultural productivity which is attributed to the gradual decline in soil fertility originating primarily from anthropogenic causes including continuous tillage and mono-cropping as well as reduced agricultural inputs.

The growing population has exerted pressure on rangelands due to more demand for goods and services.

The use of rangelands is intensifying, resulting in extensive rangeland degradation and desertification. The land use shift from the original tropical rainforests to savannahs and other non-agricultural activities (e.g. construction, charcoal burning, bricklaying and animal grazing) has significantly contributed to the degradation of soil. Loss of soil fertility has been manifested through loss of organic matter mainly caused by farmers removing the post-harvest biomass leaving the soil unreplenished and with a negative nitrogen balance.

It is no longer possible to apply the old soil management practices of bush fallowing and shifting cultivation that would restore fertility to the damaged soils.

To assess rangeland condition, a methodology often referred to as Rangeland Health Assessment can be performed. This provides tools that help land users interpret the landscape and react in time before land degradation becomes irreversible. Rangeland health assessment is about evaluating ecosystem processes using indirect methods to determine whether an ecosystem is at risk or healthy under the current management scheme. Constructing a rangeland health methodology requires understanding of ecosystem processes and how they are expressed in the environment.

Rangeland health is defined as the degree to which the integrity of the soil, vegetation, water and air, as well as the ecological processes of the rangeland ecosystem, are balanced and sustained. Integrity in this case refers to "maintenance of the functional attributes characteristic of a locale, including normal variability" It has replaced the terms 'range condition' and 'ecological status'

Rangeland Soils:
Rangeland soils are often characterized by low fertility, poor drainage, and rough topography.

Specific things to consider with rangeland soils:
Soil erosion
Soil erosion can cause the loss of nutrients, organic matter, and fine-size soil particles, which can decline soil fertility.
Disturbance
Some disturbance can help maintain soil health and biological diversity however, too much can be detrimental and lead to permanent ecological changes.
Livestock grazing
Livestock grazing is the most common economic use of rangelands, but may degrade rangeland health.
Rangeland degradation
Rangelands are threatened by a variety of natural and anthropogenic causes, including climate change, drought, aridity, and desertification.

Methods
Nakasongola District was selected as the study area because of its specific location in the center of the cattle corridor. The District covers an area of 4,909 km 2 and is located between latitudes 0 0 57' 44.89" and 1 0 40' 42.76" North and longitudes 310 58' 03.77" and 320 48' 00.29" East (Figure 1). Earlier studies (Nakasongola 2011) on the soils and land use in Uganda classified the soils of Nakasongola district in the driest part of Buganda Province. These rangelands were identified as a 'hot spot' with severe land degradation, pasture and water scarcity that were translating into high livestock mortality and poverty. The District has hence received national attention to help solve the environmental problems and save dependent communities

Nakasongola District is classified under the banana-millet-cotton farming system (MAAIF, 1995). Because of the less stable rainfall, there is a great reliance on annual food crops basically millet, sorghum, groundnuts, cassava, pigeon peas and maize, with cotton as a major cash crop and livestock production dominating in the drier areas of the District.

Key methods to improve soil health include: Implementing Rotational grazing practices, managing livestock stocking rates, planting diverse native plant species, use of cover crops, minimizing tillage, monitoring nutrient levels and use of fertiliser and controlling erosion through strategic vegetation placement.

We implemented all these methods on farms in the Nakasongola District of the Ugandan Rangelands and observed the effects over a period of time.

Figure 1. Uganda showing the location of Nakasongola district

Results

Rotational grazing

Moving livestock between different pastures regularly prevents overgrazing and allows vegetation to recover, ensuring even manure distribution. For example; regenerative grazing in Nakasongola district is crucial for restoring degraded rangelands and improving livestock management, particularly in the face of climate change and land degradation. By focusing on soil health and pasture productivity, it can enhance livelihoods and reduce the risk of overgrazing and its consequences.

Adaptive stocking rates:

Adjusting the number of livestock based on available forage prevent overgrazing and maintains healthy plant communities. In Uganda, studies have shown that carrying capacity can vary significantly, with the lowest carrying capacity occurring during the long dry season (June to August) and the highest during the short rain season (September to November).

For Ankole region, pastoral systems in southwestern Uganda, a stocking rate of 1.41 ha/TLU is considered sustainable

Plant diversity
Introducing a variety of native plant species with different root depths to enhance soil structure, nutrient cycling, and resilience to drought. Examples of plants include; Pongamia (*Millettia pinnata*) and Croton nuts (*Croton megalocarpus*)

Cover cropping
Planting temporary cover crops during fallow periods to protect the soil from erosion, add organic matter, and improve soil structure.

Minimal tillage
Reducing soil disturbance through minimal or no tillage practices to preserve soil structure and microbial activity.

Nutrient management
Regularly monitoring soil nutrient levels and applying necessary fertilizers strategically to avoid excesses and maintain soil balance.

Erosion control:
Implementing practices like contour planting, grassed waterways, and windbreaks to minimize soil loss from wind and water erosion.

Monitoring and assessment:
Regularly monitoring soil health indicators like organic matter content, microbial activity, and soil structure to evaluate the effectiveness of management practices

Conclusion
The benefits of improved soil health in rangelands include:

Increased forage production and quality, enhanced water infiltration and retention, improved biodiversity and ecosystem services, greater resilience to drought and extreme weather events, and reduced soil erosion.

The encroachment of grasslands by bare and woody vegetation has led to a decline in pasture biomass yield and therefore has strong implications on the sustainability of pastoral livelihoods in the semi-arid rangelands of Nakasongola. The low pasture biomass in woody understory implies that most native pasture species in the rangelands of Nakasongola are not shade tolerant and therefore increased woody encroachment will most likely wipe out indigenous nutritive pastures in the rangeland. Organic matter, nitrogen, calcium and magnesium are the most critical nutrients limiting pasture biomass. Rangeland management strategies for improving soil quality and pasture production should therefore be strongly focused at increasing the levels of these nutrients.

There is a need for intensification and transformation of cropping systems from low input to high input agriculture so as to reduce opening up of new land every season in search for fertile soils. Opening new lands for cultivation is among the most insidious practices devastating the sustainability of rangeland ecosystems.

Pastures under pressure: restoration of high-altitude rangelands in Bhutan and Nepal

Srijana Joshi[1]; Yi Shaoliang[1]; Kesang Wangchuk[1]; Tashi Dorji[1]; Ramesh Timilsina[1]; Rajesh K Rai[2]

[1]International Centre for Integrated Mountain Development; [2]Institute of Forestry, Tribhuvan University, Nepal,

Keywords: High altitude pasture; restoration; *Rumex nepalensis*; shrub encroachment; weeds

Abstract:
Rangelands comprising 60% of the land area in the Hindu Kush Himalaya (HKH), are predominantly managed under pastoral production systems. The high-altitude rangelands provide critical nature-based solutions to societal challenges, including climate change, biodiversity loss, water scarcity, and food security. Mountain pastoralism, characterized by the seasonal migration of livestock between different elevation pastures, significantly contributes to the economy, food and water security, nutrition, health, cultural identity, indigenous knowledge systems, and biodiversity. In mountainous countries like Nepal and Bhutan, mountain pastoralism also alleviates pressure on lowland areas where land and resources are scarce. However, over the past few decades, government restrictions on traditional pasture management practices, such as cutting and burning, have led to alpine pastures being overtaken by shrubs, significantly reducing forage quality and availability. Additionally, these pastures face severe impacts from erosion, scree flows due to melting glaciers, permafrost thaw, and intense rainfall. Transitional and winter grazing areas suffer from overuse, erosion, and invasion by unpalatable plants, resulting in poor fodder production. Shrub invasion by *Rhododendron lepidotum* and *Berberis spp* and land erosion is further diminishing the availability of high-value medicinal plants and herbs, while critical water sources are also drying up for wildlife, livestock, and herders. This degradation is negatively affecting the biodiversity and ecosystem services, leading to the unprofitability of pastoralism, youth out-migration from mountain regions, and the erosion of traditional pastoral cultures. To address these issues, we are piloting rangeland restoration projects in Tseko, Bhutan, and Shailung, Nepal. These projects employ a combination of methods, including prescribed burning, cutting, thinning, uprooting of weeds such as *Rumex nepalensis* and water management. Through these efforts, we aim to restore and sustainably manage rangeland resources, thereby enhancing ecosystem services, improving pastoral livelihoods, and preserving cultural heritage.

Introduction

Rangelands cover 60 percent of Hindu Kush Himalaya (HKH) and are home to more than 25 -30 million indigenous communities (Sharma et al. 2007). These high-altitude rangelands play a vital role in supporting pastoral livelihoods and maintaining ecological functions, including soil stabilization, carbon sequestration, water regulation, and biodiversity conservation (Joshi et al., 2013; Xu et al., 2019). Rangelands are socio-ecological systems, providing critical ecosystem services and sustaining indigenous knowledge systems (Hruska et al. 2017). The livelihoods of pastoral communities in the HKH are linked to rangeland health, as these ecosystems provide essential grazing resources for livestock. However, the increasing pressures from climate change, overgrazing, unsustainable land-use practices (Wang et al., 2019) and grazing-ban policies pose significant challenges to the sustainability of these rangelands (Singh et al. 2022). In addition, in recent decades the rapid encroachment of unpalatable shrubs and weeds in high altitude rangeland has been widely reported as one of the major causes of rangeland degradation that has drastically reduced forage availability, posing a serious threat to livestock productivity and herders' incomes (Wangchuk et al. 2013; Barsila 2022; Roomi et al. 2023). However, the sustainability of mountain pastoralism depends on the availability of high-quality fodder from seasonal pastures at different elevations. Shrub invasion and land erosion further diminish the growth and availability of highly valued medicinal plants and herbs. In some instances, pastures are fully overrun by pioneering woody species, while critical water sources for wildlife, livestock, and herders are drying up. Consequently, these trends have led to adverse effects on rangeland, making mountain pastoralism economically infeasible. Thus, an integrated approach and careful management are required to avoid negative implications of shrub encroachment and weed invasion. Several studies have reported that prescribed burning is a common tool used for rangeland management (Lohmann et al. 2014; Toledo et al. 2014). Prescribed burning frequently helps to lower the risk of wildfires, manage the spread of woody vegetation, reduce soil erosion, enhance plant diversity and wildlife habitats, and boost forage production for grazing livestock (DiTomaso et al 2010; Alcañiz et al. 2018). While some studies reported that prescribed burns implemented in the summer can benefit restoration by preventing woody encroachment while also controlling an invasive grass (Novak et al. 2021). The main objectives of our restoration trial were to assess the extent and impact of rangeland degradation in two high-altitude sites, Tseko in Bhutan and Shailung in Nepal, and implement targeted restoration interventions. In both the sites, due to the lack of proper management and other reasons, many of these pastures are degraded due to shrub encroachment and made unusable by rampant growth of *Rumex nepalensis* and other weeds species. To address these issues, we applied integrated approaches that include prescribed burning, cutting, thinning, water management, and weed removal. By combining traditional knowledge and modern restoration practices, we aim to enhance forage availability, support ecosystem services, and build resilience among pastoral communities.

Methods

The study was conducted in two high-altitude rangelands: Tseko in Bhutan and Shailung in Nepal (Figure 1 and Figure 2). In Tseko, the first restoration efforts involved multiple methods: prescribed burning of *Rhododendron lepidotum*, cutting woody shrubs such as Berberis spp. and Rosa spp., thinning blue pine (*Pinus wallichiana*), water management through the construction of water ponds, and the management of weeds like *Rumex nepalensis*. Prescribed burning trails were carried out in March, April and June 2024. During these trails, the main plant communities of the rangeland and dominant species were identified in burned fenced, unburned fenced and unburned unfenced plots. A total area covering 0.28 ha area was used for burning. Water management interventions included the construction of strategically placed water ponds to improve water availability for livestock and wildlife and increase soil moisture in the landscape.

In Shailung, Nepal, restoration was carried out in Godavari Community Forest and Kalinchowk Community Forest in May 2024.The approach focused on measuring grass recovery and determining the carrying capacity of rangelands through enclosures. We set up 10 enclosures covering the wider area, five were established at 3000 meters and five at 2900 meters. Each enclosure measured 2m by 2m, and biomass was harvested from 1-meter square plots to monitor growth. Additionally, 20 water ponds measuring 4.5m by 3 m by 0.6 m were constructed in collaboration with yak herders. These ponds were strategically placed to ensure water availability across grazing areas and enhance landscape-level water retention.

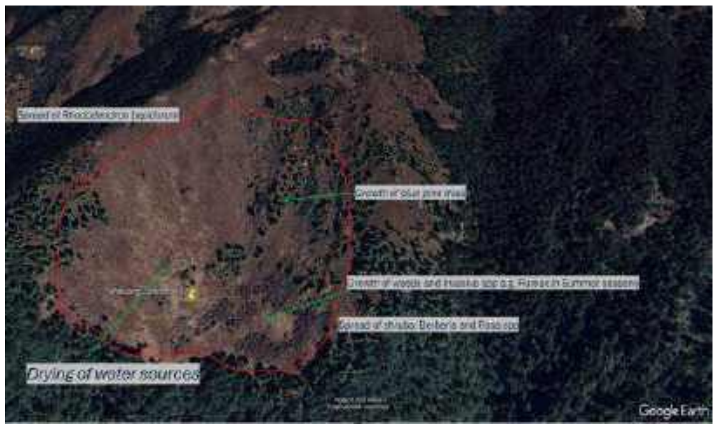

Figure 1: Restoration sites in Tseko, Bhutan

Results

Preliminary results from Tseko indicate the effectiveness of prescribed burning and cutting in improving forage yields and managing shrubs. Two months after implementing prescribed burns, the forage yield in burned and fenced plots was 4.55 t/ha compared with 4.21 t/ha in unburned, unfenced plots. In burned but unfenced plots, forage yield was significantly lower at 0.21 t/ha, likely due to grazing pressure. Fern height was tallest in burned-fenced plots, suggesting that burning facilitated fern growth while protection from grazing allowed for recovery. Cutting management effectively controlled *Berberis* spp., with regrowth heights varying from 54 cm to 190 cm, depending on site conditions. Forage biomass was significantly higher on managed sites compared to unmanaged ones, highlighting the effectiveness of active restoration practices. The *Rumex nepalensis* plant population was highest in the mown plot and lowest in the dug plot, while *R nepalensis* biomass peaked in the plot that was both mown and reseeded. Forage biomass was greatest in plots that were mown and reseeded, as well as those dug traditionally with branches of sapphire berry. In Shailung the estimated forage biomass is 366.5 kg/ha, with a utilization rate of 50% and a carrying capacity of 0.51 AU/ha, highlighting the overgrazed and degraded condition of the rangelands. With a yak population of 462, the area requires approximately 2,100 hectares of grazing land, further emphasizing the imbalance between forage demand and availability. The current biomass is measured at 145.5 kg/ha. Water ponds have shown promising results in improving water availability for both livestock and wildlife, enhancing moisture levels in the landscape, and supporting the regeneration of forage grasses.

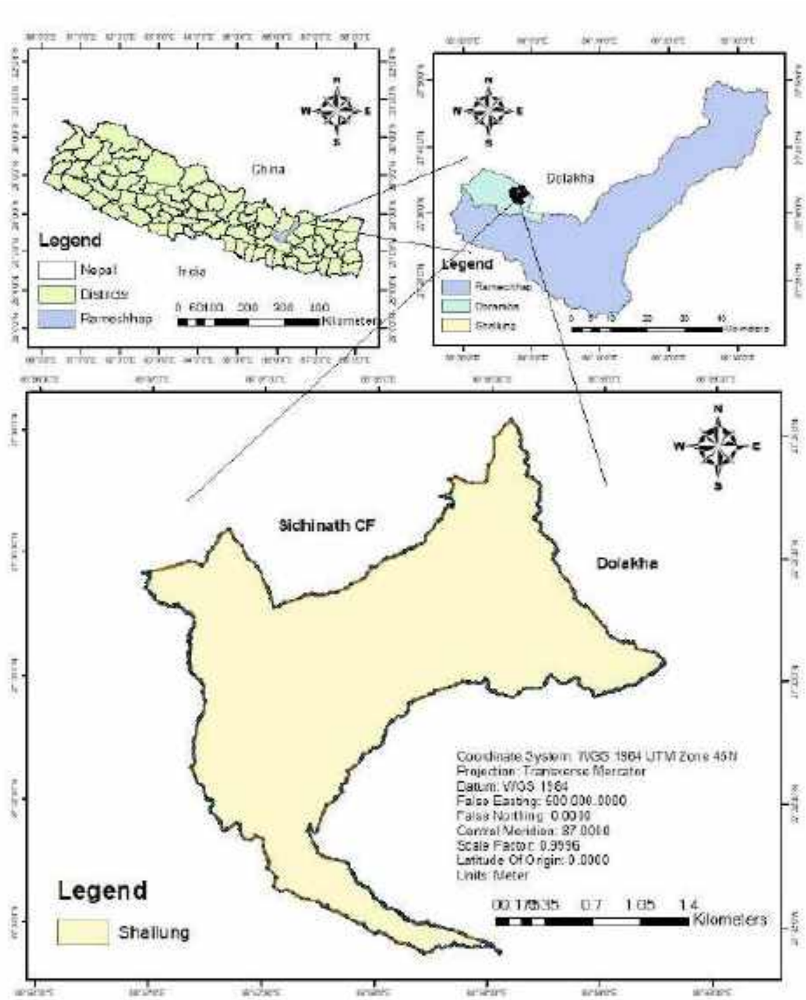

Figure 2: Restoration sites in Shailung, Nepal

Discussion

High altitude rangeland provides vital ecosystem services including biodiversity conservation, livelihood support, carbon storage and water regulation. However, they are increasingly threatened by shrub encroachment, poor management, soil erosion, overgrazing, medicinal plant extraction, and climate change highlighting the urgent need for both protecting native vegetation and restoring degraded areas. Restoring high-altitude rangelands presents significant challenges, particularly in areas with limited accessibility and rugged terrain. The pilot restoration action in Tseko, Bhutan, and Shailung, Nepal, highlight the importance of integrated strategies to tackle pasture degradation in high altitude rangeland. The initial trials demonstrated benefits such as improved forage production, reduced shrub encroachment, and enhanced water availability through a combination of prescribed burning, cutting, weed removal, water management, and active community involvement. However, restoring degraded rangelands is a long-term process requiring sustained efforts, multidisciplinary collaboration, and continued monitoring (Kuniyal et al. 2021). The initial trials conducted in the first year of action are just the beginning, and these results must be closely monitored over time to ensure their effectiveness.

Destocking of livestock as a global phenomenon

Sala, OE[1]; Anadón, JD[2]

[1]Global Drylands Center, School of Life Sciences and School of Sustainability, Arizona State University, Tempe, AZ, USA.; [2]Instituto Pirenaico de Ecología (IPE-CSIC) – Zaragoza, Spain.

Key words: Degradation, overgrazing, abandonment

Abstract

Global rangelands are currently perceived as rapidly degrading because of overgrazing. Here, we report on our analysis of global stocking rates during the last 20 years. We found that regions containing 45% of the global livestock are being destocked, undergoing rapid reductions in livestock density since the 60s. On the contrary, the rest of global rangelands have exhibited a sharp increase in stocking rates. These trends intensified in the last 20 years. Our analysis shows that although almost half of the global rangelands exhibited destocking in the last 20 years, total meat consumption and per capita meat consumption have increased throughout the world. This trend resulted from increases in total number of cattle, sheep, and goat but even larger increases in pork and poultry.

We suggest that our report may lead to a shift in the rangelands paradigm from the idea of overgrazing as a dominant driver of degradation to a region-specific approach that assesses the global consequences of both overstocking and destocking for the functioning of the Earth system, including the carbon, water, and energy dimensions of global change. We conclude that it is critical to understand the global implications of these phenomena and develop management techniques for rangelands that are being overstocked as well as those that are either being abandoned and or rapidly destocked. A large fraction of rangelands research has focused on restoration, for example we, as rangeland scientist, have developed management techniques to reintroduce species that were lost because of overgrazing or eliminate invasive species. Now, we face the challenge of managing large areas that have been destocked or just abandoned. These rangelands need to be managed to avoid negative societal consequences ranging from biodiversity losses to wildfires. The challenge is large because managing abandoned rangelands is different than managing degraded lands and varies regionally.

Introduction

Rangelands represent a large fraction of the terrestrial surface, and their main use is livestock grazing (Asner et al. 2004). Moreover, 30% of the human population depend on livestock grazing for their subsistence (Steinfeld 2006). In addition, rangelands have a large impact on the global carbon cycle (Ahlström et al. 2015). The importance of rangelands is highlighted by the generalized perception that rangelands are rapidly degrading (Alkemade et al. 2013), and therefore they are losing their ability to provide ecosystem services on which large fraction of the population depends.

Here, we tested the degradation perception by evaluating changes in stocking rates in the last 20 years. Specifically, we evaluated if there were geographical patterns, with some areas of the world being overgrazed while others were not. We explored potential drivers that might explain the observed trends in stocking rates. Finally, we discuss the implications of varying global stocking rate patterns on research needs and rangeland management.

Methods

We analysed data from FAOSTAT (FAO 2024) for global trends in stocking rates for each of the 18 regions recognized by FAO that are Eastern Europe, Eastern Asia, Oceania, Western Europe, South Africa, Northern Europe, Southern Europe, North America, North Africa, South Asia, South America, Central America, including the Caribbean region, South East Asia, Western Asia, East Africa, West Africa, Mid Africa and Central Asia. The data base included different types of animals, such as cattle and sheep. We converted all the animal types into a common unit using FAO standardization technique, which considers variability in region and animal species. We evaluated changes from 2004 to 2024. We assessed meat production efficiency for each region as the ratio between meat production and number of animal units per region.

Results

Our first finding was that global rangelands are not all overgrazed. In contrast, we found that in the last 20 years, 45% of the area of global rangelands has experienced a reduction of stocking rate. Destocking in 45% of global rangelands coexist with increases in stocking rate in the rest of the world. Destocking has been occurring in Australia, North America and Europe (Table 1). In contrast, Africa, Asia, and South and Central America have exhibited increases in stocking rate.

Table 1. Rate of change of cattle for the period 2000–2021 in the ten FAO regions with the largest cattle stocks. The rate of change is expressed as the log response ratio (i.e., log (N2021/N2000)). Data source: FAOSTAT.

Region	Cattle 2000-21
Central America	0,10
Eastern Africa	0,27
Eastern Asia	-0,19
Eastern Europe	-0,19
Northern Africa	-0,05
Northern America	-0,03
South America	0,10
Southern Asia	0,05
Western Africa	0,28
Western Europe	-0,09

Once we have established trends in global stocking rates, we explored the mechanisms behind this pattern. The first hypothesis is that destocking responded to a reduction in meat consumption. However, meat consumption has increased in the last 20 years in areas experiencing both destocking and increasing stocking rates. And meat consumption per person and total consumption both have increased reflecting global increases in affluence and population.

Finally, the increase in meat production in regions experiencing destocking resulted from increases in the global efficiency of meat production (Thornton 2010). Increased efficiency has been documented in the past because of several husbandry improvements ranging from veterinary care to more water holes that result in better animal distribution (Oesterheld et al. 1992).

Discussion

Our findings have major policy and management implications. Destocking has positive and negative implications. Destocking has the potential of exacerbating biodiversity loss as demonstrated by large-scale syntheses of many studies across the world (Milchunas and Lauenroth 1993) and supported by ecological theory (Milchunas et al. 1988). Similarly, destocking leads to accumulation of standing dead that make rangelands prone to more frequent fires (Walsh et al. 2014). Destocking has also positive impacts reducing soil erosion and increasing soil-carbon stocks.

Most of the rangeland research has focused on understanding impacts of overgrazing on ecosystem functioning and developing tools to reclaim overgrazed rangelands. Therefore, our understanding of how to manage abandoned and destocked rangelands is scarcer. Policy, which is driven by research and drives research, has also mostly aimed at ameliorating the impacts of degradation resulting from overgrazing. As demonstrated through this study, the destocking of almost half of global rangelands highlights the need for greater research on the impacts of destocking on biodiversity, the carbon and water cycles as well as its impacts on albedo that directly affect the planetary energy balance. A better understanding of the effects of destocking may generate new tools to manage destocked lands in ways that match the increasing and changing demands that people impose on rangeland ecosystem services (Yahdjian et al. 2015).

The Global Land Outlook Thematic Report on Rangelands and Pastoralists: framework and theory of change for sustainably managing and restoring rangelands

Herrera Calvo, PM[1]; Alexander, S[2]

[1]Food and Agriculture Organization of the United Nations (FAO), Rome, Italy, email: pedro.herreracalvo@fao.org; [2]United Nations Convention to Combat Desertification (UNCCD), Bonn, Germany, email: salexander@unccd.int

Key words: Sustainable rangeland management, governance, land degradation neutrality

Abstract

The United Nations Convention to Combat Desertification (UNCCD) released its Global Land Outlook Thematic Report on Rangelands and Pastoralists (GLO) on 21 May 2024. The report offers a singular perspective on the sustainable management of rangelands and the critical role of pastoralists and extensive livestock systems, focusing specifically on their capacity for advancing towards Land Degradation Neutrality.

This paper offers a methodological approach to the narrative of the GLO. It starts by analysing the Driver-Pressure-State-Impact-Response (DPSIR) model of rangeland health and degradation status. It then explains the role of this model in the design of a Theory of Change for the report and the transition towards a conceptual framework for managing rangelands as social-ecological systems. Finally, the presentation links this methodology with the case studies and the actions and recommendations of the report.

Effective governance of rangelands requires a better understanding of their capacities, dynamics and the future supply and demand for their goods and services. The challenge is to ensure that these vast landscapes are managed in a sustainable manner while addressing the synergies and trade-offs under trans-disciplinary and multi-actor frameworks. This approach demands a strong scientific background but also a holistic and flexible conceptual framework that can lead to clear objectives and practical means of implementation, including policy frameworks, direct action, improved governance and better investments.

Introduction

The United Nations Convention to Combat Desertification (UNCCD) released its Global Land Outlook Thematic Report on Rangelands and Pastoralists on 21 May 2024. The report explores the links between rangelands and local communities. The report offers new entry points, possibilities, and recommendations for policymakers and other stakeholders that encourage greater attention, financial support, and investment

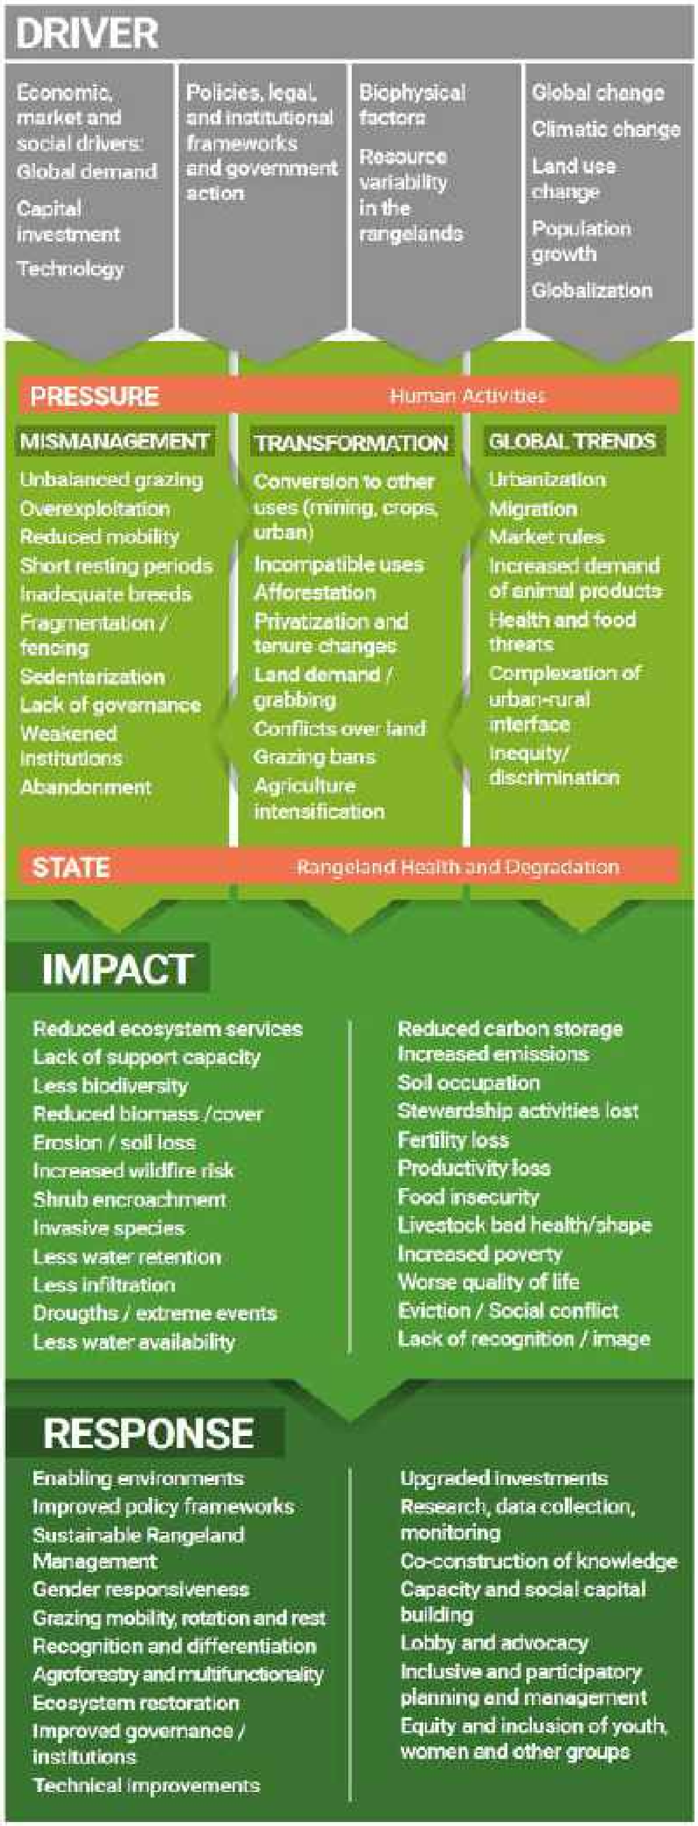

Figure 1. Rangelands' health and degradation status diagram designed for the GLO Rangelands report based on the DPSIR model

in Sustainable Rangeland Management (SRLM). It concludes that local, multi-actor, transdisciplinary, adaptive, and inclusive approaches are needed to improve the health and sustainable productivity of rangelands and the livelihoods of their stewards. The GLO Rangelands report also unravels the role and untapped potential of pastoralism and other extensive livestock management systems in reducing land degradation, contributing to just and equitable rural development and food security, protecting the rangeland commons, and generating transformational change towards climate resilient societies, while improving the health of these critical landscapes and the livelihoods of their communities.

This paper presents the methodology applied in the analysis and the narrative of the GLO seeking to encourage substantial change in the conceptual framework currently applied to combat desertification and degradation in rangelands, through sustainable management practices under pastoralist and other extensive livestock systems.

Methods

The methodology applied to sustain the rationale of the GLO Rangelands report starts with the definition of rangelands and then it is developed through three stages: health / degradation model, conceptual framework and Theory of Change. The actual methodology of building the framework for the report wasn't sequential but iterative, complementing each stage with the outcomes of the other two.

Results

The report substantiates a definition of rangelands based on grazing activity of open ecosystems by livestock and/or wild animals. Thus, they are considered as complex social-ecological systems (Hruska et al, 2017) whereby natural resources provide a broad range of goods, services, and values that must be considered in functional assessments (FAO, 2019). The base natural and semi-natural ecosystems hosting those rangelands are populated by indigenous vegetation predominantly comprised by grass, grass-like plants, bushes, or shrubs, including open forests and agroforestry systems.

The first stage consists in composing a rangeland health / degradation diagram (Fig 1) based on the Driver – Pressure – State – Impact - Response (DPSIR) model (Burkhard & Müller, 2008), which addresses complex challenges at the interface between society and the environment (Troian et al., 2021). The DPSIR model analyses rangeland health and degradation status, drivers and trends, addressing the complex trade-offs and interactions at the interface between rangelands, society and the environment.

The second stage allocates the agents and fluxes described in this model in a broader framework supporting the conceptualization of rangelands as social-ecological systems. This way, the DPSIR health / degradation model precedes the actual conceptual framework represented in Figure 2, where the elements and relationships shaping rangelands are organised through a multifunctional approach that links rangeland health and their management systems. The framework shows how they are intimately linked within the same social-ecological system. Thus, a systemic approach is needed to understand and sustainably manage rangelands, especially under pastoralist systems.

This way, the complex network of relationships among these elements in diverse political and social environments shapes the use and management of rangelands. Addressing land governance challenges opens the scope to the whole territory and to all stakeholders involved, a prerequisite for meeting national and global objectives addressed in the report (Davies et al., 2016). Accordingly, the conceptual framework allows the definition of a Theory of Change that shapes the whole report and organises their targets, means and outcomes. The complex network of relationships among these elements in diverse political and social environments shapes the use and management of rangelands.

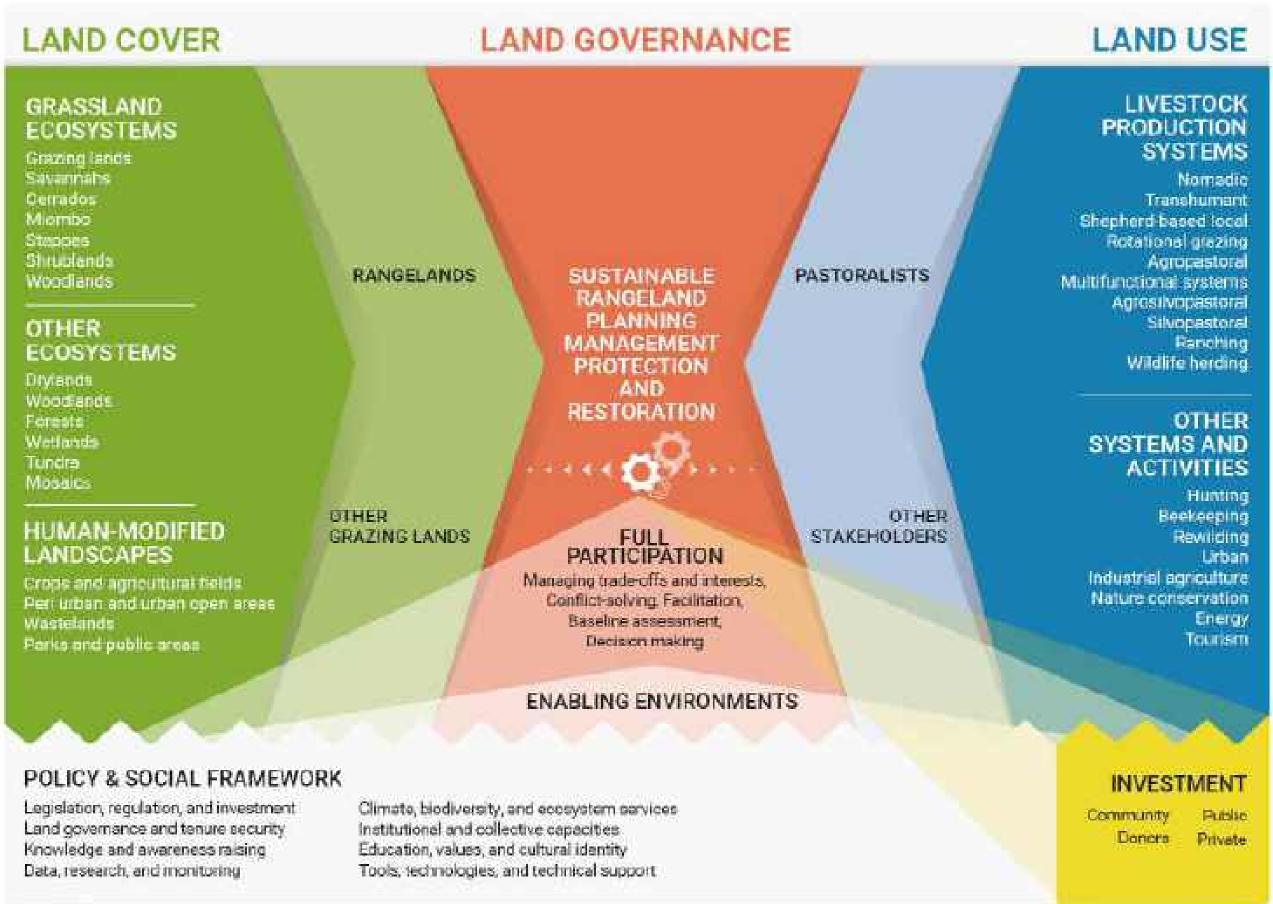

Figure 2. Conceptual framework for addressing rangelands sustainable management and governance as displayed in the GLO-Rangelands report.

Using the rangelands health/degradation model and the conceptual framework, the report was able to build a Theory of Change, displayed in Figure 3. This Theory of Change enables the development of the aims of the report, exploring the complex environmental, social, and economic dimensions that link rangelands and local communities and addressing the important role and untapped potential of pastoralism and extensive livestock management systems to contribute to a just transition, climate resilience, and more equitable rural development.

Discussion and Conclusions

There are notable disparities in the assessments of rangeland degradation which estimate its extent and degree globally. The mix of biophysical, social, and economic factors influencing land, its production, performance and health are often viewed subjectively (FAO, 2013). The estimates of rangeland degradation have changed over time, reflecting the progress made in the understanding of rangeland dynamics and indicators, assessment and monitoring tools, and management and land use systems (Onyango et al, 2021). Besides, there are still critical gaps in the knowledge, data, and interpretation of rangeland dynamics. Rangelands demand more research, data collecting and monitoring effort related to economic analysis, carbon pools, water cycle regulation, shrub encroachment and specifically their spatial and temporal use.

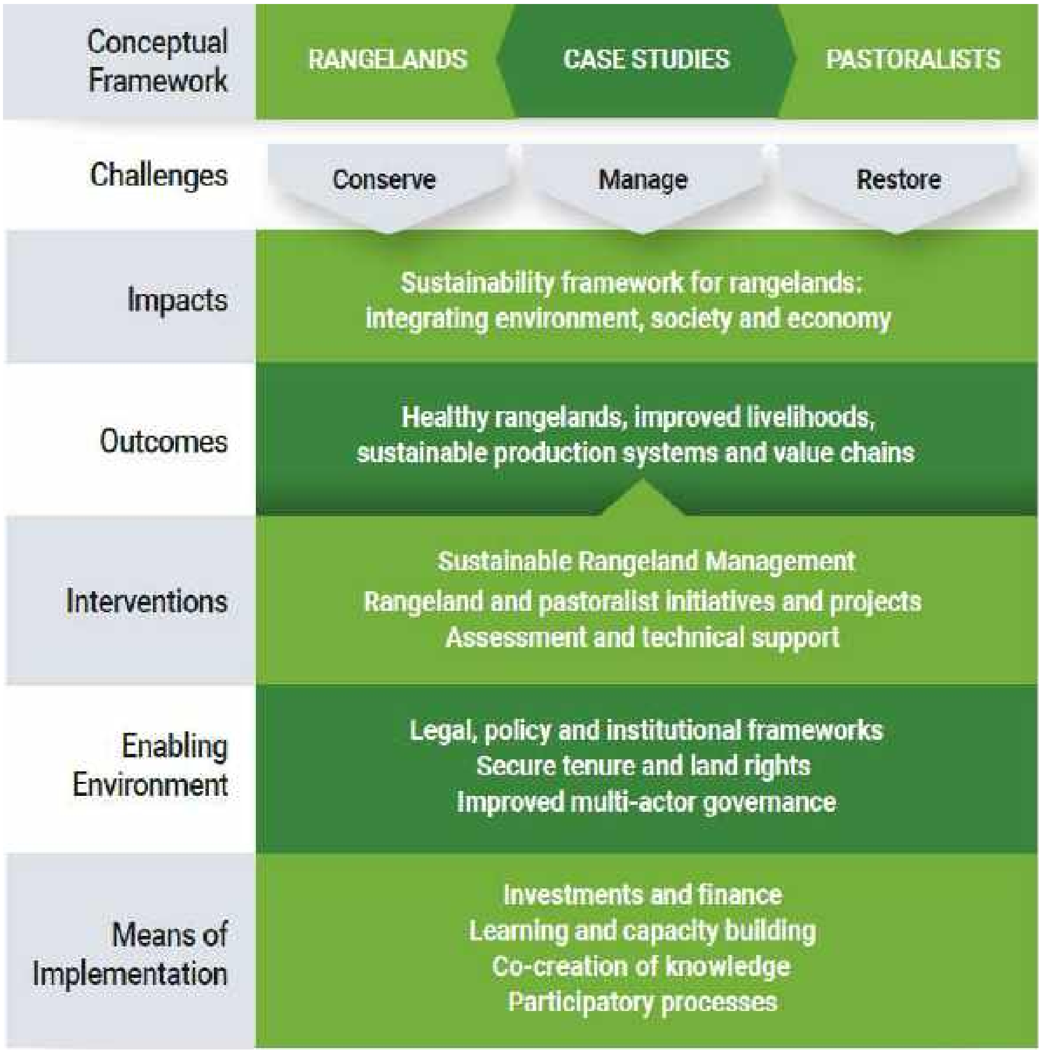

Figure 3. Theory of change developed within the GLO-Rangelands report.

The effective governance of rangelands requires a better understanding of their dynamics, capacity, and the future supply and demand for their goods and services. There has been a recent shift from the unsustainable demand for the tangible or market goods produced on the rangelands, to policies and regulations that recognise and value the wider range of services they provide to people, nature, and the climate (Yahdjian et al, 2015) The challenge is to ensure that supply and demand meet in a sustainable manner while addressing the synergies and trade-offs under transdisciplinary and multi-actor frameworks.

The complex network of relationships among these elements in diverse political and social environments shapes the use and management of rangelands. Addressing land governance challenges opens the scope to the whole territory and to all stakeholders involved, a prerequisite for meeting national and global objectives addressed in the report. However, it is important to recognise that many of the challenges confronting rangelands originate beyond local communities and are not under their control, although they should be a fundamental component of its governance.

The conceptual framework (Figure 2), complemented with the DPSIR framework (Figure 1), and the Theory of Change (Figure 3) arising from them provides the rationale for the GLO Rangelands report. This framework also underpins the global effort to protect rangelands and contributes to the effectiveness of initiatives at national and local scales. As many rangelands share common features, multi-scale perspectives and context-specific interventions can often help refine a global approach to plans, strategies, case studies and good practices. Additionally, the framework can also help to inform specific response measures, management systems, legal advances and governance schemes that can be used by different initiatives.

This framework has provided guidance for the analysis of case studies and projects collected in the report, using a common lens to address their specific features and focal points, ultimately shaping the recommendations collected in the report and its policy brief.

Herd effect and deep ripping to restore claypans in western New South Wales rangelands

McDonald, SE[1]; Finlayson, G[2]; Orgill, SE[3]; Strong, C[4]; Andersson, K[1].

[1]NSW Department of Primary Industries and Regional Development, Orange, NSW 2800, Australia; [2]Bokhara Plains, Brewarrina, NSW, Australia; [3]Select Carbon, 275 George St, Brisbane QLD 4000 Australia; [4]Australian National University, Acton, ACT, 2601, Australia

Key words: Grazing management; herd effect; ripping; animal impact; rangeland restoration

Abstract

Historic soil degradation, primarily due to overgrazing and drought, has led to the widespread formation of bare, scalded 'claypans' throughout the rangelands of south-eastern Australia. Mechanical interventions such as ripping and water ponding have been used to restore claypans over the last ~70 years, with varying success. Strategic management of livestock to restore degraded land has increasingly gained attention in recent decades as an alternative to resource-intensive mechanical restoration methods or complete destocking. This study compared the effects of intense cattle impact (~400-600 cattle held overnight on 0.5 ha of claypan + hay) with deep ripping (a single tine, to 30 cm depth with one meter row spacings) across three replicate claypans on 'Bokhara Plains' in the semi-arid rangelands of western New South Wales (NSW), Australia. Two years following the interventions, results show a significant increase in plant cover (up to 50%) and diversity for both the cattle and ripping treatments, compared to the control (initially 0% cover), and a reduction in salinity of the upper soil profile. Differences in vegetation cover between the cattle and ripping treatments were less obvious, though there were differences in plant composition with higher species richness under the cattle treatments at some replicates. These results demonstrate the effectiveness and need for targeted management to restore scalded areas and regenerate land condition in rangeland grazing systems.

Introduction

Historic soil degradation, primarily due to overgrazing and drought, has led to the widespread formation of bare, scalded 'claypans' throughout the rangelands of south-eastern Australia (Cunningham 1987). These soils are often saline and dispersive, with sealed surfaces that constrain plant emergence, water infiltration and nutrient cycling. With no or little vegetation growth or cover, they are vulnerable to wind erosion and unable to support livestock production, and even under conservative grazing management, many have failed to recover naturally. Increasing water infiltration (and the subsequent benefits this brings by leaching salts and reducing salinity), surface soil roughness and niches for seed to establish is required to effectively restore degraded scalds (Cunningham 1987, Green 1989).

In extensive rangeland grazing systems of semi-arid NSW, Australia, this has historically often been achieved through mechanical interventions including deep ripping, furrowing or water ponding (e.g., see Cunningham 1967, 1970, Green 1989; Wakelin-King 2011). 'Herd effect', is purported to achieve similar benefits through intensive trampling (hoof action) of livestock to break the soil surface and provide the addition of nutrients and seed through livestock dung and urine (Savory 1989). However, the use of strategic livestock management (herd effect) to restore degraded land has not been scientifically trialled in NSW rangelands.

This trial sought to understand how deep ripping or high density and intensity grazing by cattle for short durations (herd effect) affects the restoration of soil and pasture on degraded scalds in north-western NSW.

Methods

The trial was located on 'Bokhara Plains', approximately 30 km north of Brewarrina, NSW Australia (29°40'29"S, 146°56'37"), on the Barwon River floodplain, Wongal Land System (Walker, 1991). The climate is semi-arid, with an average annual rainfall of 385 mm and a summer dominant rainfall pattern. Soils on Bokhara Plains are predominantly grey vertosols. Vegetation is comprised of open woodland and grasslands, with isolated whitewood and coolabah and understorey of Mitchell grass (*Astrebla* spp.), Native millet (*Panicum decompositum*), forbs, annual and perennial subshrubs (*Atriplex* spp., *Sclerolaena* spp., *Maireana* spp., *Rhagodia spinescens*). Across Bokhara Plains, and the broader landsystem, there are large areas of scalds, characterised by very low vegetation cover and saline and sodic soils. Three scalded areas across different paddocks (4 – 10 km apart) on Bokhara Plains were selected as replicates of the trial. Each replicate claypan was divided into ~0.5 ha plots which were randomly assigned one of the following treatments: 1) herd effect (cattle); 2) ripping; and 3) control (no treatment). Further detail on treatments is provided below.

Herd effect treatment

At replicates 1 and 3, cattle (400-600 Livestock units, LSU) were held overnight on plots three times between May 2022 and April 2024. At replicate 2, cattle (680 LSU) were held on the plot for two hours in April 2022 (one time only). Prior to introducing cattle, on each occasion two large haybales were spread throughout the plot to introduce organic material and increase activity and movement of livestock in the plot. Each replicate experienced animal impact at a different timepoint.

Ripping treatment

In each replicate, a single tine behind a tractor was used to rip to depth of ~30cm, in a spiral formation. Each rip line was approximately 1 m apart. Replicates 2 and 3 were ripped in April 2022, while replicate 1 was ripped in September 2022 (the same time that cattle initially impacted the herd impact plot).

Vegetation and soil monitoring

In April 2022 (prior to installation of treatments), April 2023 and June 2024, ground cover (percent cover of plant, litter, cryptogam, coarse woody debris, dung and bare ground), herbage mass and plant composition (percent cover by species) was assessed in 0.25m^2 quadrats every 10 m (replicates 1 and 3) and 15 m (replicate 2) along three transects in each treatment plot (7 quadrats per transect, 21 quadrats per plot). At five permanent locations in each plot, all species within a larger 5x5m quadrat were identified. In June 2024, seven soil cores were collected along each transect and composited by depth 0-5cm, 5-10cm, 10-20cm and 20-30cm. Salinity (electrical conductivity, ECe) was assessed through laboratory analysis (Shaw 1999; Rayment and Lyons 2011; Method 5A2b and 3A1) to estimate effects of treatments on soil salinity.

Results

Vegetation cover was greater under the cattle treatment relative to the control at two of the three replicate scalds, while the ripping treatment had a positive effect across all three scalds (Fig. 1). Compositional differences between the three treatments were most apparent in the third replicate, which included a greater proportion of native perennial grass (e.g., *Eragrostis setifolia, Sporobolus caroli, S. actinocladus, , Tripogon loliiformis)* and non-native perennial grass *(Lolium perenne*, assumed to be imported with the hay) cover in the cattle treatment than the ripping and control treatments. Species richness was greater in the cattle treatments at the first and third replicates, while the control and ripping treatments had similar richness values to each other across all replicates (Fig. 2). Two years post cattle and ripping treatment, salinity (EC) of the upper soil layers (0-20cm) at replicates 1 and 3 was lower under cattle and ripping, while differences at replicate 2 were smaller and constrained to the 0-5 cm surface layer (Fig. 3).

Discussion

Both ripping and high intensity animal impact for a short duration in combination with additional organic material (hay) had a positive impact on the restoration of degraded scalds across Bokhara Plains, increasing ground cover and plant diversity and decreasing soil salinity. The greatest response (including a reduction in the amount of bare ground and >50% increase in plant and litter cover) was apparent at the third replicate where cattle had impacted the area overnight three times in the two years prior to the final monitoring occasion. Replicate 2 experienced the least cattle impact, with only two hours of cattle impact in April 2022, more than two years prior to final sampling, and had the smallest response, similar to that of the control treatment. This variability in response highlights the potential role that the timing, duration and frequency of animal impacts to achieve desirable results and suggests achieving greater disturbance by holding livestock for longer (overnight) is more effective than one-off, very short periods of time.

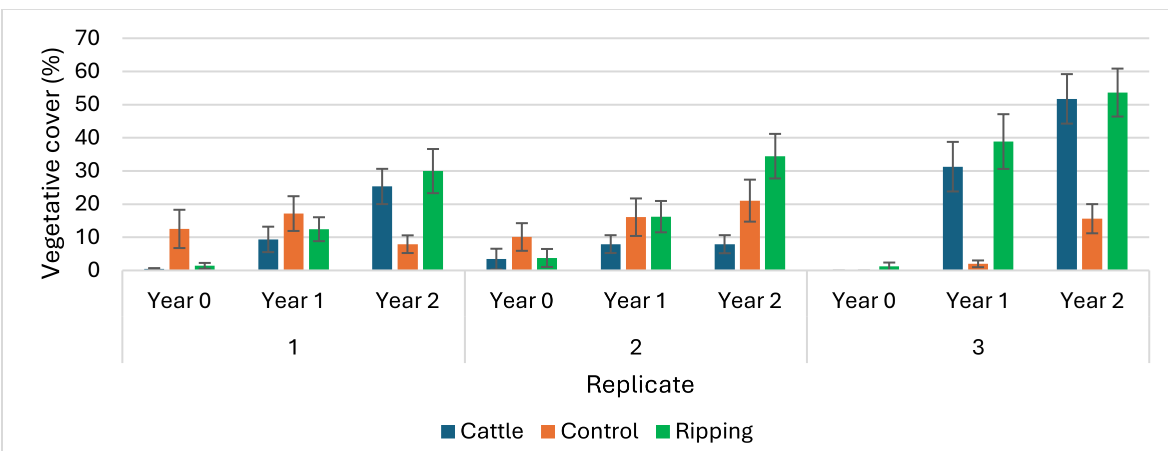

Fig 1. Average vegetative (plant and litter) cover for cattle, ripping and control treatment plots across three replicate scalds, measured prior to trial installation in April 2022 (Year 0), April 2023 (Year 1) and June 2024 (Year 2), ± 1 standard error.

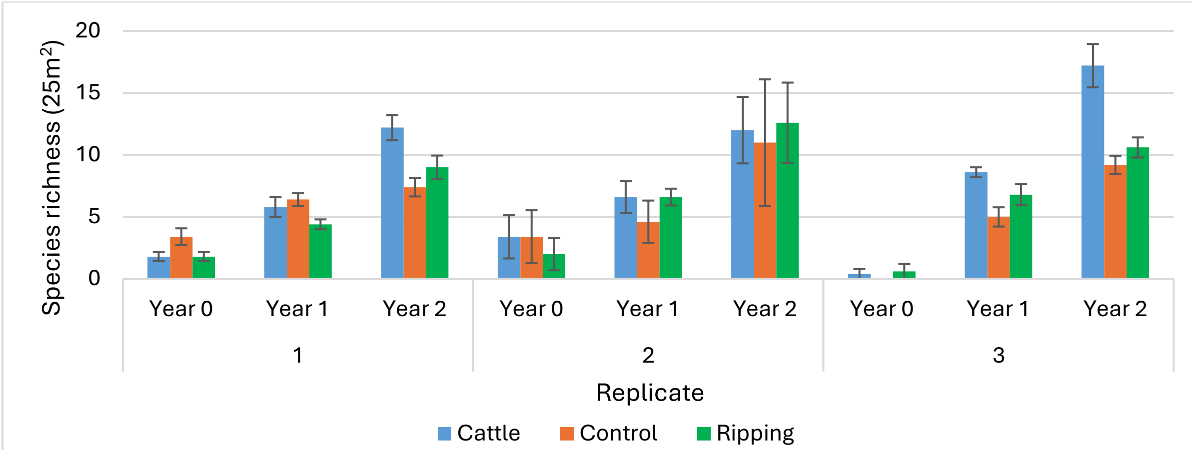

Fig 2. Average species richness (number of plants per 25m^2) for cattle, ripping and control treatment plots across three replicate scalds, measured prior to trial installation in April 2022 (Year 0), April 2023 (Year 1) and June 2024 (Year 2), ± 1 standard error.

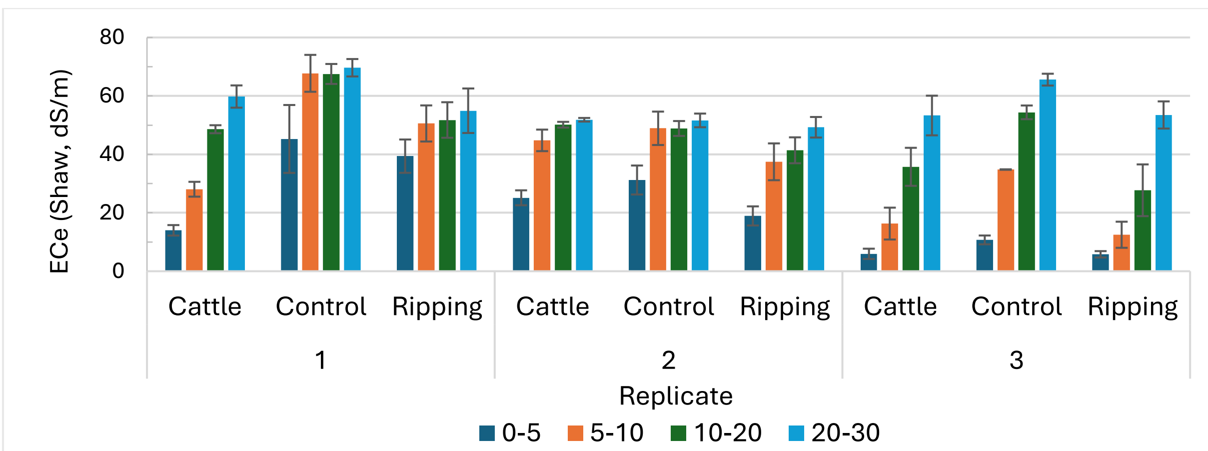

Fig 3. Electrical conductivity (ECe, Shaw 1999) of soil profile layers (0-5cm, 5-10cm, 10-20cm, 20-30cm depth) for cattle, ripping and control treatment plots across three replicate scalds in June 2024, two years after treatment, ± 1 standard error.

There are few published studies on the use of herd effect to restore degraded rangelands, and no studies we are aware of compare with mechanical restoration methods such as ripping. However, positive results observed in this study are similar to those reported by Barnes and Hibbard (2016), where forage growth was significantly greater one year following animal impact in night pens. The benefits of ripping to rangeland restoration have been documented throughout the world (e.g., Jones 1966; Miyamoto et al. 2004), however, long-term effectiveness of these treatments is often dependent on soil type (Friedel et al. 1996). The application of high-density animal impact in this study was in conjunction with addition of organic material (hay) and we are therefore unable to separate the potential impacts of herd effect and the organic material. Seed from the hay likely contributed to a proportion of plant growth observed within the herd effect treatments (e.g., *Avena sativa* and *Lolium perenne*). Studies in Australia have documented beneficial effects of addition organic materials to create patches for resource capture and germination of perennial grasses (e.g., Bean et al. 2015).

The decrease in surface salinity under the cattle and ripping provides improved conditions for plant establishment and growth, providing a positive feedback cycle as increased plant cover further reduces the draw of salts to soil surface. Periods of above-average rainfall over the duration of the trial also resulted in some improvement in the control areas in 2023 relative to that recorded in 2021, however this increase was generally greater in the cattle and ripping treatments.

These results demonstrate the effectiveness of targeted management actions in restoring scalded areas on the Darling Riverine Plains. For long term remediation of these sites, it will be important to sustain the changes that have been achieved so far by continuing to carefully manage grazing pressure of both domestic and unmanaged herbivores. Further research examining the impact of timing of animal impact (i.e, in dry versus moist conditions), duration and frequency of impact, with and without addition of organic material, and combinations of both mechanical and animal impact is recommended, alongside continued monitoring of the trial site to understand long-term benefits of the management interventions.

Effects of different intensity grazing on ground-dwelling arthropods, especially Coleoptera

Wang, YD[1]; Shi, CJ[1]; Li, YL[1]; Cheng, JW[1]; Li, FY[1]

[1] Key Laboratory of Ecology & Resource Use of the Monoglian Plateau, School of Ecology & Environment, Inner Mongolia University, Hohhot, 010021, China

Key words: adaptive grazing management; insects; plant leaf traits; plant community attributes; soil moisture

Abstract

In order to investigate the effect of grazing on the inherent Arthropod-Plant relationship, various adaptive intensity grazing management experiments were conducted on typical steppe in Inner Mongolia. At the community level, arthropod richness was higher in light and heavy grazing than in moderate grazing, but there was no significant difference between grazing and no grazing. Both arthropod communities and Coleoptera prefer to survive in relatively dry soil environments. The lower the plant biomass, coverage, and height, the higher the Coleoptera abundance, likely due to grazing shaping a more open feeding space for visual predators. However, dry soil and more open feeding space are accompanied by more intense grazing interference, and the stronger the direct interference, the lower the biomass of arthropods, especially Coleoptera. The direct disturbance of grazing to arthropods (involuntary feeding and trampling) may often be underestimated, these direct disturbances may mask the indirect disturbance of grazing to arthropods through plants, and grazing may cause arthropods to choose a more stable environment rather than a better one. This means that it is necessary to incorporate surface arthropod-related monitoring data into the sustainable development and utilization management system of grasslands.

Introduction

Large herbivore grazing has profound influence on soil physiochemical properties and biological communities (Lu et al. 2022), including arthropods that play a crucial role, in grassland ecosystems (Wilson 1987). On the one hand, the unconscious foraging and trampling of large livestock has a strong and direct effect on arthropods (Van et al. 2015), which is often underestimated. On the other hand, the large herbivore grazing induced variation in soil properties and plant communities can cascade to arthropod communities, and this 'bottom-up" effects (Hunter and Price 1992) of transmitting the variation in soil properties to plant communities and then to arthropod communities have been extensively investigated in grassland ecosystems (Lu et al. 2021).

The abundance and diversity of arthropods increase with the increase of plant production (Lu et al. 2021), as more food resources can support more abundant and diverse herbivores, and the increase includes increase of generalists, specialists and unidentified predators (Lu et al. 2022). In addition to plant quantity, the vegetation environment, especially height and coverage, is also an important factor affecting arthropods. Many herbivores and predators may use chemical odour sensing and/or visual media search mechanisms to find their host plants or prey rather than searching randomly (Michel et al. 2007). The changes in vegetation height and coverage can alter the complexity of vegetation structure, thus the wind in vegetation canopy and the ability of arthropods searching for the odour concentration of host plants and prey (Cardé and Willis 2008); it can also directly affect the arthropods' visual search ability for host plants and prey (Randlkofer et al. 2010). Zhu et al. (Zhu et al. 2012) also found that plant structural heterogeneity (coefficient of variation of plant height) had a greater impact than plant species diversity on insect diversity in a meadow grassland.

The aim of this study was to elucidate the influence of large herbivores grazing on arthropod communities. The following two questions were studied: (1) What are the effects of large herbivores grazing on arthropod communities or Coleoptera? (2) How are the effects of grazing on plant communities and soil water content cascaded to arthropod communities or Coleoptera? The answers to these questions will deepen our understanding of the role of arthropods in maintaining ecosystem function and help develop management strategies to protect grassland ecosystems.

Methods

Study site

This study was carried out with the Grassland Ecosystem Research Station of Inner Mongolia University, located in the Xilingol region of Inner Mongolia, China (44°15′ N, 116°31′ E, 1146 m a.s.l.), using four intensity grazing platforms (each paddock has 0, 3, 6, and 9 two-year-old sheep, named CK, LG, MG, HG; Fig.1). For specific regional climatic conditions, vegetation types, grazing designs and sampling methods for plant indicators, see (Shi et al. 2023).

Arthropod sampling and identification

The pitfall traps (plastic cups of 7cm in diameter and 7cm in depth) were used to sample the arthropods in the grasslands before the last rotational grazing of the season in August 2019, 2020 and 2021. Two trapping points, 10 m apart from each other, were set up on relatively consistent vegetation in each paddock, with three traps at each point. Approximately 5 ml of glycerol and 50 ml of 75% alcohol solution were added to each trap. The traps were placed in the grassland before 9:00am in a no-rain day for continuously collecting arthropods for 48 hours. All collected samples were stored in 75% alcohol solution, and returned to the laboratory and identified with optical microscopy according to references (Li et al. 1987). Specimens were identified to the family as far as possible, and a few unidentifiable arthropods to order. Adults and larvae were counted separately for most completely metamorphosed arthropods as they have different feeding habits. After identification, arthropods were placed on dry filter paper to constant weight, and weighted to 0.0001 g.

Soil water content

The top soil (0 – 10 cm) was sampled using the drill of 5 cm at the location close to the trapping points (3 drill at each point) after the arthropod collection and brought back to the laboratory for determining soil water content (SW) by weighing in fresh and dry after over-drying at 105 °C.

Data processing and statistics

The relative abundance (RA) of an arthropod order, i.e., the percentage of the arthropod order abundance in total arthropod abundance, were calculated. Based on the RA, We found that Coleoptera accounted for 45.54% of the total community, so we focused on Coleoptera in addition to the community. The effects of large herbivore grazing on the arthropod traits as well as sampling years were also analyzed using repeated measure analysis of variance. Plant indicators were reduced to an indicator axis VPCA by PCA analysis (58.97%). Greater VPCA represents greater plant biomass, coverage and height, while density and species richness are reversed. The effects of vegetation and soil factors on arthropod communities or Coleoptera were studied by linear or nonlinear fitting.

Results

Effects of grazing on ground-dwelling arthropod communities or Coleoptera.

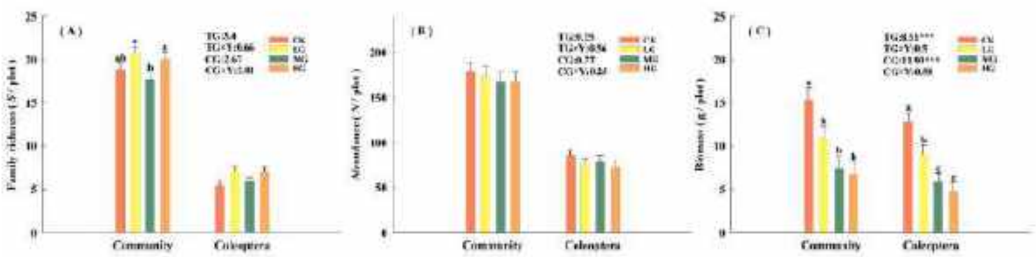

Fig. 1 Effects of different grazing intensities on ground-dwelling arthropod communities or Coleoptera. Different lowercase letters indicate significant differences between treatments (Duncan, $p<0.05$). T represents the total arthropod community; C represents Coleoptera; G stands for grazing; Y represents the year; G×Y represents the interaction between grazing and years. The number indicates the *F* value, and *** indicates $P<0.001$.

Effects of grazing on plant communities or soil water content.

Table.1 Effects of different grazing intensities on vegetation, plant leaf characters and soil. All values are mean ± standard error. Lowercase letters a, b, and c indicate significant differences in the same indicator (Duncan, $P<0.05$).

Discussion

Our results suggest that the difference in arthropod family richness across grazing intensities may be related with the grazing-induced changes in vegetation environment and the resources available to arthropods. In the *LG* grassland, vegetation height was uneven and structure was complex, and this type of vegetation provides a diverse living space (Zhu et al. 2012) and support a high arthropod family richness. In the *MG* grassland, the vegetation height variation and structural complexity was lower, thus support a lower arthropod family richness (Table.1). In the *HG* grassland, although vegetation structure was simple, the abundant faeces and blood of large herbivore provide more diverse food resources for scavengers and parasites (Van et al. 2015), which may be major factors for relatively high arthropod family richness in *HG* grasslands.

Grazing did not change the abundance of arthropod communities and Coleoptera, and neither community nor Coleoptera preferred moist environments. Indeed, low soil water content increases arthropod survival (O'Neill et al. 2003). But this change in soil water content is caused by grazing (Lunt et al. 2007). Similarly, grazing reduces plant biomass, plant height, and cover, which provides better hunting space for visual predators (Coleoptera) (Michel et al. 2007). The positive effects of grazing (drier soil and more open feeding space) are accompanied by stronger negative effects (trampling, unconscious feeding), and the reduction in plant biomass means fewer herbivores, suggesting that the two effects can cancel each other out to a certain extent (Van et al. 2015).

In no-grazing or light grazing grasslands, the vegetation is tall and dense, and the litter layer is thicker, which can provide adequate food (Lu et al. 2022) and a more stable living environment for arthropods (Pétillon et al. 2008). However, high grazing intensity increased the damage to arthropods caused by involuntary foraging and trampling (Wang et al. 2024), which is often underestimated. For example, while beetles' hard elytra allows them to adapt to more diverse environments (Parker 2016), beetles are also more likely to die when trampled by large herbivores. At the same time, some Coleoptera insects have faked death (Humphreys and Ruxton 2018), which may also increase the probability of being trampled to death.

Grazing reduced the biomass of arthropod community and Coleoptera. In the case of Coleoptera, which are mostly predators, this could disrupt the ecological balance of the entire ecosystem. At the same time, the direct disturbance of grazing appears to have a stronger effect on arthropods, changing the arthropod's preference for a suitable environment. This suggests that, in addition to the impact of environmental and management factors on arthropods, more attention needs to be paid to arthropod adaptation to different grassland use patterns.

Key words: Herder household mobility; factor analysis; ecological, economic, and social factors.

Abstract

Mongolia's heavy dependence on pastureland makes sustainable pasture use crucial. Historically, nomadic Mongolians maintained ecosystems by frequently moving livestock, a practice essential for pasture sustainability. Despite its importance, research on the factors affecting herder household mobility (HHM) is limited, especially using econometric modelling to identify and estimate these factors. This study examines socio-economic and ecological factors influencing HHM in four Mongolian provinces using pooled data econometric models.

The research addresses two main questions: 1) What social, economic, and ecological factors influence HHM decisions? 2) What policy implications arise from these factors? The study was conducted in 11 sub-districts across four provinces, using stratified random sampling based on probability. Data were collected from the same 253 households over three years in 2019, 2020 and 2022, resulting in a total of 759 observations.

The ecological factors such as the number of households sharing the same pasture (24.9%), water output in the pasture (26.7%) and drought (41.6%) promote greater mobility. Economic factors include livestock wealth, which contributes to a 45.2% increase in mobility distance. Finally, the social factors that increase mobility distance include the female household head (76.1%), the distance to the district center (57.2%), and adherence to local government plans (62.1%).

Conversely, ecological factors such as better vegetation conditions (30.2%) correlate with shorter HHM distances. Among the economic factors, increased fuel prices (54.8%) and owning a truck by a herder (18.2%) reduce mobility distance. Social factors that reduce mobility distance include larger family sizes (17.3%) and older household heads (38.2%).

The study's insights offer crucial implications for policy-making aimed at enhancing sustainable HHM in Mongolia. Understanding these factors can help devise strategies to support herder communities while maintaining pastureland sustainability, ensuring both ecological balance and the well-being of herder households.

Introduction

Pastureland provides essential ecosystem services, including livestock forage, carbon sequestration, and water flow regulation (Rodríguez-Ortega et al., 2014). However, climate change and land-use changes have negatively impacted Mongolia's rangelands, leading to reduced pastoral mobility and increased environmental degradation (Fernández-Giménez et al., 2018). In 2018, pastureland covered 71.6% of Mongolia, feeding 64.7 million livestock (Agipar et al., 2019; NSO, 2024). The rapid growth of livestock, which has more than doubled since 1990, has resulted in overgrazing, with 57% of rangelands degraded as of 2016 (Densambuu, B et al., 2018).

Sustainable pastureland management, essential for balancing ecosystem health and herder livelihoods, relies on mobility strategies such as seasonal and *Otor* movement (long distance movement) (Gonchigsumlaa & Damdindorj, 2021). Yet, since the transition to a market economy in the 1990s, mobility has declined due to privatization and weakened institutional support (Fernandez-Gimenez & Le Febre, 2006). Reduced herder household mobility (HHM) exacerbates rangeland degradation, undermining livelihoods and livestock productivity (Kerven, 2003; Humphrey & Sneath, 1999) of herder households (HHs).

This study uses econometric models to investigate socio-economic and ecological factors influencing herder household mobility in Mongolia, aiming to inform policies that enhance mobility and promote sustainable rangeland use.

Methods

The study was conducted in 11 sub-districts (core sites) across four provinces: *Tuv*, *Khentii*, *Dornod*, and *Sukhbaatar*. Using stratified random sampling, 320 HHs were selected in 2019, representing 22% of the herder population. The sample size decreased to 289 in 2020 and 253 in 2022 due to household migration, status changes, absences, endemic quarantine, and COVID-19 lockdowns. To generate balanced panel data, the same HHs were surveyed yielding 759 observations from 253 HHs over three years.

The annual total distance of HHM, measured by km (**lnDIS**[4]) was selected as the dependent variable, which we want to explain using independent variables (total distance moved for three types of HHM: between and within seasonal camp mobility and *otor* mobility (Gonchigsumlaa & Damdindorj, 2021)). We divided the independent variables into ecological, economic and social factors. **Ecological factors** include vegetation condition (**AVEG2**), rated from 1 (Very poor) to 5 (Excellent), to capture vegetation changes before and after pasture use (Fernández-Giménez et al., 2018); water availability (**WAT**), categorized as 1 (Bad), 2 (Average), or 3 (Good) (Lkhagvadorj et al., 2013); and two dummy variables for Dzud (harsh winter) (**DZUD**) and drought occurrence (**DRO**), indicating whether these disasters occurred in the previous year (Fernández-Giménez et al., 2018). **Economic Factors** include annual income of the HH, by Mongolian Tugrik (MNT) (**lnINC**); livestock number of the household, by sheep unit (**lnSHU**); number of households using the same pasture, to express the pasture competition (**lnHH**); dummy variable indicating whether the household owns a truck (**TRUCK**) (Lkhagvadorj et al., 2013); fuel price per liter (**lnFUEL**) (Gonchigsumlaa & Damdindorj, 2021); and dummy variable indicating whether the HH lost their pasture (**LPA**). Social factors include family size (**lnFM**); gender of the HH head, (0=Male, 1=Female) (**GEN**); age of the household head (**lnAGE**); HH head's number of years spent on herding livestock, as for experience (**lnEXP**); annual average distance between district center and the HH location in km (**lnDSC**); dummy variable whether the household move in accordance with the local government plans (**PLA**); and dummy variable whether the household is a member of a herder organization (**ORG**).

We run four types of econometric models for analysis including Pooled OLS, Pooled OLS with clustered robust standard error, Fixed effect model (FE), and Random effect (RE) model.

Results

Descriptive statistics

For seasonal-camp mobility, a household moved an average distance of 35.4 ± 37.05 km, with a minimum distance of 0 km and a maximum distance of 292 km. As for within-seasonal-camp mobility, a household moved an average distance of 4.5±12.9 km, with a minimum distance of 0 km and a maximum distance of 196 km. Also, for *otor*, a household moved an average distance of 12.8±41.8 km, with a minimum distance of 0 km and a maximum distance of 460 km. Overall, an average HH moved 4.8 times for 52.6±65.1 km on average, with a minimum distance of 1 km and a maximum distance of 565 km.

Robustness of Test Results

The dataset comprises panel data for 253 households over three years (T=3, N=253). Seven of the 17 explanatory variables are dummies, which could lead to multicollinearity. However, the Variance Inflation Factor (VIF) test showed low multicollinearity, with an average VIF of 1.31 (well below the threshold of 5) (James et al., 2013). Wooldridge's test for serial correlation did not detect first-order autocorrelation (Prob > F = 0.1135). Fixed Effect (FE) and Random Effect (RE) models are widely used for panel data analysis. FE models account for within-entity variation, controlling for time-invariant characteristics (Torres-Reyna, 2007), making them suitable for our dataset. In contrast, RE models assume no correlation between entity-specific effects and predictors. The Hausman test, which compares FE and RE, rejected the null hypothesis (Prob > chi2 = 0.0017), favoring FE (Hausman, 1978). To address heteroskedasticity concerns affecting Hausman test, the robust Sargan-Hansen test was also applied (Mark E Schaffer & Steven Stillman, 2006), confirming FE as appropriate (P-value = 0.0003). The restricted F-test compared

[4] In the abbreviations of the variables, if there is a "ln" then it means that the variable is natural log transformed.

FE and Pooled OLS, favoring the latter (Prob > F = 0.0000) as a more optimal model. Similarly, the Breusch-Pagan test (Prob > chi2 = 0.0000) supported RE over Pooled OLS (Vijayamohanan Pillai N., 2016). Finally, the Chow test (Prob > F = 0.0000) confirmed Pooled OLS as the best fit for the data. Based on these results, the robust Pooled OLS model was selected for analysis.

Model results

In the table below, we compared the results of four different estimators including Pooled OLS, Pooled OLS with clustered robust standard error, Fixed effect model (FE), and Random effect (RE) model.

Table 1. Results of the models: Factors affecting the distance of herder household mobility

Source: Results of Stata software, OLS analysis of data from 759 herder households

As shown in the table, the difference between default and cluster-robust standard errors for the Pooled OLS model was minimal, likely due to the short panel data. A notable exception was the variable “ORG,” which was not significant at the 15% level under robust errors. The model’s coefficient of determination (R^2 = 0.2087) indicates that 20.87% of the variation in mobility distance is explained by the included factors. The relatively low R^2 value in the pooled OLS model indicates that while the included variables explain a portion of the variation in household mobility, other unobserved factors likely play a significant role. Variables such as the education level of the household head, the annual income, access to diversified or improved livelihood opportunities etc. Despite this modest R^2, most variables were statistically significant, with 12 showing meaningful effects at 85-95% confidence levels.

Ecological Factors: Vegetation condition after pasture use (AVEG2) negatively influenced mobility distance (-0.359***), while factors like increased household competition for pasture (lnHH), water availability (WAT), and drought occurrence (DRO) had positive effects, with mobility distance increasing by 24.9%, 26.7%, and 41.6%, respectively.

Economic Factors: Wealth (lnSHU) positively affected mobility distance (0.275***), while owning a truck (TRUCK) (-0.201*) and rising fuel prices (lnFUEL) (-1.583*) reduced it.

Social Factors: Family size (lnFM) (-0.211***) and the age of the household head (lnAGE) (-0.657***) reduced mobility distance, while female household head (GEN) (0.566***), distance from the district center (lnDSC) (0.373***), and adherence to local government plans (PLA) (0.483***) positively influenced mobility.

Discussion

Research on herders' mobility often focuses on ecological factors, with less attention given to socio-economic drivers. Mobility is a crucial strategy for utilizing unevenly distributed forage and sustaining livestock. Herders understand long-term pasture dynamics but struggle with short-term changes, risking ecosystem health if traditional knowledge is lost (Oyundelger et al., 2024, *unpublished manuscript*).

Short-distance mobility is often constrained by limited grazing areas within administrative units, exacerbating pasture degradation. However, reciprocal grazing agreements can mitigate this (Fernandez-Gimenez & Le Febre, 2006). Mobility strategies, such as fall *Otor*, are effective in reducing the impacts of climate shocks like Dzud (Baival & Fernández-Giménez, 2012).

Economic constraints, including high fuel costs and limited labor, also influence mobility. Wealthier households with larger herds tend to migrate farther (Fernández-Giménez, 2001), while those lacking resources are less mobile (Baker & Hoffman, 2006). Policy interventions like the proposed Pastureland Law and improved pasture use planning can enhance sustainable mobility and resilience (Fernández-Giménez et al., 2018).

Strategic shock management, supported by modern tools such as savings and insurance, could further strengthen herders' resilience. Policymakers should focus on integrating these strategies while fostering collective action through Pasture User Groups (Kasymov et al., 2023).

Based on the research result two policy implications were derived. Firstly, the successful implementation of pasture use planning is critical for fostering pastoral mobility and mitigating overgrazing. Local administrations must take an active role in regulating pasture use and determining the timing of seasonal movements. While ecological factors and traditional practices influence mobility, local administrative organizations should establish clear schedules for seasonal movement in collaboration with herders. This ensures that winter and spring pastures are well-maintained and protected post-migration. Coordination with Pasture User Groups and herders' communities is essential to enforce these schedules and promote sustainable pasture management practices. Secondly, developing supportive infrastructure such as water points, livestock corridors, and seasonal shelters is essential to enable herders to move efficiently between pastures. Policies should incentivize adherence to established mobility plans and provide resources for maintaining infrastructure. Integrating these measures with broader sustainable rangeland management policies will help reduce competition for resources, improve pasture conditions, and ensure the long-term viability of pastoral livelihoods.

Acknowledgements

The authors extend their gratitude to the Federal Ministry of Education and Research (BMBF) of Germany for funding the project “MORE STEP – Mobility at Risk: Sustaining the Mongolian Steppe Ecosystem”, under which this study was conducted. We extend our sincere gratitude to the Mongolian University of Life

Sciences for their support in implementing the project and to the herder households for their valuable participation in the surveys.

Linking rangeland condition to grazing management practices: lessons learnt from champion farmers in the grassland and savanna biomes

Finca, A[1]; Ngoako, N[1]; Ntombela, K[1]; Pule, G[1]; Zondani, T[1]; Malepe, K[1]; Tjelele, J[1]; Samuels, I[1]; Cupido, C[1]

Key words: Savanna, Grasslands, Rangeland Management

Abstract

Sustainable management of rangelands plays a key role in rangeland health and the opposite leads to degradation with implications for livestock production. This study explores the relationship between rangeland condition and rangeland management practices among champion farmers within grassland and savanna biomes in South Africa Sixty champion farmers, representing diverse livestock enterprises, were selected through workshops involving government officials, researchers, and agricultural organizations. The selected farmers were interviewed using semi-structured questionnaires, to establish their rangeland management strategies. Questions were framed around (i) current state of the rangeland in the farm (ii) farm management strategies (iii) changes over time. The vegetation condition of the farms, was assessed using a combination of ground-based techniques, including cover abundance and step point. Cover abundance was measured in 10 X 20 m plots, while the step point technique utilized 100 m line transects. Data collected from these methods provided insights into veld condition scores, grazing capacity and species diversity. A total of 35 grass species across different ecological groups were identified, with Increaser II species being the most dominant, suggesting previous over-grazing but showing signs of improvement with the presence of Decreaser species such as *Themeda triandra*. The average grazing capacity was 9.1 ha per large stock unit (LSU), with 72% of farms in good condition, indicated by an average veld condition score of 60%. These positive outcomes are attributed to the farmers' knowledge and experience in veld management. The farms with moderate rangeland condition, averaging 50% veld condition score, attributed this to limited extension support, land availability, and woody plant invasion. Key findings highlighted the importance of appropriate stocking rates, rotational grazing, and veld resting for sustainable livestock production. Overall, this study underscores the critical role of effective grazing management practices in maintaining rangeland health and provides valuable lessons for other farmers in similar biomes.

Introduction

Sustainable management of rangelands plays a key role in rangeland health and the opposite leads to degradation with implications for livestock production. Moyo (2008) notes that patterns of rangeland use and management differ according to ecological areas, tenure systems, institutions and traditional practices.

A good rangeland management strategy should take into account both the ecological processes and economic viability (Hawkins et al. 2017). The most common grazing management strategies in South Africa include rotational grazing, seasonal herding, holistic planned grazing (HPG) and continuous grazing. Rotational grazing formally implies that the rangeland is subdivided (fenced) into small areas called paddocks or camps and that the livestock are moved from one camp to another at different times of year. The camps not in use are rested to allow the grasses to renew energy reserves, rebuild vigor and deepen their root systems, so as to ensure maximum production in the long term (Oates et al., 2011). Briske et al. (2008) reports that one of the aims of such a grazing system is to improve species composition, which is achieved during the resting periods. Seasonal herding also applies the same principle as rotational grazing, however instead of the use of fences to define areas that should be grazed at certain times of the year, the herders make the informed decision based on their knowledge of the rangeland. HPG is a rotational, time-controlled grazing strategy that is commonly known as high-density, short-duration stocking (Skovlin 1987; Butterfield et al. 2006). This method employs high-density livestock management with fences or herders, imitating the natural movement of wild herbivore herds to improve rangeland condition and the health of the animals (Savory and Butterfield 2016). In this grazing system, timing is everything and livestock are kept bunched up and moving so that they cannot return to the same plant for a second bite (Kruger, 2012). HPG requires high levels of infrastructure and manpower, hence in South Africa it has mostly been applied successfully in the commercial sector but is not considered a viable strategy for communal rangelands (Hawkins et al. 2017). Lastly, continuous grazing means that the entire grazing land is grazed throughout the year, including during the dry season. Since grazing management strategies are described as 'planned efforts by rangeland managers to leave some grazing areas unused for at least a part of the year', continuous grazing is viewed by some as the absence of a grazing management strategy (Howery, 2000). The benefits of continuous grazing as opposed to rotational grazing include its low capital investment requirements because there is less need for fencing and the provision of water. Additionally, livestock do not have to be moved from one camp to another, making management decisions simpler (Beetz and Rinehart, 2010). This study explores the relationship between rangeland condition and rangeland management practices among champion farmers within grassland and savanna biomes.

Methods

Study Site Description

The study was conducted within the savanna and grassland biome, which combined, occur in 8 provinces, except for the Western Cape province (Figure 1). The savanna biome is the largest biome in South Africa covering about 33% and represents complex landscapes that are made up of a mosaic combination of grasses, umbrella shaped trees and shrubs (Furley, 2016). The biome is divided into dry and wet/meisic savanna receives seasonal rainfall that ranges from 400 – 1000 mm and 800 – 2000 mm respectively. While the grassland biome is the second largest biome in South Africa and covers 29% of South Africa's land area. The grassland biome is dominated by grasses and have relatively few large trees and shrubs. Bulbs and forbs. The biome receives annual rainfall which ranges from 400mm – 2000 mm.

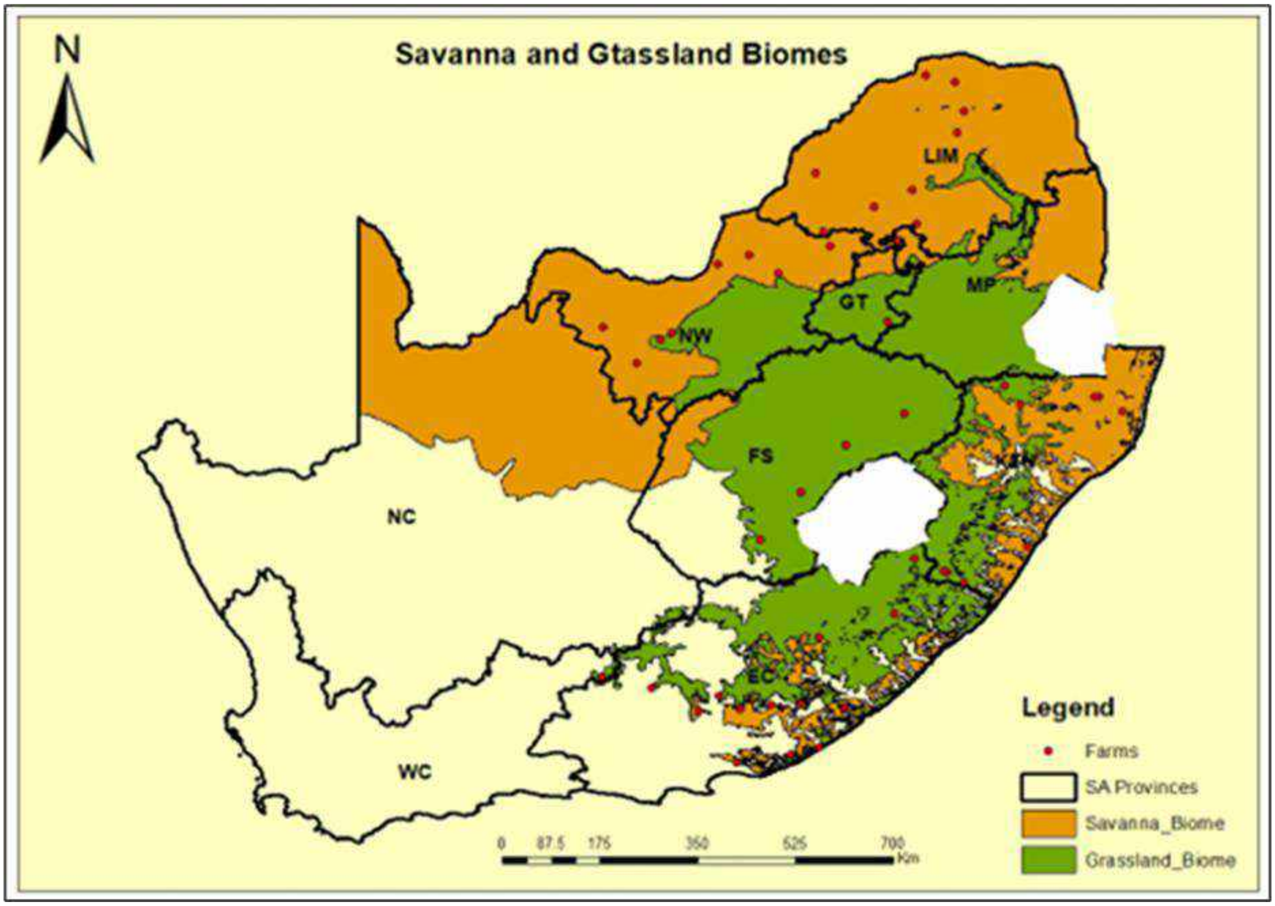

Figure 1: Biome Map showing the savanna and grassland biomes as well as the locations of surveyed famers across the provinces.

Farmer surveys

In-person interviews were conducted with 60 farmers who were selected within the grassland and savanna biomes. The selection process involved multiple stakeholders who were working closely with the farmers in the respective provinces (agricultural extension officers, researchers, retired scientist etc.). Farmers who met the selection criteria were then contacted for their consent to participate in the study and these included both male and female farmers, represented across the different livestock farming enterprises (large, small and game stock) and the different production systems (communal, small-scale and commercial). A semi-structured questionnaire with open-ended questions framed around (i) current state of the rangeland in the farm (ii) farm management strategies and (iii) changes over time, were administered to participating farmers.

Vegetation survey methods

A combination of ground-based techniques, employing an agronomic approach (cover abundance) (Westfall et al. 1996) and ecological approach (Step point) (Hardy and Tainton 1993) were used to assess the vegetation condition of the 60 farms that were selected for this study (35 in the savanna and 25 in the grassland biome). These two techniques were used concurrently at each site chosen as representative of various homogenous vegetation units. Due to temporal and spatial constraints, only two or three sites were surveyed in each farm or communal grazing area. At each site a 250 m transect (5 x 50 m) was laid out where the step-point method was conducted. Along each transect, grass species were identified and recorded as either a hit (when the spike strikes into the plant) or nearest plant (when the spike hit next to a particular plant species). Bare ground was recorded if no grass species were found within a 0.5 m radius from the point. Through the step-point method, Ecological Index (EI) was determined by classifying species into their ecological index groups (Vorster, 1982). The EI was then used to determine veld condition score (%) and grazing capacity (ha/LSU) for every sampled site (farm).

For the cover abundance sampling technique, plots of 10 X 20 m ($200m^2$), were used. All identifiable grass, tree and shrub species rooted in each of these plots were identified following Westfall et al. (1996). This method was used to determine plant canopy cover which is based on mean crown diameter and mean crown-to-crown spacing, derived from Edwards (1983). The mean crown diameter was used to determine cover using Plant Number Scale (Westfall et al. 1996), while the transect width was based on 4/5th of the intra-species mean crown-to-crown gap. The number of individuals of species of interest were counted within this transect length and width to determine individual species frequency.

Results and Discussion

Results from the interviews showed that a majority of farmers participating in this study have grazing plans which are informed by their rangeland condition and 70% (especially commercial and land reform farms) used a rotational grazing system. This grazing system was favoured because it allows the rested areas sufficient time to recover. The farmers shared that they divided their farms into three or more camps with each having drinking water. According to some farmers, they rotate their animals three to four months between camps depending on the condition of the grass. Other types of rangeland management systems used by farmers included herding, holistic planned grazing and adaptive management. The communal areas that were part of this study shared that they used herding to conduct rotational grazing without fences. Eighty-two percent of the farms surveyed keep livestock records and regard it as the best way to manage livestock. About 85% of the farmers mentioned that they keep rainfall records which assist with predicting droughts so proper planning can be implemented. They mentioned that they collected their rainfall data from their rain gauges and weather Apps. Microsoft Excel was the most favoured program for record keeping, while some used different phone applications. Farmers indicated that keeping farm records is important for proper planning, managing risks and overall management of their farms. The access and use of different information sources also emerged as a way to supplement the farmer's knowledge on good management practice. The most used sources of information included the internet, farming magazines and agricultural agencies. There were a few farmers who also make use of drones and remote sensing on their farms. According to one farmer, he uses drones for security purposes, monitoring watering points, livestock and even vegetation.

The results from the vegetation surveys showed that the average grazing capacity, veld condition score and farm size varied among the different farming systems (Table 1). Based on the grazing capacity and veld condition score the commercial and land reform farms were in good condition while the communal farms were in moderate condition. A total of 35 grass species across different ecological groups were identified, with Increaser II (grass species that increase when the rangeland is over grazed) species being the most dominant, suggesting previous over-grazing but showing signs of improvement with the presence of Decreaser (grass species that decrease in population when grazing pressure increases) species such as *Themeda triandra*.

Table 1: The average farm size, cover abundance and average veld condition score of the different farming systems.

Farming system	Average Farm size (ha)	Average Grazing capacity (ha/LSU)	Average veld condition score (%)	Veld condition status
Commercial	2180	6.7	61	Good
Land Reform	1056	8.8	63	Good
Small scale	897	11.9	52	Moderate

Conclusions

Farmers have shown they possess the knowledge and skills to manage their livestock and rangelands under the different tenure types and farming systems. The best lessons learned from farmers in these biomes was on the importance of applying good veld management principles in order to maintain the rangeland in a good condition.

Water ecology and management in rangelands

Exploring trade-offs between water and carbon linked to woody encroachment in a native semi-arid grassland, Eastern Cape, South Africa

Weideman, C.[1]; Palmer, AR.[2]; Smart, K[3]

[1] Department of Environmental Science, Rhodes University, PO Box 94, Makhanda 6140, South Africa; [2] Institute for Water Research, Rhodes University, PO Box 94, Makhanda 6140, South Africa; [3] EFTEON, National Research Foundation, Pretoria

Key words: Eddy covariance; woody encroachment; ecosystem carbon regulation; ecohydrology; ecosystem water use efficiency

Abstract

Woody encroachment has been widely documented in rangelands over approximately the last century. It is generally believed that this increase in aboveground biomass leads to increases in C sequestration, which, due to deeper rooting systems and leaf area of trees, implies a cost in terms of water availability due to increased evapotranspiration. To explore the evidence for this hypothesised trade–off in functionality, we installed a pair of identical eddy covariance flux towers in a native semi–arid C_4 grassland and an adjacent encroaching *Vachellia karroo* woodland in the Eastern Cape, South Africa, with otherwise similar site characteristics, and compared carbon © and water budgets over the period September 2019 to February 2022.

The woodland was marginally more productive than the grassland, but these C gains were offset primarily by disproportionately large dry season respiration effluxes, resulting in the grassland sequestering 65% more C than the woodland (389 g m^{-2} vs. 235 g m^{-2}) over ~20 months of concurrent data. Differences in water use were negligible, however, with the woodland evapotranspiring just 9% more water than the grassland (845 mm vs. 775 mm), equivalent to 78% and 70% of total rainfall (1103mm), respectively. Ecosystem water use efficiencies were essentially identical over the study period (2.7 g C m^{-2} [kg H_2O]$^{-1}$), with the grassland slightly more efficient in the dry season (2.6 vs. 2.5 g C m^{-2} [kg H_2O]$^{-1}$).

We found no evidence to support the hypothesis of a trade–off between C and water linked to encroachment at our sites. Given the complexity of ecohydrological and biogeochemical responses to vegetation shifts in these systems, however, and the wide variation in results reported in previous work, there is a clear need to replicate similar studies across broad environmental and climatic gradients towards improving understanding of these processes and developing coherent policy for rangeland management in the context of global change.

Introduction

Woody encroachment and proliferation has accelerated over the last century, understood to be a response to changing land management, biogeochemical, and climate drivers (O'Connor et al., 2014). This process has been particularly rapid in drylands, defined as regions with an aridity index of < 0.65 and characterised by open ecosystems typically comprising a dynamic complex of woody C_3 plant functional types and C_4 grasses (Archer et al., 2001). These systems account for nearly half the terrestrial land surface and, despite comparatively low levels of productivity relative to tropical and boreal forests, they play a major role in regulating the global C budget because they are so extensive globally, thus dominating the trend and inter-annual variability of the land sink (Ahlström et al., 2015).

Carbon dynamics in drylands are typically complex and non–linear, oscillating between net sources/sinks over seasonal and annual timeframes in response to management, high rainfall variability, and frequent drought. However, although the mechanisms are poorly understood and detailed accounting in many regions lacking (Biederman et al., 2017). Evidence of the effects of encroachment on C regulation in these systems is equivocal, and previous studies have reported increases, decreases, or no change in C sequestration rates relative to original vegetation types, because factors including rainfall thresholds, species functional traits, time since encroachment, and soil type all interact to mediate biogeochemical responses to varying degrees (Barger et al., 2011; Hughes et al., 2006).

Similarly, while increases in woody cover have been shown conclusively to lead to elevated water use and associated declines in catchment yields due to higher leaf area and deeper rooting systems of trees relative to grasses (Le Maitre et al., 2020), much of this work has focused on commercial forestry and alien invasive species in mesic and humid environments; the pattern is less clear in dryland systems. Impacts of vegetation shifts on the water balance tend to decrease with aridity, with semi–arid systems occupying a transitional zone along this continuum, and for which ecohydrological processes are least well understood (Huxman et al., 2005).

Despite these uncertainties, policy and planning relating to encroachment in drylands is often predicated on the assumption that higher aboveground biomass associated with increases in woody cover generally leads to increased C sequestration, reduced catchment runoff based largely on ecohydrological theory and extrapolation of data from different climatic regions and non-native species (Department of Environmental Affairs, 2019). Broad generalisations that do not account for the complexity of biogeochemical and ecohydrological responses to vegetation shifts in these systems hinders the development of effective responses to accelerating global change in these systems.

In South Africa, approximately 10 % of the land surface has experienced woody encroachment to varying degrees since the 1990s, with highest rates recorded in semi-arid and dry sub-humid grasslands and savannas with annual rainfall > 500 mm (Skowno et al., 2017). *Vachellia karroo*, a deep–rooted nitrogen fixing legume, is among the most prolific of approximately 40 identified encroaching species in the northern and eastern parts of the country. We compared ecosystem C and water budgets using paired eddy covariance technology in a native semi–arid C_4 grassland and adjacent encroaching *V. karroo*–dominated woodland in the Eastern Cape Province of South Africa over a period of ~30 consecutive months, to evaluate potential trade–offs in functionality linked to woody cover increases in these systems.

Methods

A pair of identical open–path eddy covariance systems was installed on a commercial livestock ranch near Adelaide in the Eastern Cape, South Africa, (-32.742, 26.471; ~770 m.a.s.l), and data analysed for the period 1st September 2019 to 28th February 2022. The towers provide high frequency (10 Hz) measurements of mass (CO2) and energy (sensible and latent heat) exchanges above vegetation canopies averaged over 30-minute intervals and integrated over footprint areas of several hectares.

The flux sites are separated by a distance of 890 m and located on flat or gently undulating topography. Soils are shallow (~0.75 m) and consist of a clay/loam complex over Beaufort Series sandstones. Mean annual precipitation is 730.4 (±158) mm, with mild dry winters (JJA) and hot, relatively humid summers (DJF) (Koppen classification *Cfa*). Rainfall is strongly seasonal, with ~70 % occurring over the austral spring and summer/early autumn months (Oct–Mar). Mean annual temperature is 17.7 (±3.2) ºC, with warmest temperatures in January (22.5 [±0.8] ºC) and coolest in July (13.2 [±1.5] ºC).

Vegetation at the grassland comprises a variety of perennial C_4 grasses, with several dwarf shrub species present in low abundances, and a sward height of ~0.4 m in the growing season. The woody component at the encroached site is dominated by *V. karroo*, with cover ranging from ~20–40 % and a mean canopy height of ~5 m; the herbaceous layer comprises largely continuous cover by a range of C_4 grass and forb species. Both sites are utilised for grazing by domestic livestock and wild game at stocking rates of ~4 ha LSU^{-1}.

Results

Daily net ecosystem C exchange (NEE), gross primary production (GPP), ecosystem respiration (R_{eco}), and evapotranspiration (ET) at each site are shown in FigureA; intermittent power and sensor failures over the total 912 days of measurement resulted the loss of 28% of data (254 days) from the grassland tower (GRA), predominantly during the 2020/2021 and 2021/2022 growing seasons, and 5% of data (43 days) from the tower at the woodland site (VKA) in the 2019 dry season; a total of 615 days concurrent data were obtained, comprising 230 and 385 days of growing and dry season data, respectively.

Both systems generally functioned relatively similarly in terms of C and water regulation, with similar flux phase and amplitude over the 615 days of concurrent data. Near–complete failure of late spring rains in 2019, corresponding with the end of a severe multi–year regional drought, resulted in a truncated 2019/2020 growing season, with marked declines in physiological activity well into summer of that year, but with some recovery evident from January 2020 onwards. VKA was almost uniformly marginally more productive than GRA over the 615 days, with 8% higher total gross photosynthetic uptake (2278 vs. 2103 g C m^{-2}). These C gains were offset by relatively larger respiration losses at VKA, however, with a total efflux of 2042 g C m^{-2} relative to 1713 g C m^{-2} (16%), resulting in 65% more C sequestered at GRA (389 vs. 236 g m^{-2}) over the 615 days. Water use at the two sites reflected differences in productivity, with just 9% more ET measured at VKA than GRA (845 vs. 775 mm), equivalent to 78% and 70% of total rainfall, respectively, over this period (1103 mm), and the difference assumed to have been converted to surface runoff.

The bulk of the difference in the C and water budgets between the two systems is explained primarily by dry season physiology, however; while both gross C uptake and ecosystem respiration were higher at VKA in both seasons, the difference in total dry season respiration efflux between the two systems was double that measured in the growing season (220 vs. 109 g C m^{-2}, respectively), resulting in 93% more C fixed in the dry season at GRA (114 vs. 8 g C m^{-2}) relative to 17% more in the growing season (275 vs. 228 g C m^{-2}) (Figure 1). Seasonal differences in water use between the two systems reflected this trend, with 16% more ET measured at VKA in the dry season (341 vs. 288 mm at VKA and GRA, respectively) relative to 3% more in the growing season (504 vs. 487 mm).

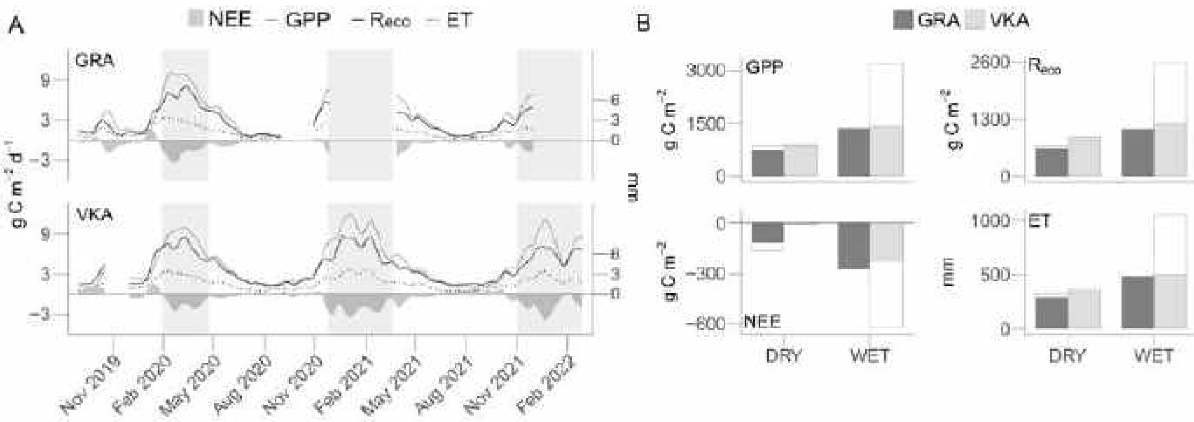

Figure 1: Daily NEE, GPP, R_{eco}, and ET measured at GRA and VKA over the study period; vertical grey bars indicate growing seasons (A). Total C and ET fluxes measured in dry (n = 385 days) and wet seasons (n = 230 days) over periods of concurrent data availability; white bars indicate sums calculated based on all available data at respective sites (B).

Growing season evaporative indices, calculated as the ratio of ET to precipitation, were almost identical (0.62 and 0.64 at GRA and VKA, respectively), with effectively all available rainfall utilised in the dry season (0.9 and 1.07, respectively), although the ratios of E:T in respective systems and seasons are undetermined. Ecosystem water use efficiencies (WUE_E), expressed as the ratio of daily GPP (g C m^{-2}) to ET (kg H_2O m^{-2}), over the study period were essentially identical (2.7 g C m^{-2} [kg H_2O]$^{-1}$); GRA was marginally more efficient in the dry season (2.6 vs. 2.5 g C m^{-2} [kg H_2O]$^{-1}$), however, with growing season values of 2.8 g C m^{-2} [kg H_2O]$^{-1}$ at both sites.

Discussion

Despite higher levels of productivity linked to increases in woody biomass at VKA, the grassland sequestered significantly more C than the woodland, attributable primarily to disproportionately larger dry season respiration effluxes at the former. The source of the additional dry season C losses at VKA is unclear, but since differences in GPP measured in each system were consistently relatively marginal, we anticipate that these likely originated from microbial decomposition of soil organic matter and necromass, although the underlying mechanisms would require further investigation. Reflecting differences in productivity, differences in total water use between the two systems were negligible and presumably explained by shallow soils and the absence of subsurface water at the flux sites, which constrains competitive advantage in terms of access to water conferred by deeper tree rooting systems relative to grasses in semi-arid environments. In this regard, topoedaphic and physiographic (upland vs. riparian) contexts are likely to be key factors in predicting the water use impacts of woody cover increases in water limited systems (Huxman et al., 2005).

Our data do not support claims of increased C sequestration and water use linked to encroachment in these systems, with the grassland sequestering 65% more carbon than the woodland at similar water use efficiencies. Given the complexity of ecohydrological and biogeochemical responses to vegetation shifts in drylands, and wide variation in results reported in previous work (Barger et al., 2011; Biederman et al., 2017; Hughes et al., 2006), our results underscore the need to replicate similar studies across environmental and climatic gradients to improve understanding of these processes and develop coherent policy for effective rangeland management in the context of global change.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Put your money where success has been – a rapid review of interventions to improve pastoral land condition in the southern rangelands of Western Australia

Penny, NR[1]; Williams, AR[2]

[1]Department of Primary Industries and Regional Development, Nash Street, Perth, WA, 6000;
[2]Williams Ag-Environmental Consulting, PO Box 841, Bridgetown, WA 6255

Key words: regeneration techniques, evaluation, WA Goldfields

Abstract
The paper reports on a six-day study trip of rangeland regeneration efforts implemented between 1984 - 99 in the Goldfields Region of Western Australia (WA). Results of land regeneration efforts have been influenced by the extent and severity of degradation, fragility of soil type, episodic flooding and drought, and the degree of total grazing pressure (TGP) control. Locally endemic plant species fared better than sown native species. The long-term effect of cultivation has been variable as have the benefits of shallow water ponding. The benefit of any cultivation has depended on the proximity of seed source areas of native species. Plant establishment has been improved where the water ponding has made the surface soil more sodic and cracked. Deeper, longer-lasting ponding behind bulldozer-built banks has been effective in rehabilitating rangelands. A small study of fracturing hardpan with explosives has shown benefits. Measurement of Mulga (*Acacia aneura*) trees planted in water-ponded areas has allowed an assessment of mean annual increments of carbon that could inform future carbon farming initiatives in the rangelands.

Introduction
The WA Department of Primary Industries and Regional Development (DPIRD) Southern Rangelands Revitalisation Program (SRRP) supports pastoralists to improve land condition for livestock production. The SRRP is reviewing rangeland regeneration efforts to understand their short and long-term effectiveness, which will benefit pastoralists and other rangeland uses. The southern rangelands of WA have experienced long term degradation, with a mean of 25% in poor condition, and one per cent being severely degraded and eroded (SDE) (DAFWA 2017). More productive types of pastoral land have a greater proportion of degradation, reducing productivity and profitability. Government and land managers have spent decades trying to improve land condition on this very small area of SDE to the detriment of focusing on the management of the whole landscape. The best publication from WA on mechanical range regeneration remains Addison (1997). This bulletin describes many of the cultivation techniques used in the Goldfields and was informed by experience gleaned from sites such as those visited in this study.

The Goldfields has seen many changes over the past thirty or so years. Many pastoral leases are now held by mining companies and overseas financial interests with fewer owned by family entities. Climate change is leading to higher mean temperatures throughout the year, lower winter rainfall with increased occurrence of drought, and more intense rainstorms and, therefore, more flooding events (BoM 2024). There were several areas with mature dead Mulga, which is attributed to severe drought and high temperatures experienced in 2019 (Paul Axford, pers. comment). The feral goat eradication program (1993-8) temporarily reduced grazing pressure. Wild dogs and dingoes are no longer controlled and effectively ate the local sheep industry, driving the change to cattle production. Dogs, dingoes and an extended dry period (2019 – 2023), have greatly reduced grazing pressure by native and feral species. On our 1,000 km trip through the Goldfields, we saw a total of four kangaroos. Many pastoralists have entered into carbon farming projects based on the regeneration of above ground biomass.

Methods

Prior to our 6 day tour (21 – 26 October 2024) we obtained whatever old research plans, site assessments, reports, monitoring records and relevant papers we could find. A desktop assessment used time lapse remote sensing images to detect change, confirm locations to visit, and inform rapid assessment methods (Table 1).

Table 1. Range of rapid assessment techniques employed

Types of assessment / measurement employed	How assessments were used
Visual observations	Assess persistence of earthworks and influence on regeneration
Time lapse remote sensing	Assess direction of change
Photographs with GPS locations	Current condition and allowing for future re-assessment
Photos of monitoring sites	Present reassessment (need original monitoring photos)
Drone footage	Gradations in cover and soil conditions - for future detailed assessment
Report soil surface changes	Assess effects of water on cultivations and ponding banks
Soil penetrometer tests	Assess any long term benefits of cultivation
Plant species, locations and sizes	Assess effects of water ponding on plant establishment and growth
Trial plant / species survival	Assessment of plant species that established and matured
Native plant colonisation	Effects of cultivation and proximity to seed source areas
Cross section across ponds	Measure land slope and bank height
Canopy and height measurements of Mulga trees of known age	Assessments of annual increments in above ground biomass & carbon content that might inform future carbon farming and water ponding initiatives

Results

We assessed regeneration sites on 5 leases, one in the Southern Goldfields where the Mallen niche seeder was trialled, and 4 in the north-eastern Goldfields which variously received broad scale disc pitting, chisel ploughing, seeding, grader built banks and dozer built banks. Photo records show all the sites prior to treatment were in poor condition or SDE. Project files consistently identify a common purpose of demonstrating methods to rehabilitate degraded and eroded areas. North-eastern Goldfields rainfall in the year of assessment was greater than the median and above average. For the 6 years prior, it was below the median and average.

Cultivations and soils
Soil cultivation aims to provide a seedbed for plants to establish, and can extend winter and summer growth periods by increasing the amount and longevity of water infiltrating the rooting zone. Our penetrometer tests showed infiltration benefits from initial cultivation had been lost. On disc pitting cultivation from 1985, 14 pitted sites had a mean penetrometer depth of 6.8cm compared to 20 non-pitted sites that had a mean depth of 6.2cm. Disc pitted sites from 1984 on a more alluvial site adjacent to a waterway showed mean (n= 10) penetrometer readings of 8.2cm (pitted) and 4.6cm (non-pitted).

Most sites in the north-eastern Goldfields were on hardpan plain land units with shallow, restricted soil depth over hard pan. These areas once supported preferential grazing. (The Nambi site in Humpy paddock was an alluvial plain that exhibited saline and/or sodic conditions.) These are some of the most challenging areas to rehabilitate. Soil profiles commonly contained ironstone gravel. As cultivated soil fretted or eroded away, gravel was left behind on the soil surface.

Plant establishment
Fencing off trials from all forms of grazing is essential, as is fence maintenance if long term observations are to be made. The exclosures on Mungari (near Kalgoorlie) and Sturt Meadows (Browns Paddock) have remained stock proof, which allowed us to make some observations. Accessions of *Atriplex amnicola* (573, 577, 580, 586, 588 and 949) planted on cultivation by a Mallen niche seeder (Malcolm and Allen 1981) in the Browns Paddock exclosure established well, but were only assessed in 1985, the year they were planted. Judging by remains of stems, a few of each accession (4 to 12 plants) lived a long time, but eventually succumbed to local conditions. Alternatively, plants of some species sown by a Mallen niche seeder at the Mungari exclosure on Gumland Land System in a slightly wetter, more sheltered site have survived or have completed their life cycle and produced seeds. However, plants have not spread away from the cultivated lines.

Surviving examples of the species sown on Mungari include *Atriplex vesicaria, A. bunburyana, A. nummularia,* and *Maireana pyramidata*. Other species have since established inside the exclosure, including *Cratystylis subspinescens, C. conocephala, Eremophila scoparia, Maireana georgii, Ptilotus exultatus, P. obovatus* and *Aristida contorta*. This and other locations where native species established on cultivated areas close to native seed sources may reflect that successional processes cannot be bypassed entirely by cultural interventions (Hacker 1989).

Different forms of ponding banks
'Accidental' shallow ponding in the Mungari exclosure caused by cultivation on the contour by the Mallen niche seeder, has made the soil more sodic and has increased cracking. This has caused a dense establishment of the colonising species mentioned above.

Grader-built ponding banks were established on Sturt Meadows around 1985-86. In the large catchments, such as flow through Browns and Top Bullock paddock on Sturt Meadows, overtopping runoff has washed away much of the soil from the grader-built banks, leaving a gravelly strew and a bank with minimal elevation (5-20cm). Most ponds remain bare, but, in places sufficient soil moisture has been retained to allow the establishment over time of a range of native species. As an example, along a 250m length of bank we found 8 *Acacia aneura* (Broad leaf), 1 *A. aneura* (Narrow leaf), 7 *A. craspedocarpa*, 6 *A. tetragonophylla*, 2 *Senna* spp, and 1 each of *Eremophila fraseri, Marsdenia australis* and *Solanum lasiophyllum*.

We visited bulldozer-built banks at Melita and Sturt Meadow Stations. The Melita banks were designed and supervised by John Law to reduce erosion and rehabilitate the area by impeding runoff and increasing soil infiltration. An explanation is provided in Law 1993. The work was a collaboration between the mining industry, pastoral industry and government. One of the first changes attributed to the banks was increased aquifer recharge. This caused Heron Well on the east side of the highway that that had been dry for a long time to start producing water again (John Law, pers. comment). Of the interbank areas, the banks decreased the length of slope for all locations typically increasing the stability of soil surfaces and vegetation density. The banks caused water ponding for approximately 5% of the overall area. This varied between interbank areas from less than 5% to up to 25%. Ponded areas experienced the greatest increase in vegetation density and size. It has taken several years before the banks have started to show their benefit. This was partly due to feral goat grazing some years ago (Jim Addison, pers. comment). Remote sensing scenes of the banks from April 2005 and July 2024 show a great improvement in the cover by native plants, particularly Mulga and halophytes (Fig. 1). Plants near the bank were twice as tall as those further away and had more than double the canopy area.

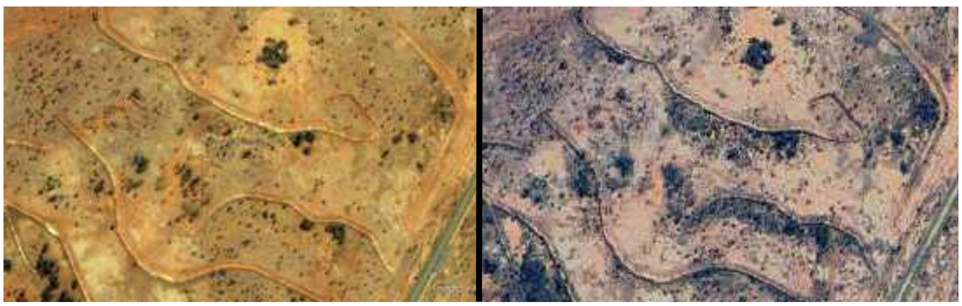

Fig 1. Centre of Melita 'Big Banks' system. Google Earth images in April 2005 (left) & July 2024 (right)

The bulldozer-built banks / ponds at Sturt Meadows were constructed as part of a research program of a consortium of Japanese universities. Here local trees (*Eucalyptus camaldulensis, A. aneura, E. salubris*) were planted in 1999 to assess growth rates. The site was on hardpan on severely degraded land that had been part of a stock route. On one research site the hardpan under all but one of the ponds (Pond 5) was fractured using explosives (Shiono et al. 2007). While many trees in all the other ponds have continued to grow, most trees in Pond 5 are dead. So, fracturing the hardpan (with explosives) will assist aquifer recharge, plant establishment, root penetration and plant nitrogen nutrition. Landscape rehydration works can be sub-surface as well as on the surface!

Based on an assessment of annual increments in above ground biomass and carbon achieved from Mulga trees of known age within ponding banks at Sturt Meadows, we estimated that a Mulga tree density of 10 trees/ha growing within ponding banks could sequester 0.4-3.0 tonnes C/100ha/yr. A density of 40 trees/ha within ponding banks might sequester 1.6-12.0 tonnes C/100ha/yr.

Discussion, Conclusions and Implications

Obtaining regeneration records was challenging and when available, mostly hard copy held variously by the Department, former Department staff, and lessee. Located records will be digitised before more records are lost. Some records may be found in journals (e.g. Williams 2002).

Of the areas that 39 to 41 years ago received cultivation, seeding, or grader banks, many have sustained minimal regeneration. It is hypothesised some initial plant germinations did not persist due to either degraded soils and landforms, limited natural seed sources, seasonal conditions, grazing impacts, or a combination of these. The data to explain the relative importance of ecosystem drivers was limited. The big banks sustained the greatest regeneration. The cost of bulldozer-built ponds might be hard to justify. However, where they have multiple uses (aquifer recharge, carbon farming, range regeneration) they may be of economic benefit, especially where pastoral and mining interests work together for mutual benefits.

Ongoing management and TGP control are essential. Wild dog predation has reduced grazing pressure from kangaroos and goats. This may assist control of TGP to improve outcomes from future regeneration events. Regeneration work should be preceded by investigating soil conditions (e.g. hardpan presence and depth, salinity and sodicity) and catchment characteristics. Addison (1997) contains some guidelines for cultivation under various soil conditions. Cultivation should be proximal to native seed source areas to extend the regeneration of native species while foregoing the expense of seed of less well acclimatised species. Grader-built banks are likely suited only to small catchments with controllable runoff to prevent overtopping.

Many regeneration efforts focus on the most noticeably degraded areas where recovery is slowest (Hacker 1989, Addisson 1997). Improvements to grazing systems and strategically located works (mechanical and land management) to arrest the progression of erosion into better condition asset areas, may provide a faster and greater return on investment. Short funding periods of up to three years acted against effective holistic planning and implementation which requires a long term (20-30 year) program.

Acknowledgements

The paper is dedicated to the late John Law who pioneered the design and practice of deep ponding banks in the WA Goldfields. DPIRD funded the fieldwork and paper. We are grateful to Paul and Peter Axford (Sturt Meadows Station), Northern Star Resources Ltd, Glencore, Zenith Australia Investment Holding Pty Ltd for supporting the project; Jim Addison, Tony Crook and Samantha Van Wyngaarden for local information; Phil Thomas for historical records; and Dr Hideki Suganuma, representing the Japanese Project at Sturt Meadows Station, for project information and permission to include growth assessments of Mulga trees on their sites.

Managing groundwater in South Australia's rangelands

Smith, A[1]; Short, J[1]

[1]SA Arid Lands Landscape Board

Key words: groundwater; pastoral; water metering; stock consumption; arid

Abstract

Ground water is the only reliable water source in the Far North of South Australia with approximately 70% of the water take coming from the Great Artesian Basin (GAB). Management of the GAB resources is critical to the health of ecological communities including GAB Springs and the viability of the pastoral, mining and tourism industries in the South Australian Arid Lands region. Demands on the GAB are likely to increase in the future due to the projected growth in mining, petroleum, and geothermal industries.

Much of South Australia's pastoral region falls within the Far North Prescribed Wells Area where water take is managed through licenced allocation. The South Australian Licenced Water Use Metering Policy requires licensed water to be taken through an approved method. Water meters are the default method for accounting for groundwater take however alternatives to water metering can be considered and documented within a meter implementation plan.

With guidance from an advisory group consisting of pastoral industry members with an interest or experience in groundwater management, along with government representation, field trials are in progress testing water accounting solutions against key criteria of reliability, practicality, cost and accuracy.

Trial sites have been selected to ensure water accounting methods are tested across a variety of land types, hydrogeological conditions, and consider water consumption of native and feral animals. The results of the field trials will guide development of policy and accounting methods that meet the requirements associated with managing a prescribed groundwater resource in a way that does not significantly impact a pastoral business; ideally adding value to the businesses such as improved understanding of stock water requirements and water point management and security.

The presentation will provide background on groundwater policy in South Australia and an overview of the field trials including progress and learnings.

Introduction

South Australia's Far North Prescribed Wells Area (FNPWA) is an area of over 315 000 square kilometres covering much of the South Australia's arid area (Fig. 1). Groundwater is the principal source of water for town water supply, domestic, watering stock, petroleum and mining production purposes. The springs fed by the Great Artesian Basin aquifers support rare and vulnerable flora and fauna protected under the Environment Protection and Biodiversity Conservation Act 1999 (EPBC Act) and hold significant Aboriginal cultural values.

Pursuant to the Water Resources Act 1997, the wells in the Far North PWA were declared as prescribed wells on 27 March 2003 as a means of encouraging responsible use of groundwater. Subsequently a Water Allocation Plan (WAP) was developed in accordance with the Natural Resources Management Act 2004 enabling a licencing and compliance system to manage the groundwater resources, to ensure extraction is undertaken in a sustainable manner and to protect the Great Artesian Basin springs.

Licenced stock allocations are determined at a rate of 100 L per day per head of cattle and 20 L per day per head of sheep with an additional buffer of 20% to account for water use by native and feral animals from stock watering points (SAAL Board 2021). Groundwater extraction by the Pastoral industry for stock and domestic purposes is estimated to be 15% of the overall groundwater extraction in the Far North PWA (SAAL Board 2021). However, despite South Australia's policy that all licenced water use needs to be metered (DEW 2019), measurement of the actual use has not been implemented, contributing to significant uncertainty in water balance calculations and groundwater modelling.

The Accounting for Groundwater Take in the Far North PWA project has been developed in response to community concern, raised in 2019/20 during consultation on the Water Allocation Plan for the FNPWA, about the potential impact of water metering on pastoral businesses in the Far North. Concerns centred on the practicality and cost to purchase, install, maintain and monitor meters in remote areas, compounded by the number of bores many landholders utilise and the high temperature and pressures experienced in the central and northern areas of the PWA.

Whilst metering of water extraction is considered the most accurate method of determining take, alternative approaches to water accounting, including non-meter options, can be considered in accordance with principle 1.7 of the SA Licensed Water Use Metering Policy which is flexible and recognises on-ground regional implementation issues. Flexibility provisions including alternatives for metering must be documented in a meter implementation plan (MIP) for a prescribed water resource and made publicly available.

SA Arid Lands (SAAL) Landscape Board and Department for Environment and Water (DEW) are investigating various water accounting options including alternatives to water metering to enable development of an appropriate MIP (referred to as a Water Accounting Implementation Plan in the WAP) for the FNPWA.

Landholder participation in the planning and conduct of the Accounting for Groundwater Take project will be critical to ensure the trial is representative of the on-ground conditions.

Methods

Project Governance

The delivery of the Accounting for Groundwater Take project is reliant on groups and units within government and the community. A supportive program governance framework was developed to provide the structure, decision making process, roles and responsibilities for managing the program.

An advisory group of 5 pastoralists and property managers in the FNPWA was established through an expression of interest (EOI) process. All had an interest and experience in groundwater management for cattle and/or sheep enterprises. A chair for the group was selected from outside the pastoral region to ensure neutrality and to bring a different perspective to the group. The advisory group is also supported by staff from the SAAL Board and DEW.

The group met regularly at the early stages of the project to establish and investigate water accounting options; provide advice regarding the suitability of potential water accounting methods for trialling in the Far North; and support the trials, including identifying participants, expertise and reviewing progress.

Field Trial Methodology and Selection

Six trial sites (pastoral leases, 'stations') were selected for this project; three from Expressions of Interest and three "shoulder tapped" to ensure a broad array of stock, hydrogeological and geographical land systems were captured in the trial sites. The stations selected have both hydrogeological conditions with high artesian temperatures and pressures, and non-artesian conditions where water extraction was by submersible pump connected to solar power. Having a diversity of land systems recognises stock water requirements will vary with grazing conditions, vegetation type and water quality. Figure 1 provides the location of the participating stations within the FNPWA, with the different scenarios of the 6 stations provided in Table 1.

Within the stations, trial sites were carefully selected to maximise the trial's success in determining stock water consumption. Fenced paddocks with no open water storage such as dams or waterholes were chosen. Bores and associated water points (tanks and troughs) and water distribution pipework were required to be in good condition and free of open or uncontrolled flows. Stock type and number, including stock movements into or out of the paddock, had to be known and recorded.

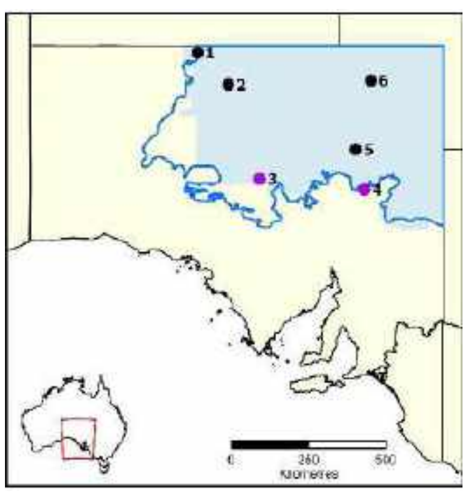

Fig. 1. Location of participating stations (numbered) in the Far North PWA (blue shading); extent of the Great Artesian Basin (blue line); black markers = cattle enterprises, purple = sheep enterprises.

Table 1. Water accounting monitoring scenarios

Station	Stock-Cattle Consumption	Stock-Sheep Consumption	Sub Artesian (pumped bore)	Artesian Bore	Artesian Bore - high temp./pres.
1	✓		✓		
2	✓		✓		
3		✓ (Merino)	✓		
4		✓ (Dorper)	✓		
5	✓			✓	
6	✓				✓

Water meters of varying types are utilised in all trials to-date, to enable monitoring of water consumption, to determine the accuracy of an alternate accounting method and to assess reliability of the meter itself. Meters are connected to telemetry where practicable to enable remote access to the data. Video or still photos from field cameras installed at water points enables identification of water consumption from non-native (e.g. camels and horses) and native animals. Rainfall, temperature and evaporation data was also collected, either on-site at the water points where sensors are installed, or from the nearest Bureau of Meteorology (BOM) weather station.

The land managers at each station provided regular information during the trials including; stock numbers and movement, stock type (e.g. heifers, calves), presence of surface water after rain events, manual instrument reads and assistance with trouble shooting.

Trials have progressively commenced since 2023 and will run for a minimum of 18 months subject to weather conditions. Trials may need to run significantly longer if the seasons are mild or experience above average rainfall.

All findings and observations will be documented and a report will be provided to the Department for Environment and Water to assist the development of a Water Accounting Implementation Plan suitable for the region. This plan may include one or potentially multiple approved water accounting methods that can be adopted by a licence holder depending on their on-ground conditions.

Results

At time of writing Station 2 and 3 (Fig. 1) had commenced trials with preliminary results obtained. Both trials aimed to determine stock water consumption by measuring the total water usage within a paddock and dividing that by the known head of stock. Footage from field cameras enabled analysis of other animal take from the waterpoint/s.

Water Usage - Cattle

Over 12 months from November 2023, water usage from the Station 2 field trial has ranged from 28 L/head of cattle during the cooler months to 79 L/head during summer, with an average of 38 L/head. Field cameras have identified that other animals including camels, kangaroos, reptiles, birds and dingoes are also drinking at the water points.

Water Usage - Sheep
The Station 3 trial commenced in August 2024 and based on the first 3 months water take has averaged 5 L/head of sheep. This includes other take identified in video by kangaroos and a small number of cattle that have managed to push through fences and accessed the water points at times.

Equipment Reliability
A total of 7 installed turbine water meters have been utilised in the trials to date, operating without issue once successfully installed and configured.

Troubleshooting has been necessary at both trial sites with difficulties in correct installation of meters and connection to telemetry and has been complicated by the remoteness of the sites which has significantly delayed site preparation.

One equipment failure has been experienced to-date with a single water meter no longer reporting to telemetry. Field investigation is required to confirm the cause of the issue.

Equipment Cost
The equipment cost of individual trials was anticipated to vary depending on the accounting method and existing infrastructure. Equipment (meters, cables, telemetry components) for individual trial sites were expected to cost between $5000 and $15000 depending on number of water points and meters.

The cost of installation of the trials has been higher than estimated averaging over $15,000. The additional costs can be contributed to additional equipment needed to install meters and link-in with either existing or new telemetry.

Professional installation of meters will be implemented for future trial sites which is expected to increase the cost of each trial by $8,000 - $15,000 depending on the number of meters and pipework modifications required.

Discussion
Early trial results for the first 2 stations indicate water take for cattle and sheep is significantly less than the 100 L per day per head of cattle and 20 L per day per head of sheep as prescribed in the Far North WAP. This includes take by other animals, both native and non-native, evaporation and other losses such as regular trough maintenance.

The results to date are very site specific given the size and diversity of the SA Arid Lands Region. The locations of this study have also not been in drought conditions and other trial sites may return different usage numbers which will need to be considered against the many factors that may influence the results, such as stock breed, age, weather and the on-ground conditions.

While the results are insufficient for in-depth evaluation there are early learnings on water usage for the active trial sites and observations on technical, logistical matters and costs associated with installing meters and other technology in the pastoral region.

While equipment reliability has generally been good over the relatively short time the trials have been running, the lack of services and the remoteness of the area has complicated and delayed installation, troubleshooting and repairs, contributing to the costs of the trials being higher than originally estimated.

All findings and observation will be documented and will assist the development of a Water Accounting Implementation Plan suitable for the region.

Creating and enhancing green spots in the arid zone of western NSW, Australia

Theakston, P[1]; Dohnt, B[2]

Key words: green spots; rangeland rehabilitation; habitat

Abstract

Arid zone biodiversity adheres to a boom-bust cycle. During periods of ample surface water and vegetation, species reproduce quickly and spread across the landscape (boom period). In contrast, during extended dry periods (bust period), species numbers decline and retreat to locations that remain moist, called "green spots". Green spots vary in size and extent, from individual landscape features, such as gilgais, ephemeral wetlands and creek line waterholes to extensive healthy floodplains.

Widespread degradation occurred in the arid zone of western NSW between the period of the 1890s to the late 1940s, creating legacy erosion issues. Present day degradation occurs to a lesser degree, which impacts on green spots, reducing their size and extent.

This project created and/or enhanced green spots on six pastoral properties in arid western NSW, creating a total of 37 localised green spots and rehydrating 850 ha of floodplain. Rangeland rehabilitation earthworks were used in an expanded way to create more persistent green spots, rather than solely for groundcover establishment for pastoralism.

Introduction

The arid zone of western New South Wales (NSW) experiences periods of substantial surface water and vegetation, separated by very dry conditions of irregular length and severity. Surface water and vegetation become increasingly rare as dry conditions prevail. The areas that remain moist within this vast and dry landscape are called green spots. Green spots vary in size and extent, from individual landscape features, such as gilgais, ephemeral wetlands and creek line waterholes to extensive healthy floodplains. Relictual populations of native animals become reliant on green spots as the dry period progresses (Woinarski 1992) competing with domestic livestock who also rely on these areas. The unpredictable nature of the boom and bust cycle can have severe consequences for the quality and extent of green spots.

Widespread degradation occurred in western NSW between the period of the 1890s to the 1940s (Condon 2002a). For example, during the 1940s drought, Beadle (undated) recorded creek line waterholes, previously 20 feet deep, filled with sediment due to accelerated erosion in the hinterland. Present day degradation occurs to a lesser extent and severity (Condon 2002b) with causes being: livestock grazing behaviour (Pringle and Landsberg 2004); excessive total grazing pressure and infrastructure development (Pringle et al. 2011) and historic over-stocking causing legacy erosion (Fanning 1994). These factors potentially cause the destruction of green spots by the erosional process described by Pringle (2006).

The erosional process starts with increased runoff due to lack of groundcover combined with nickpoint development. A nickpoint is an incision on the natural land surface where flows concentrate resulting in increased erosive power. Causes of nickpoint formation are varied, some examples are: cattle paths lowering the outlet sill of a wetland, "unplugging" the wetland; or a farm track cut into natural ground level which channelises flows. Nickpoints can develop into headcuts, where water falls over a vertical face causing undercutting and collapse of the wall. A headcut progresses upslope, along the path of strongest flow, resulting in gully erosion. These flow paths are the green spot areas, and once a headcut expands through them, they disappear and are replaced with a dryland system (Pringle 2020). This erosional process can occur quickly, with headcut retreat rates of up to 32 metres per annum being measured in western NSW (Graves et al. 2024).

Western Local Land Services (WLLS) implemented a project in 2023 to create and enhance green spots on six pastoral properties in the arid zone of western NSW. WLLS is a government agency concerned with improving both agricultural productivity and management of natural resources. WLLS has experience in implementing arid rangeland rehabilitation works, the primary purpose of which is to control erosion and establish groundcover for pastoralism (Green 1989). This project sought to expand the use of these rehabilitation techniques to include environmental/biodiversity outcomes through creating longer lasting refugia while controlling erosion and improving groundcover.

Methods

Funding provided by the Environmental Trust of NSW enabled projects to be undertaken on six pastoral properties in western NSW (NSW Environmental Trust 2024). Participants were identified based on previous involvement with rehabilitation projects and capacity to deliver.

Project areas were chosen in collaboration with land managers and were either existing green spots that were being threatened by gully expansion or previous green spots that had been severely degraded.

Green spots can be either localised or extensive. To create localised green spots, a dimensional approximate definition was formed based on existing, healthy green spots in the project areas. A green spot was defined for this project as a depression that holds water for at least one month, with a minimum depth of 0.5m and a minimum area of 50m^2, keeping the surrounding vegetation green for longer. Extensive green spots are healthy floodplains which hold water after flows have ceased. In this project, perched floodplains, which no longer receive floodwater due to dewatering caused by gully headcuts, were rehydrated, creating extensive green spots.

Design and layout of projects incorporates a drainage ecosystem perspective, creating and/or enhancing green spots in appropriate locations (Tinley and Pringle 2014a; 2014b) using heavy earthmoving machinery to construct earthen banks. A range of techniques were used, which included check banks, diversion banks, champagne banks, water ponding (Harrison 1994; Quilty 1972a,b; Rhodes 1987) and variations of these techniques based on the author's experience and practice (Theakston and Anderson 2023).

Results

Over the six projects, 37 localised green spots were created in the form of wetlands/waterholes which met the defined minimum dimensions of 0.5m depth and 50m^2, and approximately 850 ha of perched and degraded floodplain was also rehydrated.

Goodwood Station Green spot project

One example of creating localised green spots and rehydrating a floodplain to address legacy erosion occurred on Goodwood Station, owned and managed by Zane and Louise Turner. In western NSW, erosional processes were triggered by the introduction and mismanagement of domestic stock over 140 years ago (Fanning 1999) and current land managers are largely dealing with the resulting erosion.

The project area is a valley side, supporting banded chenopod vegetation with contour patterned small ephemeral waterholes, locally known as gilgais. Apart from the contour-patterned gilgais, the area also has a cluster of relatively deep gilgais (up to 0.8 metres deep) covering 3 hectares, creating a healthy green spot (photo c). Shallow, sinuous drainage lines dissect the area and in their uneroded state contain ephemeral waterholes upheld by sediment sills, forming corridors of green spots (Pringle &Tinley 2003). However, in the current state, instead of shallow sinuous channels, the drainage lines are erosion gullies (photo b) due to firmly established erosional processes as described by Pringle (2006). Any green spots that may have existed along the drainage lines have disappeared due to channel incision and headcut retreat "unplugging" moist areas. Furthermore, the gully is widening due to bank undercutting and collapse and expanding due to lateral gullies, with retreating headcuts threatening to dewater the cluster of deep and healthy gilgais.

The cluster of deep gilgais was an isolated green spot, separated by 1.6 kms from the closest other healthy green spot, located in the valley floor creek line. This creek line contains numerous waterholes up to 1.0 metres deep once creek flows cease (photo a). The project involved creating a corridor of 16 localised green spots connecting the valley floor waterholes with the cluster of deep gilgais. At the same time, re-hydrating 80 ha of a narrow floodplain along the shallow drainage line, recreating sinuous flow.

The average distance between the re-created green spots is 192 metres (83m–410m). The section of the drainage line with the larger gap of 410 metres was healthier and less incised, therefore it was considered not necessary to re-create any green spots along this length.

A total of 7,450 metres of banks were constructed, including large check banks combined with diversion banks intersecting the incised drainage line (shown on figure 1). These are larger banks of 1.0 metre high with a base width of 5.0 metres. Water ponding and champagne banks were constructed (not shown in Figure 1 for sake of simplicity) to rehydrate the narrow surrounding floodplain. Champagne banks are short diversion banks (<100 metres long) which direct flows away from incised drainage lines. They spill the flows from one bank to the other, spreading the water away until a safe re-entry point is found into the drainage line, whilst creating sinuous flow.

The earthworks for the green spot projects were only recently completed, so there is not yet evidence of groundcover and biomass responding positively. However, based on a recent study looking at water ponding in similar landscapes and climates, it is expected that the landscape treated in this project will respond in similar positive ways. In this study, the highest average biomass for ponded sites was 2161 (+- 650) kg/ha, compared to the control area of 254 (+-54) kg/ha (McDonald et al. 2022). Similar results are expected for the water ponding areas within the green spot projects given sufficient rainfall and time.

Discussion

Arid rangeland rehabilitation works have traditionally focused on improving ground cover and vegetative biomass. To achieve maximum groundcover and biomass, the ideal water ponding depth is established at 10 cm. Deeper ponding depths cause waterlogging of soil and encourage the growth of water adapted plants not suitable for pastoralism (Rhodes 1987). This project intentionally increased ponding depth to a minimum of 0.5 metres to encourage water adapted plants and provide longer lasting surface water to create a more diverse habitat.

The design of the green spot projects also includes water ponding banks and diversion banks that pond shallow water (less than 10cm) to improve groundcover and biomass, which is especially suited to pastoralism. This project expands the potential of arid rangeland rehabilitation works to include not only groundcover establishment for pastoralism, but also creation of longer lasting green spots to provide habitat for small native mammals.

The longer lasting green spots have been created in degraded, incised drainage lines. The incised line is up to 1 metre lower than the natural land surface and by constructing a check bank across the incised line, a pond is formed, which becomes the green spot. The check bank with its corresponding diversion bank directs flows onto the adjacent floodplain which rehydrates the area and creates sinuous flows. The actively eroding features can be used to create positive environmental outcomes alongside pastoralism.

Green spot destruction is a major cause of arid small mammal decline (Morton 1990), and by expanding the use of arid rangeland rehabilitation works to address environmental goals, in addition to pastoral goals, it is possible to create and increase suitable habitat to support arid small mammal populations. The distance between re-created green spots should be such that arid small mammals can travel. Frank and Soderquist (2005) recorded a Stripe-Faced Dunnart (*Sminthopsis macroura*) covering 300 metres in one night and Moseby and Read (1998) recorded Bolam's Mice (*Pseudomys bolami*) moving on average 187 metres (110m-374) in a few hours, utilising burrows or shelters. It is considered by ecologist that 200 metres is within the travel range of most arid small mammals (James Val, pers. comment). These travel distances serve as a guide to the distance between re-created green spots, especially if the object is to extend the range of suitable habitat.

WLLS will be conducting fauna monitoring on these projects to determine whether small mammals find and utilise the newly created habitat.

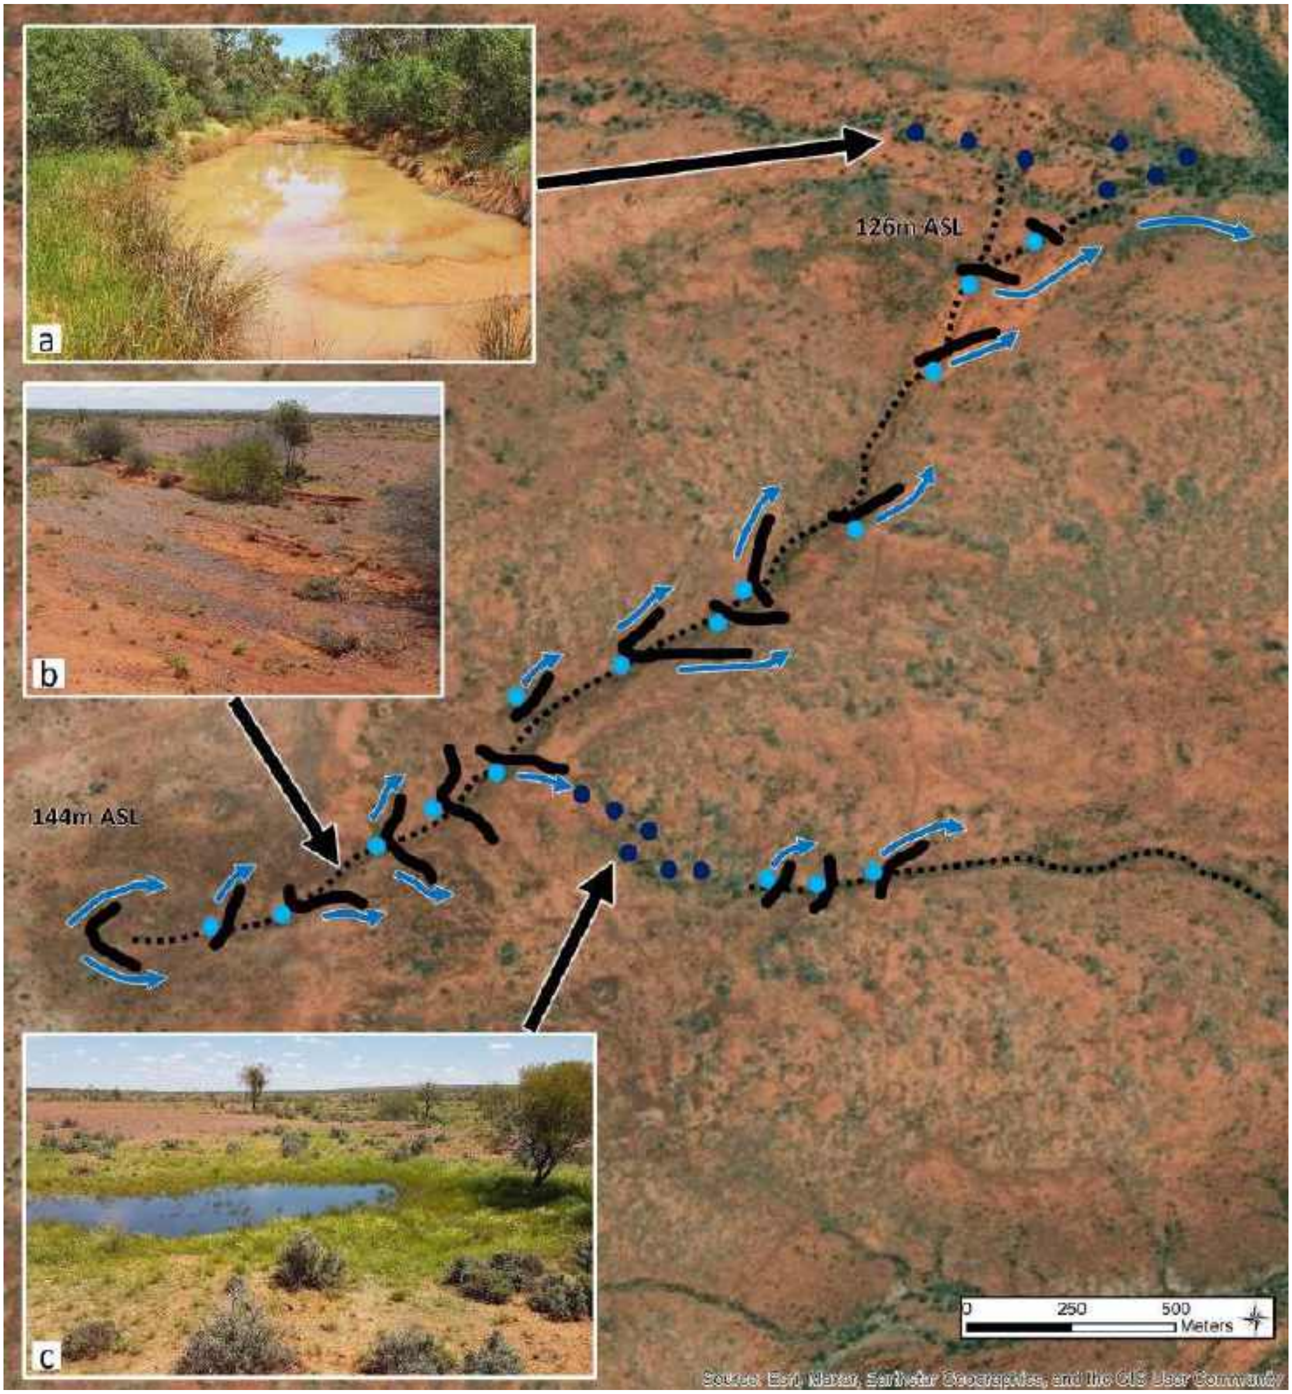

Figure 1: Simplified layout of Goodwood green spot project. Solid black lines represent check banks combined with diversion banks which pond water in the incised gully, creating localised green spots, then release flows onto surrounding floodplain. Dotted line represents incised gully. Blue arrows represent flows. Dark blue points represent existing, healthy green spots. Light blue points represent re-created green spots, creating a corridor of green spots. photo a) creek line waterholes. photo b) incised drainage line. photo c) cluster of deep gilgais.

Assessing sediment diatoms for water quality index in the protected wetlands of Vettangudi Bird Sanctuary, India

Kannan Dorai Pandian[1]

[1]Associate Professor, Thiagarajar College (Retired), Madurai, India. Madurai – 625 009, Tamil Nadu, India. Email: dkannantc@gmail.com

Keywords: Temporary Pond Ecology - Biological water quality – Phytoplanktons and Diatoms Diversity – Biotic interactions – Physical conditions of pond water

Introduction

Assessing water characteristics through key quality parameters is essential for understanding the ecological health of rangeland resources and forms a critical foundation for effective freshwater pond monitoring. Aquatic plant organisms, particularly phytoplankton—primary producers that include blue-green algae, green algae, diatoms, desmids, and euglenoids—significantly influence the chemical composition of water, a key determinant of productivity. Among these, diatoms and microflora are recognized as essential primary producers and serve as critical indicator species, providing valuable insights into the ecological health of inland freshwater pools (Lougheed et al., 2015).

Biomonitoring ponds by analyzing the assemblages of microflora and microfauna is an essential tool for assessing pond health, as these assemblages are strongly influenced by pollutant loads. Understanding the potential role of diatom algae in regulating water quality is particularly important in ponds with high levels of biological interaction. This knowledge is fundamental for developing effective management guidelines and ensuring the sustainability of freshwater wetland ecosystems.

The time-dependent hypersensitivity of diatoms to environmental changes (Stevenson, 2014) underscores the importance of thoroughly understanding the complex relationships between physico-chemical water quality parameters, thereby enabling more effective assessment of pond conditions. In the present experimental pond, avian diversity was identified as a significant biotic interaction affecting the pond ecosystem (Mahesh et al., 2018).

Although numerous studies have explored diatom diversity in relation to water quality in freshwater wetlands, there remains a significant knowledge gap concerning biotic interactions, particularly allocanthous pollution, and their impact on water quality as indicated by diatom presence in ephemeral ponds. To address this gap, the present investigation aimed to relate the physical conditions and chemical composition of pond substrata to the presence of diatoms, recognized indicators of water quality parameters.

Water samples were collected from three adjoining temporary ponds within the Vettangudi Bird Sanctuary, Sivagangai District, Tamil Nadu, India, to achieve this objective.

Study area

The Vettangudi Bird Sanctuary (latitude 10º 06.57'N, longitude 78º 30.81'E) encompasses three temporary drainage ponds: Vettangudipatty, Chinna Kollukudipatty, and Periya Kollukudipatty. For this study, the Periya Kollukudipatty (PKD) pond was selected as the experimental site. The sanctuary is in the villages of Vettangudipatty and Kollukudipatty within Thiruppathur Taluk, Sivagangai District, Tamil Nadu, India. The PKD pond hosts many migratory birds annually, primarily between November and February. Additionally, it serves multiple purposes for local communities, including domestic use, irrigation through channel systems, collection of fuelwood, minor forest products, and cattle grazing during the summer when the ponds dry up.

Methodology

Water samples were collected from three randomly selected points in the experimental pond between November 2013 and March 2014. Sampling was conducted at 06:00 hours during each collection period using clean plastic bottles. The samples were then transported to the laboratory for further analysis. Sampling and analytical procedures followed the standard methods outlined by Beutler et al. (2005). The pH of the water was measured using a pH meter (Elico, India), and water temperature was recorded immediately after sampling. Total Dissolved Solids (TDS), conductivity and dissolved oxygen (DO) were analyzed using a water analyzer kit (Systronics, Model No. 371).

Bulk water samples were filtered through a phytoplankton net with a mesh size of 45 microns and preserved using 4% formalin and Lugol's iodine solution. Diatom species were identified and photographed using a Euromex light microscope (Holland) at 1000× magnification. At least 500 valves per slide were counted and identified to the species level. Special hyrax mounts were used to prepare slides, and the morphological structures of the diatoms were observed under the microscope. Species identification was carried out based on the manuals by Anand (1988) and Karthick et al. (2013).

Results and Discussion

The physico-chemical condition of water determines the planktonic status of an aquatic ecosystem. The analyzed water quality parameters (Table 1) clearly indicate a gradual increase in alkalinity from January 2014 toward the end of the sampling period. This increase was accompanied by a deterioration in water quality, as evidenced by elevated levels of total dissolved solids (TDS), salinity, acidity, and alkalinity. Notably, higher dissolved oxygen (DO) levels were observed during January, February, and March 2014, which can be attributed to the inflow of fresh rainwater replenishing the pond. Diatom algae-produced oxygen is known to facilitate the bacterial degradation of polycyclic aromatic hydrocarbons (PAHs), phenolics, and organic solvents in benthic environments. However, as organic nutrient levels in water bodies increase, DO tends to decline (Manral and Khudsar, 2013). Additionally, the aggregation of microalgae and diatoms during this period likely contributed to reduced DO levels.

A high TDS level is indicative of eutrophication in aquatic systems, often resulting from increased nutrient inputs, such as excreta from migratory birds sheltering in the pond during the study period. This eutrophic state was further confirmed by the presence of pollution indicator microalgae species, including *Cosmarium contractum*, *Lepocinclis sphagnophila*, *Spirogyra webri*, and *Oscillatoria okeni*.

Data analysis revealed monthly variations in total diatom cell counts and species diversity at the Vettangudi Bird Sanctuary Pond (VTG pond). Of the 32 species identified across 20 genera of phytoplankton, including diatoms and microalgae, 20 species belonged to Bacillariophyceae, 8 to Chlorophyceae, 5 to Cyanophyceae, and 2 to Euglenophyceae. The pond's nutrient loading, primarily driven by the migratory bird population, classifies it as dystrophic. Pond physico-chemical properties, including elevated organic matter, CO_2 levels, and high pH, were responsible for supporting specific phytoplankton communities (Jena et al., 2013).
The dominance of Bacillariophyceae was attributed to the alkaline pH conditions. This finding aligns with studies by Shetty and Gulimane (2023). The presence of *Spirogyra sp.* further confirms the eutrophic nature of the experimental pond, consistent with observations by Adesalu and Nwankwo (2008). Additionally, the occurrence of *Lepocinclis sphagnophila* indicates high levels of organic pollution, while *Cosmarium contractum var. minutum* reflects neutral pH conditions, suggesting the existence of pure water environments within the pond.

Throughout the sampling periods, poor water quality was evident from both physical and chemical analyses, supported by the presence of pollution-indicating species such as *Spirogyra webri*. This species thrives in lentic environments, forming thick mats on the pond surface, which deplete oxygen levels and lead to anaerobic conditions. Cyanophycean species such as *Anabaena torulosa* were also observed, with their intercalary heterocysts facilitating nitrogen fixation.

The results highlight the importance of linking species occurrence and diversity indices to water quality parameters. The findings have broader implications for temporal and spatial wetland management and can inform the development of rangeland conservation guidelines for fragile freshwater ecosystems. The preference and tolerance of microalgae assemblages for specific habitats are largely dependent on the physicochemical characteristics of the aquatic environment, outcompeting other algal groups in such conditions.

The alkaline range detected during the study (Table 1) aligns with findings by Vijay Baskar et al. (2009), which suggest that alkaline conditions promote phytoplankton proliferation. The presence of *Chlamydomonas macrosphera*, *Chlorella vulgaris*, and *Phormidium tenue* indicates polluted water conditions, while *Pithophora oedogonia* (a Chlorophyceae member) forms thick algal mats on stagnant water surfaces. Additionally, *Amphora coffeaeformis* is known to accumulate herbicides like mesotrione (Valiente Moro et al., 2012). The increased conductivity levels observed during the study were likely due to nutrient enrichment from migratory avian populations (Khanthong et al., 2023), consistent with observations at the PKD pond.

Table 2: Diatoms and microalgae sps. occurrence at the Vettangudi Bird Sanctuary Pond during the experimental period

Conclusion

The study of diatom diversity and inventory reveals that the water quality of the PKD pond is deteriorating, as indicated by the analyzed physico-chemical parameters and the observed diatom assemblages. The heavy pollution and resultant eutrophication at this site are primarily attributed to biotic interactions with migratory birds utilizing the pond ecosystem. However, some moderation of the pollution load was observed due to oxygen emission by diatoms, along with the contribution of Chlorophyceae microalgae, which play a foundational role in the aquatic food chain.

This study highlights the need for further analysis of diatom diversity indices and additional physico-chemical parameters. Such investigations would provide valuable insights to develop specific management guidelines aimed at maintaining water quality, a critical feature in rangeland ecosystems. The sensitivity of algae to changes in water quality makes them valuable bioindicators of the physical and chemical characteristics of aquatic environments. These indicators could also be applied to similar water bodies to aid in the restoration and conservation of dystrophic ecosystems, preserving their ecological integrity.

Abstract

Alfalfa (*Medicago sativa* L.) is the most important forage crop grown globally. Alfalfa is often called "Queen of Forages" because of its high productivity, great animal performance, and superior nutritive value. However, producers/ranchers face several challenges such as high and inefficient use of water, alfalfa weevil infestation, and bloat problems in grazing livestock. A field study was conducted in 2020-2021 and 2021-2022 growing seasons to compare forage productivity, nutritive value, alfalfa weevil abundance, and economic returns of monocrop alfalfa and different seeding ratios of alfalfa-grass mixtures planted at different planting configurations under full and deficit irrigation. Treatments included monocrop alfalfa, 75-25% mixture, 50-50% mixed row planting, and 50-50% alternate row planting of alfalfa with each of three perennial cool-season grasses (orchardgrass, tall fescue, and meadow bromegrass) under full and deficit irrigation. Full irrigation plots received 100% ETc (crop evapotranspiration) for the whole season while deficit irrigation plots received 100% ETc for the first harvest and 60% ETc for subsequent harvests. The study design was split plot with irrigation as whole plot factor and cropping system (monoculture and mixtures) as subplot factor. Results show that intercropping alfalfa with grasses irrespective of planting configurations produces similar forage yield to monocrop alfalfa. Deficit irrigation reduced forage yield. Forage nutritive value was generally higher in monocrop alfalfa, however some mixtures produced similar nutritive value as monocrop alfalfa. Intercropping alfalfa with grasses reduced alfalfa weevil numbers. The 75-25% mixture of alfalfa and tall fescue under full irrigation produced the highest net present value. Deficit irrigation reduced costs but did not result in high net present value compared to full irrigation. Alternate row planting with orchardgrass under deficit irrigation produced similar net present value to full irrigation. Increasing unpredictability of the weather due to climate variability can make deficit irrigation a more viable and sustainable option.

Introduction

Alfalfa is the most important forage crop in the US and the fourth (6.7 million hectares) largest crop in terms of area harvested, behind corn (32.9 million hectares), soybean (30.4 million hectares.) and wheat

(15.1 million hectares) (USDA, 2020). Alfalfa has a deep taproot system allowing it to extract water from deeper depths than other forage species. It is therefore very tolerant to drought conditions. Nevertheless, alfalfa water use is high due to the its long growing season and dense canopy. About 13 cm of water is required to produce 1000 kg of alfalfa (Wright, 1988). The primary consumptive use of water by alfalfa is evapotranspiration, which is a function of the crop characteristics, weather conditions and water content in the rhizosphere. Highest yield of forage is obtained when water supplied to alfalfa from precipitation and irrigation meets the evapotranspiration needs of the crop. Alfalfa-grass mixtures are recommended as a management strategy to boost forage yield and increase profitability. Mixtures utilize resources more efficiently (Liu *et al*., 2018), resulting in higher yields compared to monocultures. Alfalfa-grass mixtures are known to improve nutritive value of forages (Adjesiwor *et al*., 2017). The seeding ratios and planting pattern of alfalfa-grass mixtures may be one of the strategies to increase yield in mixtures, but this has not been extensively explored. Alfalfa-grass mixtures also have the potential to reduce alfalfa weevil numbers. The primary objective of the study is to investigate forage productivity, nutritive value, alfalfa weevil abundance, and economic returns of monocrop alfalfa and alfalfa-grass mixtures under different planting patterns and different irrigation regimes.

Methods

The experiment was conducted from 2020 to 2022 at the University of Wyoming James C. Hageman Sustainable Agriculture Research and Extension Center (SAREC) near Lingle, Wyoming. Most of the precipitation at the study site occurs between March and October. Soil samples were collected in the summer of 2020 before planting. Soil was analyzed for pH (8.4), OM (1.8), $N–NO_3$ (30 mg kg^{-1}), P (22 mg kg^{-1}), and CEC (20.4 meq/100g). Treatments included monocrop alfalfa, 75-25% mixture, 50-50% mixed row planting, and 50-50% alternate row planting of alfalfa with each of three perennial cool-season grasses (orchardgrass, tall fescue, and meadow bromegrass) under full and deficit irrigations (Table 1). Full irrigation plots received 100% ETc (crop evapotranspiration) for the whole season while deficit irrigation plots received 100% ETc for the first harvest and 60% ETc for subsequent harvests.

The study design was split plot with irrigation as whole plot factor and cropping system (monoculture and mixtures) as subplot factor. Irrigation scheduling was based on alfalfa crop evapotranspiration (ET_c). Daily ET_c values were calculated using the American Society of Civil Engineers (ASCE) Standardized Reference ET Equation (Allen *et al.*, 2005) and alfalfa crop coefficient (K_{cr}) values (Allen & Pereira, 1998) (Equations 1 and 2). Four biomass harvest samples were taken for each treatment plot and oven-dried at 60°C for at least 48 hrs. Dry weight of samples was measured and recorded as weight per unit quadrat area, which was then used to estimate forage yield per hectare (kg ha^{-1}). Oven-dried samples were ground in a mill with a 1-mm mesh. Forage nutritive value parameters, including crude protein (CP), acid detergent fiber (ADF), neutral detergent fiber (NDF), and in vitro dry matter digestibility (IVDMD) were analyzed using Near-Infrared Reflectance Spectroscopy. Alfalfa weevils were collected using a sweep net, with ten sweeps taken from each plot. The economic value (dollar per hectare) of each treatment was determined through a net present value (NPV) analysis. Analysis of variance (ANOVA) was performed on forage dry matter yield and nutritive value data. A mixed effect model with alfalfa-grass mixtures with irrigation regime as fixed effects and block as random effect was used. Significance was declared at $\alpha = 0.05$, and post hoc mean separations were made using Tukey HSD test.

Units for the 0.408 coefficient are m^2 mm MJ^{-1}.

Results

All mixtures produced forage yield similar to the monocrop (Table 1). Intercropping with 25% grass increased forage yield by 8% compared to monocrop alfalfa under full irrigation. Under deficit irrigation, the 50Alf+50OG-AR mixture had the highest forage yield (Table 1). Full irrigation resulted in higher forage yield (Table 1). Although alternate row plantings were not significantly different from mixed row plantings under deficit irrigation, they generally yielded more for all grass species. Monocrop alfalfa had the highest CP content, significantly higher than all mixtures except 50Alf+50TF-AR (Table 1). Monocrop alfalfa had lower NDF concentration than all mixtures except 50Alf+50TF-AR. Monocrop alfalfa recorded similar dry matter digestibility as all mixtures except 50Alf+50MB and 50Alf+50OG_AR. All mixtures recorded lower alfalfa weevil count compared to the monocrop alfalfa (Table 1). The highest count of alfalfa weevil was observed in the monocrop alfalfa while the lowest count was found in alternate row planting of mixtures. The 75Alf-25TF mixture under full irrigation yielded the highest NPV, while the lowest NPV was observed in the 50-50 alfalfa and meadow bromegrass mixture under deficit irrigation (Table 1).

Discussion

The superior yield of orchardgrass mixtures compared to other mixtures under deficit irrigation may stem from its compatibility with alfalfa. Casler (1988) noted that alfalfa-orchardgrass combinations exhibit greater vigor, ground cover, and regrowth compared to mixtures with smooth brome or ryegrass. This compatibility enhances resource use efficiency, contributing to the superior performance of the orchardgrass mixture under deficit irrigation. Full irrigation resulted in higher forage yield compared to deficit irrigation due to better leaf growth and photosynthesis (Zargar *et al.*, 2017). Under water stress, stomatal closure and reduced leaf expansion limit photosynthesis (Zargar et al., 2017), lowering forage accumulation. Although alternate row plantings were not significantly different from mixed row plantings under deficit irrigation, they generally yielded more for all grass species, likely due to reduced interspecies competition for resources like water (Lafrenière & Drapeau, 2011). The similarity in CP levels between monocrop alfalfa and 50Alf+50TF-AR is likely due to the decreased grass proportion in the 50Alf+50TF-AR mixture. Forage grasses such as meadow bromegrass, tall fescue and orchardgrass typically have higher NDF concentrations than alfalfa (Adjesiwor *et al.*, 2017; Aponte *et al.*, 2019). As a result, mixing these grasses with alfalfa increased the NDF content in the mixtures. The lower weevil counts in mixtures may result from grasses interfering with the insects' visual cues (Meyer and Raffensperger, 1974) or due to emigration of the insect from the mixed stands (Roda *et al.*, 1997). This emigration might also be driven by volatile compounds produced by the grasses (Smith *et al*., 1992). The high NPV in the 75-25 alfalfa-tall fescue mixture was mainly driven by significant total revenue, which compensated for the higher costs.

Key words: diplochory; juniper seed dispersal; woodland expansion; woodland infilling

Abstract

Juniper woodland infilling and expansion, considered threats by rangeland managers, is driven by seed dispersal. We studied the roles of birds, lagomorphs, and rodents in *Juniperus osteosperma* recruitment in the Great Basin of western Utah, USA. Recruits were disproportionately in shrub microhabitats. Birds disperse no seeds, lagomorphs almost exclusively disperse seeds to open interspaces, and only rodents disproportionately cache in shrub microhabitats. Results suggest the primary driver of recruitment is seed-caching rodents.

Introduction

Conifer expansion into sagebrush shrublands in the western USA is of concern to rangeland managers, contributing to a reduction in shrub and grass cover, increased erosion, decreased soil water, and more (Chambers et al. 2014, McIver et al. 2014). In the Eastern Great Basin this process is driven primarily by *Juniperus ostesperma*, a monoecious conifer producing modified "fleshy" cones containing a single seed; cones dry within weeks, slowly dropping to the ground over an extended period (Schupp et al. 1995, Zlatnik 1999).

Key to juniper expansion is seed dispersal, especially where seeds are deposited, which determines the biotic (e.g. seed predators, mycorrhiza) and abiotic (e.g. microclimate, soil water) environments recruits encounter and thus recruitment probability (Schupp and Fuentes 1995, Schupp et al. 2010). *J. osteosperma* seed dispersal is not well understood, but lagomorphs (Schupp et al. 1995) and rodents (Dimitri et al. 2017) reportedly disperse their seeds. Further, Juniperus spp. are extensively dispersed by birds (Chambers et al. 1999). As a first step in assessing the role of seed dispersal in *J. osteosperma* recruitment, we quantified (1) the microhabitat pattern of recruitment and (2) the microhabitat pattern of seed deposition by birds, lagomorphs, and rodents. We compare patterns of recruitment and dispersal to determine the disperser group(s) most likely driving *J. osteosperma* recruitment.

Methods
We conducted this study in a 2-ha (100 x 200 m) juniper woodland plot in west-central Utah, USA, (39º 53’ 19” N, 112º 08’ 58” W, 1774 masl), a region with hot, dry summers and cold, wet winters. We distinguish four microhabitats: 1) “Juniper,” beneath the canopy of a live *J. osteosperma*; 2) “Dead Juniper,” beneath the canopy of a dead *J. osteosperma*; 3) “Shrub,” beneath the canopy of a shrub; and 4) “Open,” interspace without woody cover. We quantified proportional microhabitat cover with the Line Intercept Method (Fiala et al. 2006) along 40, 100 m transects across the plot. We located, marked, and measured all *J. osteosperma* recruits (≤1 m height) and recorded their microhabitat. We noted “seedling caches,” where two or more recruits grew adjacent, assuming adjacent recruits likely came from a cache. We investigated seed dispersal by birds with timed watches of tree clusters during winter when cones are fresher and frugivorous bird density and diversity are highest. We assessed dispersal by lagomorphs by collecting pellets by microhabitat type along a 2-m wide 440 m long transect connecting 15 random points across the plot. Pellets were dissected to quantify seeds/microhabitat. Dispersal by rodents was sampled by coating cleaned, filled seeds with fluorescent powder and placing a set of 30 seeds in a petri dish in the middle of a powder-filled plate. Seeds were set at sunset. Before sunrise we returned and searched using an ultraviolet light, following powder trails and marking disturbed sites. We returned later to search flagged locations for caches. Analyses were based on comparing actual microhabitat distributions with expected distributions based on proportional cover of microhabitats using simple Chi-square tests conducted by hand.

Results
Recruits were not randomly distributed (n=263, Table 1). The dominant microhabitat was Open, while Shrub was substantially lower. However, recruits were much more frequent than expected beneath Shrubs and much less frequent than expected in Open.

Table 1. The proportion of each variable represented by each of the four identified microhabitat types. Significance refers to the significance of a Chi-square comparing the actual microhabitat distribution of variables (e.g. recruits) with the expected distribution based on proportional cover of the microhabitats; that is, the expected distribution if the variable (e.g. recruits) is distributed independently of microhabitat type.

	Proportion				
Variable	Juniper	Dead Juniper	Shrub	Open	Significance
Microhabitat Cover	0.16	0.02	0.25	0.58	N/A
Recruits	0.16	0.00	0.67	0.18	P<0.05
Seedling Caches	0.19	0.00	0.75	0.06	P<0.05
Bird-dispersed Seeds	--	--	--	--	--
Lagomorph-dispersed Seeds	0.04	0.00	0.00	0.96	P<0.05

Rodent-dispersed Caches	0.07	0.00	0.80	0.13	P<0.05

In over 100 person-tree-hours of observations the only bird species feeding on *J. osteosperma* cones was the Juniper Titmouse (*Baeolophus ridgwayi*), a seed predator (Fuentes and Schupp 1998).

In contrast, lagomorphs dispersed seeds (Table 1). We collected 692 pellets; 9% contained 1-4 intact seeds each for a total of 76 seeds. Many more of these seeds were dispersed to Open and fewer to Shrub than expected.

We addressed the role of rodents in *J. osteosperma* recruitment using the microhabitat distribution of "seedling caches" and of seed caches. We estimated 16% of recruits were in "seedling caches," which were disproportionately beneath Shrub (Table 1). We located 30 seed caches; congruent with the distribution of "seedling caches," many more were located beneath Shrub than expected, while very few were in Open (Table 1).

Discussion

Frugivorous birds are considered the most important dispersers of juniper, dispersing many seeds and depositing them beneath woody vegetation which is thought to facilitate establishment (e.g. Dimitri and Longland 2017, Isla et al 2024). Our evidence suggests that rodents fulfill this role in *J. osteosperma* – only dispersal and caching by rodents explains the microhabitat pattern of recruitment.

Both "seedling caches" and seed caches support the role of rodents. In both cases, caches were disproportionately frequent in Shrub and disproportionately infrequent in Open. The seed caches we located represent the first of potentially many sequential caching events. Rodents pilfer juniper seed caches, and although they consume some and larder hoard others, many are recached (Dimitri and Longland 2022). If caches in our system are pilfered, rodents apparently disproportionately recache beneath shrubs, reducing the number of seeds available for germination without altering the microhabitat distributions.

As noted, many believe that microhabitats beneath woody vegetation are favorable for juniper recruitment. Experimental seed sowings in our plot showed inconsistent, slight germination and survival benefits in Shrub relative to Open, with a small significant benefit in some cohorts during some sampling periods but not in others (Schupp et al., unpublished data). This benefit is insufficient to drive the pattern of recruitment. Facilitation appears to enhance rather than cause the distribution of recruits.

Although our work occurred within a woodland and does not directly address expansion into shrublands we can make informed speculation. First, although some rodents are restricted to woodlands, others use both woodlands and shrublands (Dimitri and Longland 2017) and likely contribute to local expansion at the ecotone through short-distance dispersal. Further, more rapid expansion might be due to diplochory, or two-stage dispersal, as has been suggested for bird-rodent diplochory of *J. occidentalis* (Longland and Dimitri 2016), with lagomorphs initially dispersing seeds out of the woodland and rodents subsequently harvesting seeds from faeces and caching some beneath shrubs. Although the density of seeds in lagomorph faeces drops off rapidly with distance from woodland edge, lagomorphs can disperse some seeds long distances into shrublands (Schupp et al. 1997). This could produce scattered reproductives far in front of the woodland that can create expanding nuclei of woodlands through local dispersal, a process known to accelerate tree movement (Clark et al. 1998).

Use of axillary buds and other demographic parameters to evaluate control strategies for perennial invasive grasses.

Hendrickson, JR[1]; Toledo, D[1]; Carrlson, AJ[1]; Kobilansky, C[1]; DeKeyser, ES[2]

Key words: Smooth bromegrass; Kentucky bluegrass; defoliation, drought, burning.

Abstract

Cool-season perennial invasive grasses are a primary management concern on northern Great Plains rangelands in the USA. Management strategies to reduce these grasses often do not consider underlying mechanisms that can explain responses. One potential way around this constraint is evaluating axillary buds, which are meristematic tissue that provide the basis for future productivity. Our research projects evaluated responses of axillary buds of two perennial invasive grasses to different management strategies. In the first experiment, axillary bud numbers per m^{-2} were collected in the spring and fall of 2020 and 2021 from plots with ambient rainfall plus 2 different simulated drought intensities (30 and 60% of the ambient rainfall intercepted). Half of the plot under each rainfall intensity was burned, and the other half was left unburned. Both burning and moderate drought reduced the number of Kentucky bluegrass (*Poa pratensis* L.) axillary buds m^{-2} to 60% of the controls; however, the impact of burning changed with season and drought intensity. Regardless of burning or drought treatment, there were still over 400 active axillary buds m^{-2} suggesting a large pool of potential meristematic tissue was available for future growth. In the second experiment, smooth brome (*Bromus inermis* L.) tillers were clipped at vegetative, tiller elongation, and reproductive stages, and the number of axillary buds, tillers, and rhizomes (total outgrowth) was estimated in the fall over a 3-year period. Both total outgrowth and proportion of axillary buds that became outgrowth were greater when smooth brome was defoliated in the reproductive phase than when it was defoliated twice in the vegetative phase, suggesting the timing of defoliation may aid in smooth brome control. Both experiments suggest that evaluating the response of axillary buds and other demographic parameters provides mechanistic insights into the potential effectiveness of different management strategies for controlling invasive perennial grasses.

Introduction

Invasion by C_3, non-native, perennial grasses has been identified as one of the major challenges facing rangelands in the northern Great Plains of the US (Hendrickson et al., 2019). In particular, two grasses, smooth bromegrass (*Bromus intermis* Leyss.) and Kentucky bluegrass (*Poa pratensis* L.) have rapidly increased (Hendrickson et al., 2021) with negative impacts on species diversity and resilience (Hendrickson et al., 2021; Toledo et al., 2014). Burning and defoliation (Hendrickson and Lund, 2010) have both been evaluated as potential control methods for these two species.

Below-ground bud banks, made up of axillary buds located at the base of perennial grasses, are a major source of population resilience in the Great Plains (Ott et al., 2019). Because of the importance of these bud banks to vegetative renewal, evaluating how axillary buds and tiller respond to different control treatments can provide insight into their effectiveness. We used vegetative outgrowth and axillary bud numbers to evaluate the responses of smooth bromegrass to defoliation and Kentucky bluegrass to burning and drought.

Methods

Both studies reported in this paper took place at the Northern Great Plains Research Laboratory (46.767085^0 N; -100'908629^o W) on loamy ecological sites (Sedivec et al., 2021). Fifty smooth bromegrass tillers were randomly assigned to 5 different defoliation treatments in three different ungrazed exclosures in 2018, 2019 and 2020 (n=30 tillers treatment^{-1}). Tillers were defoliated 1) once in the vegetative stage; 2) twice in the vegetative stage; 3) in the elongation stage; 4) in the reproductive stage; or 5) left undefoliated. Tillers were collected at the end of the field season and brought back to the laboratory where total tillers and rhizomes were counted (Total Outgrowth).

Drought and defoliation treatments were initiated on nearby sites in 2017 and continued through 2021. Each site had nine 2x2 m plots that were 1) exposed to ambient precipitation; 2) had 30% of ambient precipitation intercepted using plexiglass gutters or 3) had 60% of ambient precipitation intercepted. In addition, half of each plot was burned in the fall of 2017, 2019 and 2020. In May and November of 2020 and 2021, a cm^{-2} sample was collected using a soil probe and brought to the laboratory where is was cleaned and stained using a 0.1% 2,3,5-tripehnyl tetrazolium chloride (TTC) solution (Hendrickson & Briske, 1997). Stained buds were considered active and counted.

Results

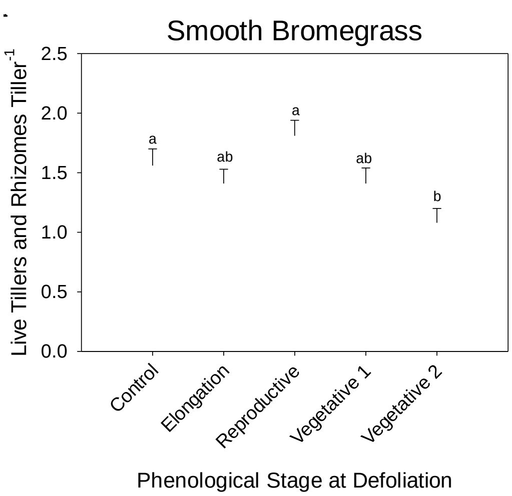

Figure 1. Number of live tillers and rhizomes for smooth bromegrass tillers defoliated at different phenological stages. Different letters over the bars indicate significant differences at P≤ 0.10.

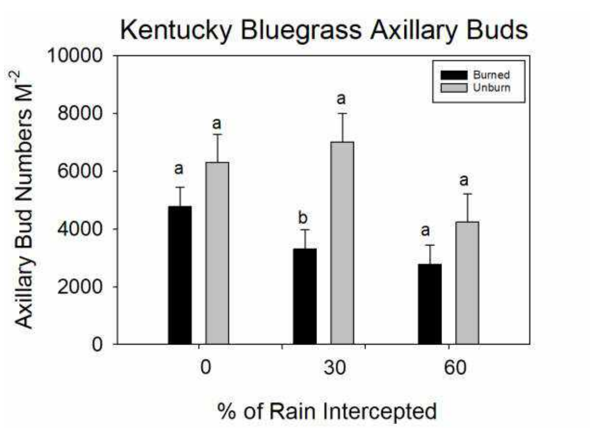

Figure 2. Number of Kentucky bluegrass active axillary buds per m^{-2}. Different letters over the bars indicate significant differences between burned and unburned plots at P≤ 0.10.

Smooth Bromegrass Defoliation

Defoliating smooth bromegrass twice in the vegetative stage reduced outgrowth (live tillers and rhizomes) compared to undefoliated controls and defoliating in the reproductive stage (Figure 1). However, outgrowth on a $tiller^{-1}$ basis still exceeded 1 indicating that outgrowth still exceeded the number required for population persistence.

Kentucky Bluegrass Response to Drought and Burning

Kentucky bluegrass had a burn by drought interaction. Axillary buds were significantly reduced by burning when 30% of the ambient rainfall was intercepted (Figure 2). Axillary bud number m^{-2} on the unburned treatments was lower when 60% of the ambient rainfall was intercepted compared to 30% ($P = 0.0575$).

Discussion [Conclusions/Implications]

Outgrowth, such as tiller and rhizome numbers, and axillary bud numbers should not be used to predict future meristematic outgrowth for these two invasive perennial grasses. For both examples, the invasive grass has adequate amounts of outgrowth or axillary buds to maintain their populations into the future. Environmental variables also impact demographic processes as demonstrated by the reduction in axillary bud numbers on the unburned portions of the rain intercept plots when 60% of ambient precipitation was intercepted compared to 30%. However, the data suggest that demographic attributes can be used to identify potential treatments or to explain why certain control measures are more successful. For example, smooth bromegrass outgrowth suggests that grazing when the grass is reproductive may increase its tiller numbers. Similarly, burning appears to reduce the number of axillary buds in Kentucky bluegrass suggesting a potential mechanism for the success of burning as a control for Kentucky bluegrass (Ereth et al., 2017; Hendrickson and Lund, 2010).

It's not the plants you can see but those you can't see: managing Australia's rangelands means managing pest rabbits

Peacock, D. E[1]; Hutchinson, M. R[2]

Abstract

European rabbits are thought to have colonised most of Australia's vast rangelands by about 1910, leaving destitute pastoralists, decreased livestock production and a degraded environment in their wake, resulting in an-going need to manage and rehabilitate these critical environments. At a broadscale, rabbit control has been implemented, with varying degrees of success, using a variety of biocontrol agents most notably myxomatosis in the 1950's and more recently rabbit haemorrhagic disease virus. Native perennial vegetation still shows these recruitment pulses due to a modern awareness that seedling survival tolerances of palatable species can be as little as one rabbit/km^2. Such low rabbit density was achieved with initial impacts of the viral biocontrols, and where land managers have undertaken landscape scale warren destruction. Utilising GPS mapping of rabbit warrens we mapped the native vegetation recruitment following destruction of approximately 28,000 warrens by a bulldozer with long ripping tines at Thackaringa Station in western NSW. Using the remotely sensed Normalised Difference Moisture Index on the 22,545 ripped and GPS-mapped warrens at Thackaringa has detected a differential recovery trend in areas where rabbits have been eradicated. Based on this initial analysis, it suggests that the potential benefits for landscape-scale restoration of native vegetation, ecological recovery, pastoralism and potential carbon storage may be appreciable. However, satellite sensors are optimised for vegetation that is not the dominant signal for the Australian geographies, necessitating the exploration of tailored analysis methods to address the unique complexities of Australia's diverse ecosystems.

Introduction

Australia's rangelands, spanning six million square kilometres and comprising 81% of the continent. Notwithstanding those in the tropical north, the remainder is inhabited and severely impacted by the pest European rabbits (*Oryctolagus cuniculus*), which became established in Australia in the mid-19th century and had colonised these rangelands by 1980 (Stodart and Parer 1988). By the late 19th century, the rangelands faced devastating rabbit plagues. By the early 20th century, the extent of rangeland degradation was seen in state legislation such as South Australia's Sand Drift Act of 1923 (Ratcliffe 1938). The battle to manage the overgrazing of the pest rabbits had its first significant success in the 1950's due to the introduction of the myxoma virus as a biocontrol agent (Fenner and Fantini 1999). The most recent significant reduction in rabbits coming with the 1995 establishment of rabbit haemorrhagic disease virus (RHDV1/GI.1) (Mutze *et al.* 1998) and then the 2014 emergence and rapid establishment of RHDV2/GI.2 (Hall *et al.* 2015) with associated rabbit reductions (Mutze *et al.* 2018).

Primary environmental benefits have been the associated recovery of some native rangeland vegetation (Burrell *et al.* 2017) and threatened fauna species (Pedler *et al.* 2016). However, though the iconic rabbit plagues have ended, rabbit impacts on rangeland vegetation remain. Recent research documents the extreme sensitivity of many species of palatable native vegetation to rabbit grazing at densities as little as one per square kilometre, where 40% of mulga (*Acacia aneura*) seedlings were eaten (Henzell 2002). At the very minimal ≥ 0.005 rabbits km^2 palatable rangeland species such as *Acacia carneorum*, *Eremophila alternifolia*, *Allocasuarina luehmannii* and *A. verticillata* cannot successfully reproduce and establish new plants (Mutze *et al.* 2016). In the management of the rangelands, the impacts of rabbit grazing have been shown to generally be much more significant in impact on native vegetation recruitment and hence availability than pastoral factors such as water points and stock grazing (Mutze 2016).

To achieve effective landscape-scale rabbit control and the associated recovery of native rangeland vegetation, biodiversity, and pastoral benefits, landholders have undertaken major rabbit warren mapping and destruction works. The objective of this study was to examine the impact of the large-scale destruction of rabbit warrens on the presumptive increase in native vegetation based on remotely-sensed estimates of Normalised Difference vegetation Index (NDVI) before and after ripping.

Methods

This study was undertaken on Thackaringa Station which is located in arid rangelands of western NSW. Of approximately 28,000 rabbit warrens that were ripped, a total of 22,545 were mapped using a Garmin handheld GPS. Once mapped, rabbit warrens were destroyed using a Cat D8/9 bulldozer with c. 120 cm ripping tines spaced 75 cm apart. The primary objective of these activities was to achieve a significant reduction in rabbit numbers and promote the recovery of native vegetation. The ripping of these warrens largely occurred yearly between 2000 to 2004 (Fig. 1).

Google Earth Engine was used to facilitate the extraction of NDVI, enabling precise temporal and spatial analysis of changes in vegetation and soil moisture. The satellite sources used included the Landsat series 5, 7, and 8 and Sentinel-2, which provided multispectral signals. Cloud anomaly removal was conducted using a combination of cloud masking algorithms, including the Sentinel-2 Quality Assessment Band and Landsat Collection 1 Level-1 QA tools. Additionally, shadow detection was applied to minimise anomalies, and a median compositing approach was used to mitigate the influence of sporadic cloud cover. Further data cleaning included radiometric correction to standardise reflectance values across different time points, enhancing the reliability of the derived vegetation indices. Control data were derived from non-ripped comparable areas, which were identified based on similar soil types, vegetation profiles, and climatic conditions as the ripped areas. These control regions were selected to ensure a valid comparison, accounting for any external variables and providing a baseline to determine the direct impacts of rabbit management interventions.

To evaluate changes in vegetation and moisture, data derived from the satellite sources described in the previous paragraph was used. The Normalised Difference Vegetation Index (NDVI), Soil Adjusted Vegetation Index (SAVI), and Normalised Difference Moisture Index (NDMI) were extracted for each warren site and the comparative control areas. These indices were analysed over a temporal span from before warren destruction through to most recently available satellite imagery. Monthly composite values for NDVI, SAVI, and NDMI were calculated by taking the median value of all valid observations within each calendar month for each polygon. This approach minimises the impact of remaining atmospheric contamination or bidirectional reflectance distribution function effects. The resulting monthly time series data for each index (NDVI, SAVI, NDMI) were analysed to identify patterns and trends. The presence and period of seasonality were assessed by examining the autocorrelation function for each index's time series. To distinguish long-term trends from seasonal variations, a seasonal decomposition using LOESS (Locally Estimated Scatterplot Smoothing) was applied to each time series. Further analysis specifically compared trends before and after 2004, as this year marked the completion of the main phase of systematic warren destruction across the study sites.

Results

Remote sensing analysis across the 22,545 mapped and ripped rabbit warrens at Thackaringa station revealed significant, sustained changes in vegetation cover and near-surface moisture dynamics over the 1988-2022 period. Vegetation indices showed clear recovery trends following the period of intensive warren destruction. The Soil-Adjusted Vegetation Index (SAVI) trend, which corrects the Normalised Difference Vegetation Index (NDVI) for soil brightness influences, closely tracked the NDVI trend throughout the period, confirming that the observed greening was not primarily a soil-reflectance artefact. Both indices exhibited peaks around 2000 and again in the mid-2010s (reaching approximately 0.30 for SAVI and 0.20 for NDVI), punctuated by a major dip around 2010-2011 corresponding to drought conditions (SAVI < 0.15, NDVI < 0.10).

In stark contrast, the Normalised Difference Moisture Index (NDMI), representing surface moisture, displayed a markedly different trajectory, particularly after 2004 and the major wet event of 2010-2011. While NDMI values fluctuated around a moderately positive baseline (e.g., averaging near +0.08 to +0.10) in the earlier part of the record, the trend shifted dramatically downwards following the 2010-2011 peak (around 0.15), declining to negative values (averaging near or below -0.02) after 2012 and remaining persistently low despite subsequent periods of vegetation recovery. This pronounced decoupling between the recovering vegetation greenness indices (NDVI, SAVI) and the declining moisture index (NDMI) emerged most strongly post-2010/11, coinciding with a very wet year in the period after intensive warren destruction efforts. This divergence was reportedly absent from matched, unripped control polygons. Seasonal decomposition using LOESS and autocorrelation analysis confirmed strong annual cycles in all indices, but the sustained post-2010 NDMI decline represents a significant trend shift beyond typical seasonal or inter-annual variability. These patterns suggest that increased water uptake by recovering perennial vegetation drew down upper soil profile moisture more rapidly than replenishment occurred, establishing a new, lower NDMI baseline in the treated areas.

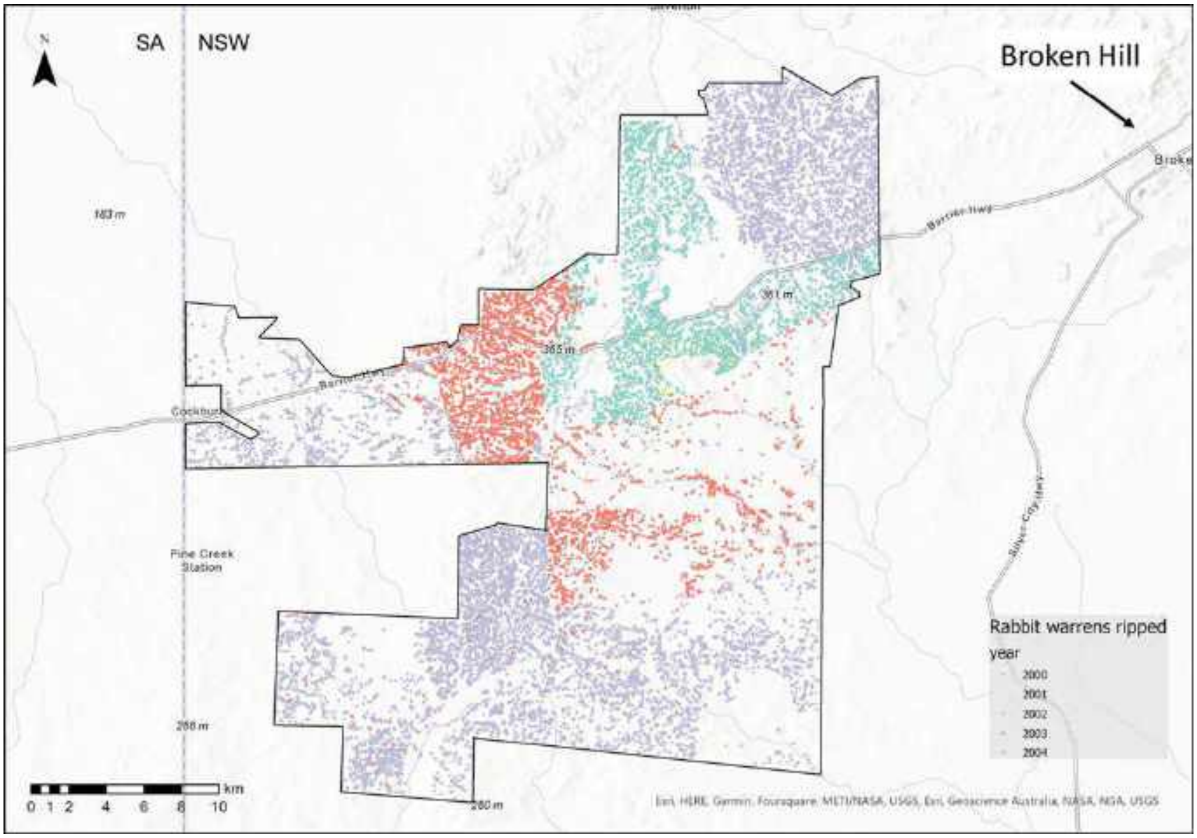

Figure 1: 22,545 mapped rabbit warrens, subsequently destroyed, on Thackaringa station (NSW).

Discussion

These findings demonstrate that landscape-scale rabbit warren destruction at Thackaringa station induced significant shifts not only in vegetation cover but also in local water balance dynamics. By facilitating the recovery of groundcover, primarily perennial vegetation, the intervention led to increased NDVI and SAVI values, indicative of greater photosynthetic biomass. Concurrently, the marked and sustained decrease in NDMI suggests increased evapotranspiration rates associated with this recovering vegetation kept near-surface soil layers significantly drier compared to the pre-treatment or early treatment period. This outcome aligns with observations from semi-arid exclusion studies, where the establishment of shrubs and perennial grasses modifies soil moisture regimes compared to denuded or annual-dominated systems.

The observed decoupling between the vegetation indices and NDMI post-intervention is critical. Because SAVI is specifically designed to minimise soil background influences on the greenness signal, its continued recovery alongside a declining NDMI strongly supports the interpretation that increased plant water uptake, rather than a spectral measurement artefact or simple lack of rainfall, drove the reduction in surface moisture detected by NDMI. This fundamentally alters the site from a quasi-fallow state around former warrens to one characterised by active hydrological cycling through established perennial vegetation.

Future research should aim to quantify these component changes more explicitly. Utilising products like Digital Earth Australia's Fractional Cover, which partitions satellite pixels into green vegetation, non-photosynthetic vegetation (dry/dormant), and bare soil components, could provide a more detailed understanding of how vegetation structure changes relate to water use. Furthermore, the advanced hyperspectral sensors aboard the Kanyini mission offer potential to refine these analyses by resolving specific spectral features related to plant pigments, water content, and dry matter, potentially improving discrimination even in complex semi-arid vegetation communities. Integrating these advanced remote sensing capabilities with ongoing adaptive management strategies, including follow-up warren control, can provide land managers with near-real-time feedback on both vegetation recovery status and associated water dynamics, strengthening the ecological and economic rationale for sustained rabbit management in Australia's rangelands.

Restoring the Banni grasslands: a model for combating invasive species, supporting natural ecosystem and empowering pastoral communities

Thacker, KD*[12];Nanjar, B[1]; Singh M[1]; Rajput KS[2]

Keywords: Restoration; India; Invasion; Prosopis juliflora

Abstract

The Banni grassland is Asia's largest grassland ecosystem, harbors unique flora and fauna, and supports over 8000 pastoral households. The pastoralists herd an indigenous buffalo breed "Banni" and have been practicing a semi-nomadic style of pastoralism for more than 500 years. This unique protected grassland is dotted with seasonal wetlands, saline-mix highly nutritive grass species, and some good patches of *Acacia nilotica* trees in some villages. In recent decades, encroachment particularly by the invasive species *Prosopis juliflora*, threatens this biodiversity hotspot by invading 50% of land. Woody shrub encroachments, converting the grasslands into woodland, is a trend witnessed globally, and harms unique biodiversity and traditional livelihoods of indigenous communities. Community Forest Management Committees (CFMCs) under the Forest Right Act 2006 have taken a multi-pronged approach to restore Banni grasslands. Through brush management techniques, they have restored over 3000 hectares across 18 villages in the last four years. The post monsoon grassland surveys were conducted by Sahjeevan's team using the random quadrat sampling method and data was analyzed to assess changes in the vegetation cover affected by invasive species. These efforts have shown remarkable recovery in vegetation cover of herbs and grasses up to 91%, species diversity up to 12 times, and biomass production up to 3.4 times in restored plots compared to invaded areas. Additionally, removal of this exotic invasive species in Nani Dadhdhar village has not only supported growth of the native tree *A.nilotica* but also amplified the population of itfourfold in the past four years. In Dedhiya village, biochar, made in Kon-Tiki kilns from *P.juliflora*and incorporated in the soil increased yield of grasses and herbs by 1.87 times compared withuntreated plots. Biochar not only helps boost soil health but also acts as a long-term (perhaps 2000-years) carbon sink and generates carbon credits. This restoration model exemplifies the power of community-driven conservation. It tackles invasive species, mitigates climate change and empowers pastoral communities, offering a blueprint for similar ecosystems worldwide.

Introduction

The Banni Grassland in Gujarat, India, is Asia's largest grassland, known for its unique semi-arid ecosystem with seasonal marshes and diverse flora and fauna. It is home to tree species like *Acacia nilotica*(L.) Willd. ex Delileand *Salvadora persica*L.; and provides habitat for fauna adapted to its conditions, including the spiny-tailed lizard (*Saara hardwickii*) and desert fox (*Vulpes vulpes pusilla*)(Bharwada and Mahajan 2012; Nerlekar et al. 2022). This grassland supports 22 local communities spread in 48 villages. The pastoralists of this area are called 'Maldharis', whose livelihoods depend on animal husbandry. They have selectively bred the Banni buffalo and Kankrej cow, which are highly valued across India (Nerlekar et al. 2022; Ravi and Krishnan 2024). For the Maldharis, the grassland's diversity is vital to their pastoral practices and sustains their primary income source (Ghosh et al. 2015).However, over 50% of the grassland has been invaded by *Prosopis juliflora*(Sw.) DC., a non-native tree introduced about 140 years ago to combat desertification. *P. juliflora* now spreads at an estimated rate of 25 km² per year, disrupting native ecosystems (Ravi and Krishnan 2024;Tewari et al. 2000). Species such as *P. juliflora* have contributed to the uniformity of plant communities globally, causing alterations in native ecosystems and displacing local flora and fauna (Mungi et al. 2019; Simberloff et al. 2013).

Community-led Restoration Efforts

To address the *P. juliflora* invasion, Community Forest Resource Management Committees (CFRMCs) formed under Forest Rights Act, 2006 have undertaken large-scale restoration efforts. These committees, empowered to conserve and manage forest resources, are working with Sahjeevan, an NGO focused on pastoralism and biodiversity conservation to clear *P. juliflora* from invaded areas since four years. Using brush management techniques, CFRMCs have restored over 3,000 hectares across 18 villages. Sahjeevan's team conducts post-monsoon surveys to monitor changes in vegetation cover and assess the success of restoration efforts.

The Role of Carbon Markets in Restoration

Carbon markets have been instrumental in funding restoration efforts in the Banni grassland. These markets allow the trading of carbon credits, with each credit representing one tonne of reduced, sequestered, or avoided carbon dioxide or greenhouse gases (Climate Promise 2022). In Banni, the biomass from uprooted *P.juliflora* was converted into biochar, generating carbon credits that were sold on international platforms. Biochar is produced through the pyrolysis of organic material in low-oxygen conditions, transforming plant waste into a stable form of carbon. When integrated into soil, biochar enhances soil fertility and provides long-term carbon storage with a mean residence time of about 2,000 years (Glaser et al. 2009; Kuzyakovet al. 2009). Biochar was also applied to grasslands in Dedhiya village to examine its impact on the natural regeneration of native grasses and herbs, aiming to promote healthier vegetation recovery and soil quality in restored areas.The total area restored under this pilot was 1100 hectares, which translated into 1530 credits produced from 695 tonnes of biochar. Here, one tonne of biochar has generated 2.2 carbon credits, consequently, 1530 tonnes of CO_2 were sequestered from the 1530 carbon credits. This biochar is currently stored underground within a grassland area. Further research is underway to investigate the large-scale application of biochar to the soil of the Banni grassland. The revenue generated from selling these carbon credits was utilized to fund large-scale restoration efforts

Methods

Sampling Design and Data Collection to check effect of restoration

In this study, a random quadrat sampling method was employed to assess species diversity, vegetation cover, and biomass productivity using a1 x 1 m frame for precise data collection. Five quadrats of these dimensions were randomly placed in eithercontrol plots (with *P.juliflora* present) and restored plots across 18 villages and data was recorded. For biomass analysis, herbs and grasses within each quadrat were clipped, and samples were collected for productivity assessment.

Assessment of Acacia nilotica Population

Despite Banni's grassland ecosystem, Nani Dadhdhar village hosts a thriving patch of the native tree *A. nilotica*. Restoration efforts four years ago aimed to support this tree population. Recently tree population was surveyed, where trees were categorized into three height classes: up to 1 meter, 1-5 meters, and over 5 meters and counted, allowing us to estimate the population structure and growth distribution of *A. nilotica* across height classes (This native tree counting drive was conducted with the assistance of local youth from the village. Fifteen young participants were involved, each assigned a specific paint color (three different colors) corresponding to particular tree height groups. They counted and marked each tree to ensure no duplication occurred during the survey).

Effect Assessment of Biochar Inoculation on Grassland Productivity

In the restored plot of Dehiya village, a biochar inoculation experiment was conducted to evaluate its effect on grassland productivity. Biochar mixed with soil was applied in 2 x 2 m fenced cages to prevent grazing interference. Two types of cages were set up: one with biochar-treated soil with dosage of 4 kg/ 2 x 2 m and another as a control (untreated soil). Each cage type was replicated six times. After 45 days, plants grown within the cages were harvested and analyzed to assess biomass productivity.

Results

Table 1 presents the ecological parameters assessed across 18 villages, comparing restored plots to control plots. The restoration efforts demonstrated significant improvements in vegetation cover, with *Gorewali* village achieving an impressive 91% cover, followed closely by *Mithadi*village at 88.4%. Species diversity also benefited from restoration, with *Dedhiya* village exhibiting a remarkable increase of up to 12 times in species diversity. The removal ofinvasive specieshas reduced competition for resources among native flora, resulting in biomass production of native grasses and herbs increases of up to 3.4 times in restored plots compared to the invaded areas of *Adhiyang* and *Bhagadiya*.

The eradication of *P.juliflora* in Nani Dadhdhar village has facilitated the growth of *A. nilotica*, leading to a fourfold increase in its population over four years. The survey recorded 2,029, 1,665, and 711 individuals in height categories of up to 1 meter, 1-5 meters, and over 5 meters, respectively. Trees exceeding 5 meters are estimated to be five to six years old, while those under 1 meter are recent recruits established within the last year and a half. This highlights the positive impact of restoration efforts.

Innovative approaches have further strengthened these restoration models. In *Dedhiya* village, biochar produced from *P.juliflora* in Kon-Tiki kilns was applied to soil in experimental plots prior to the monsoon season. Post-monsoon data revealed biomass production of 164 g and 88 g per m^2 in treated and untreated plots, respectively, indicating a 1.87-fold increase in the yield of grasses and herbs in the biochar-treated areas compared to untreated ones.

Discussion

The restoration of the Banni Grassland underscores the significant ecological and socio-economic benefits of controlling *P.juliflora* invasion. Our findings demonstrate substantial gains in vegetation cover, species diversity, and biomass productivity in restored plots, indicating the success of community-led restoration efforts. The removal of *P. juliflora* reduces resource competition, enabling native species to thrive, as evidenced by the fourfold increase in *A. nilotica* populations in Nani Dadhdhar village. This native resurgence highlights the effectiveness of the restoration and suggests positive outcomes for ecosystem functionality and biodiversity.

Meta-analyses of biochar applications reveal significant biomass increases with 41% in woody plants and 10–30% in agricultural crops (Thomas and Gale 2015). Our findings also show biochar's effectiveness, boosting biomass yield by 1.87 times in treated plots and enhancing soil fertility for long-term carbon sequestration. This supports plant growth and aligns with global climate goals, promoting sustainable ecosystem restoration funded by the carbon market.

Our study aligns with existing research, which highlights the broader advantages of invasive species management for ecosystem services, such as clean air and water, and benefits to local livelihoods through resources like grazing (Medvecká et al. 2018; Vilà et al. 2011). The involvement of local communities, especially the Maldharis, is essential, as their knowledge complements scientific strategies and fosters sustainable land management supported by literature, showing that community engagement is pivotal for long-term conservation success (Berkes 2004; Agrawal and Gibson 1999).

Future research should focus on long-term monitoring to assess ecosystem recovery, socio-economic impacts, and the risk of re-invasion. Policymakers should consider incorporating community-led restoration models into broader conservation strategies, promoting biodiversity conservation and supporting local economies. The successful restoration of the Banni Grassland demonstrates the potential of integrated management approaches to rehabilitate degraded ecosystems and secure community support for sustainable development.

Conclusion

This study underscores the successful community-driven restoration of the Banni Grassland, highlighting significant ecological improvements following the removal of an invasive species *P.juliflora*. Restoration efforts have notably increased vegetation cover, species diversity, and biomass productivity, with a strong resurgence of native tree*A. nilotica*. The active participation of Maldhari communities has been crucial, leveraging their traditional knowledge for sustainable land management. Biochar application in grassland has further enhanced soil fertility and long-term carbon sequestration. Continuous monitoring and management by the community is essential to prevent re-invasion and ensure habitat sustainability. This model illustrates the potential of integrated restoration strategies, driven by local communities and supported by carbon credits, to enhance ecosystem resilience and support local livelihoods.

Evaluation of treatment type and grass species for restoring Artemisia-dominated rangelands in the Great Basin of North America

Thacker, E[1]; Bryan, R[2]; Clifford, A[3]

[1] Utah State University, Logan NU, USA; [2] Western-enviro Vernal, UT, USA [3]Cirus Ecological Solutions Logan, UT, USA

Key words: sagebrush; restoration; grasses; rangeland; wildfire

Abstract

Decades of research and management activities have focused on restoring Artemisia-dominated rangelands. Future climate projections suggest that drought and wildfire may become more frequent; therefore, being able to restore rangelands following these events is critical for the future maintenance of ecological services. We initiated two studies, one focusing on assessing treatment types (chaining, drill seeding, and aerial seeding) for post-fire restoration, and in a separate study, we evaluated 52 grass species that were opportunistically exposed to drought and fire over seven years to determine which groups of species are resilient to these drivers. The treatment analysis relied on the Rangeland Analysis Platform tool to evaluate how burned areas responded to treatment by examining the cover estimates of functional groups before and after treatment. The functional groups varied significantly in their responses to different treatments. Overall, we discovered mild successes in perennial grass and forb establishment. Conversely, postfire invasive annual forbs and grasses were more dependent on pretreatment conditions than treatment type. We also concluded that restoration success may depend more on pretreatment conditions than treatment type. Our results also demonstrate that a wide array of plant materials can establish, persist, and resist cheatgrass (B. tectorum) invasion through drought and fire and that species selection for restoration should be based on their possession of functional traits that can meet management objectives. Thus, in the future, managers attempting rangeland restoration must carefully consider pretreatment conditions and select species for restoration based on functional traits that ensure the resilience of rangelands.

Introduction

Rangelands in the Great Basin of Western North America are subjected to frequent drought and wildfire at sporadic intervals. Sagebrush rangelands are being invaded by invasive annual grasses such as Bromus tectorum, which alter ecological processes and fire regimes (Mack 1981; Bradley et al. 2018; Young & Clements 2009; Davies 2011). Land managers are tasked with trying to restore these altered rangelands. Therefore, we first determined the outcomes of post-fire rehabilitation efforts across Northwestern Utah; to do this, we wanted to understand if post-fire treatments decreased annual forb and grass cover while increasing perennial grass and forbs; and shrubs. As range managers look forward to the future, they must grapple with the effects of climate change in altered ecosystems while maintaining ecological services provided by rangelands, such as livestock grazing, wildlife habitat, biodiversity, and carbon sequestration. Therefore, rangeland managers must choose the proper restoration species to rehabilitate degraded ecosystems, which is an essential part of the restoration process (Asay et al. 2003; Booth and Jones 2001). Land managers and restoration practitioners face difficult decisions when deciding which perennial grasses to plant for restoration. However, little research has been done on the ability of individual species and varieties of perennial grass species to survive and regenerate after fire and drought stress. Our study sought to shed light on which species and varieties are most effective at coping with wildfire, drought, and cheatgrass.

Methods

The fire restoration study examines the post-fire treatment of fires from 1999-2019. Treatment scenario groups were used to lump similar treatments into like categories. Treatment scenario groups describe the different combinations of treatment that occurred in the study area. For example, a treatment scenario is an area that received a single aerial seeding and chaining event following a wildfire.

We used the Rangeland Analysis Platform (RAP; Allred et al. 2021) to quantify vegetation before the wildfire (3 years) and every subsequent year after the wildfire post-wildfire mitigation. We used functional when analyzing vegetation cover. The groups included annual forbs and grasses, perennial forbs and grasses, and shrubs (Bryan 2022). We performed an effect size analysis to compare treatment outcomes across treatment types across time to determine changes in vegetation post-wildfire management.

When evaluating restoration species to determine which species and varieties best persist through drought, wildfire, and cheatgrass invasion, we examined the responses of 52 species and varieties. The plant materials used in this study are listed in Table 1. The study was conducted on an agricultural research farm operated by the Utah Division of Wildlife Resources' Great Basin Research Center in Ephraim, UT, USA. Seedling establishment was quantified by estimating frequency in June 2016 using a frequency grid (Vogel and Masters 2001). In the fall of 2020, an experimental burn on the research plots unintentionally burned the entire site. Persistence was measured in June 2021, and we collected the frequency of cheatgrass, annual grasses, and weeds. Our study assessed the ability of the various species and varieties to establish, persist, and resist cheatgrass invasion through drought and fire. To determine which species or variety resisted invasion and persisted through drought and grazing, we used a dimensional scaling (NMS) analysis to cluster the species that performed the best (Clifford 2022).

Results

The overall effect of the functional groups on treatments showed modest increases in annual grasses and forbs 0.31 (0.14,0.48), and perennial grass and fobs had a slightly more significant effect 0.46 (0.37,0.054). At the same time, shrubs declined -0.17 (-0.27,0.06) due to wildfires even after post-fire management (Bryan 2022). The method of postfire (aerial seeding, drill seeding, and chaining) mitigation showed little consistency in our analysis.

The NMS ordination of the responses of the 52 varieties of restoration grasses showed that varieties were clustered into four discrete groups using a hierarchical cluster analysis, accounting for 59.4% of the information Table 1.). Pairwise comparisons for the interactions showed that group 2 had a significantly higher frequency of restoration species and lower frequency of cheatgrass than all other groups for all years studied (Table 1; Clifford 2022).

Discussion

The outcomes from the different post-fire restoration methods used in West Box Elder County are variable. Our analysis did not prove that one treatment method was superior in all cases. Mild successes in perennial establishment occurred across all treatment types. Annual cover increased and appeared to depend more on pretreatment levels than treatment type. The results also indicate that the needed recovery time after fire may be longer than 15 years, especially when evaluating shrub response to post-fire treatments. The analysis reemphasized that annual, perennial, and shrub responses to treatments are highly variable and depend on many factors besides the treatment method. Factors influencing treatment success include the site's pretreatment abiotic and biotic conditions, including plant composition, soil type, health, aspect, and elevation (Boyd et al. 2012, Knutson 2014, Miller 2012). Considering these factors and acknowledging variations in treatment outcomes emphasizes the importance of avoiding extrapolating results from one successful treatment to other potential treatments. The success or failures of a handful of individual projects should not become the basis for future management decisions. Instead, examining several occurrences of a particular treatment can provide a more complete picture of the range of expected outcomes. Our research can be used to inform managers better when developing strategies for future treatments, especially when considering the treatment type that should be used and the various abiotic and biotic conditions of the proposed restoration sites. Planning restoration methods to suit individual projects best will require high levels of collaboration between stakeholders to decide where and how best treatment practices should occur.

We attempted to determine which varieties of restoration grasses could establish, persist, and resist cheatgrass over seven years, including multiple years of below-average precipitation and a fire that burned all treatments in 2020. Climate projections show increasing temperatures and periods of drought throughout the Great Basin in the future (Snyder et al. 2019). Similarly, the continued spread and dominance of cheatgrass will increase wildfire across the Great Basin (DiTomaso et al. 2010). Therefore, finding species and varieties that can establish and persist through drought and fire is critical for maintaining intact stands of perennial grasses and resisting invasion by cheatgrass. Our results suggest that the varieties found in group 2 possess some functional traits that enable them to establish, persist, and resist cheatgrass through drought and fire. Given the diversity in species found in group 2 and the variation across varieties of the same species, we recommend that restoration seed selection be based on the functional traits that allow varieties to establish, persist, and resist cheatgrass through drought and fire.

In the future, range managers must maintain rangeland integrity and function. Our study shows that our best efforts can return rangelands to the pre-disturbance condition. If the rangelands have already lost some function before the disturbance, it becomes the new ceiling for ecological conditions. Future rehabilitation will require careful study of the disturbed sites, and cautious evaluation of the plant species chosen for restoration efforts focused on plant functional traits rather than classifications. Rehabilitating rangelands needs to be more of an adaptive process rather than a recipe to ensure we maintain rangeland integrity,

Char height on fence posts as a practical proxy of flame length and fire intensity in grass fires

Danckwerts, MJ[1,2]; Midgley, GF[3]; Beckett, H[3]

[1] Global Change Biology Group, Department of Botany and Zoology, Stellenbosch University, Stellenbosch, South Africa; [2] M.J. Danckwerts Consulting (Pty) Ltd., Adelaide, South Africa; [3] School for Climate Studies, Stellenbosch University, Stellenbosch, South Africa.

Key words: Wildfires; Fireline intensity; South Africa; Grasslands; Fire behaviour

Abstract

Wildfire behavioural parameters are assessed through metrics that can be expensive to measure with sufficient resolution in real time, such as rate of spread, intensity, and severity. Wildfire researchers and practitioners are thus in need of accurate, cost-effective, and user-friendly methods to estimate these metrics. Flame length is one such established proxy metric widely used to estimate fireline intensity, however direct measurements can be challenging. Char height on tree trunks has been proposed as a cost-effective proxy for flame length, and thus fireline intensity, but its accuracy has not been widely tested.

Based on research by Williams et al. (1998) in Australian eucalypt savannas, this study explores the relationship between char height on fence posts and flame length in a South African grassland fire context. Data were collected at 143 monitoring plots within 7 landscape-scale prescribed fires in Eastern Cape mesic montane grassland. Flame length was recorded in real time using installed wooden fence posts of known height as visual aids, and grouped by fire type (head, back, flank). Char height measurements were later recorded from the soil surface to the maximum height of charring on the fence posts.

Across all fire types, the flame length (y) could be accurately estimated from char height ($y = 1.42x + 0.971$; $R^2 = 0.609$), but there were some differences between fire types. For head fires, char height yielded a strong rank correlation ($r_{s(37)} = 0.807$; $p < 0.001$) with flame length, while char height in flank fires had a moderate rank correlation ($r_{s(25)} = 0.532$; $p < 0.005$). Back fires did not show a significant rank correlation between char height and flame length ($r_{s(15)} < 0.15$; $p > 0.567$). Pragmatically, the simple doubling of *post-hoc* char height serves as a direct estimate of flame length.

This research confirms that in mesic montane grasslands of southern Africa, char height is a reliable *post-hoc* indicator of flame length, particularly for head fires, and could have wide practical application as a rule-of-thumb in these grassland ecosystems.

Introduction
Wildfires are a common occurrence in many landscapes and present significant challenges for fire management in rural or remote areas. Understanding fire behaviour, particularly the intensity of fires, is critical for both prediction and post-fire analysis, which contributes, *inter alia*, to planning suppression efforts, and protecting human and ecological assets.

Wildfire behaviour is typically assessed through various parameters, such as rate of spread, intensity, and severity, however, these metrics can be challenging to measure. Among these, measuring fire intensity directly can be a particularly tedious and time-consuming process, and as a result, empirical evaluations of intensity are not often conducted (Van Wilgen 1986; Schwilk 2003; Scott et al. 2014). There is, therefore, a demand from both researchers and practitioners for accurate, cost-effective, and user-friendly methods for measuring fire intensity in the field.

It has long been established that direct correlations exist between flame length and fireline intensity (Byram 1959; Brown & Davis 1973; Rothermel & Deeming 1980; Van Wilgen et. al. 1985; Van Wilgen 1986; Cochrane & Ryan 2009; Scott et. al. 2014), however, direct measurements of flame length during fire progression can be challenging and impractical due to the dynamic nature of fires.

In response, charring and leaf scorch height on trees have been proposed as useful and practical post-fire proxies of flame length and thus fire intensity (Van Wagner 1973; Williams 1998), offering an accessible alternative for both researchers and land managers (Williams et. al. 2003). Based on data collected from a series of fire experiments conducted between 1990 and 1994 in eucalypt savannas at the Kapalga research site, Australia, Williams et. al. (1998) showed that the height of char and scorch on savanna trees were both associated with fireline intensity. These relationships between flame length, height of char (and scorch), and fireline intensity have been corroborated in literature (Byram 1959; Van Wilgen et. al. 1985; Van Wilgen 1986; Cochrane & Ryan 2009), but their accuracy and applicability have not been widely tested in different systems.

Previous research has explored the relationship between fire intensity and various fuel and weather conditions, however, little attention has been given to the potential for physical markers, like char height, to provide post-fire, accessible data for fire behaviour assessment. This study explores the relationship between char height on fence posts and flame length in mesic montane grasslands of the Eastern Cape, South Africa.

Fence posts are commonly found in many rural and wildland-urban interface areas, where they could provide a simple and immediate reference for fire behaviour. By examining char height in relation to flame length measurements under different fire conditions, we aimed to establish a field-based method for estimating fire intensity that could complement traditional fire behaviour prediction models.

Methods
The study was conducted on seven landscape-scale controlled burn sites across the Eastern Cape province of South Africa from early September to mid November 2019. These burn sites were comprised mostly of mesic montane grassland and occasional savanna vegetation. The prescribed burns were conducted as planned management burns to remove moribund and unpalatable material, as well as control woody encroachment (Figure 1).

Figure 1. Example of prescribed management burn, conducted for the purposes of removing cured, unpalatable material.

Dry, untreated wooden fence posts (>3m) were planted prior to burn treatments, at 143 monitoring plots situated within the seven landscape-scale burn sites.

Flame length and fire spread type (head, back, or flank) were recorded observationally at each monitoring plot (n = 143). Objects of known height (planted fence posts) in the fire's path, were used as visual aids when measuring flame length (Van Wilgen 1986). Weather conditions (wind speed and direction, relative humidity, and temperature) were recorded at one-minute intervals, in the vicinity of the fire, using a portable weather station (Campbell Scientific; R.M. Young Company). Fuel load and degree of curing were also recorded.

Where charring occurred, it was recorded on the planted fence posts. Height of char was measured in centimetres, from the base of the post, at the soil surface, to the maximum height of charring, following the methods proposed by Williams et. al. (1998) (Figure 2).

The entire dataset met the assumptions for normality, so linear regression analysis was used to test the relationship between char height and double (2x) char height (dependent variables) and real-time flame length (independent variable). For the individual fire types, non-parametric tests were required, so Spearman's rank correlation was performed to validate associations between char height and flame length.

Results

The approximate mean weather conditions prevailing for the duration of each prescribed burn are summarised in Table 1. In terms of the formal Fire Danger Rating System (Lowveld) for the Republic of South Africa (Government Gazette Notice 1099 of 2013), weather conditions recorded for each monitoring plot, translate to Fire Danger Indices (FDIs) ranging between 30 and 72, in the mid "Green" and upper "Orange" zones, respectively. The total mean FDI for all monitoring plots was 43.44 ± 6.69. The total mean fuel load and curing percentage for all monitoring plots were 6.76 ± 1.72 ton/ha and 72.6% ± 6.97%, respectively.

Figure 2. Example of charring on pre-planted fence post. Charring occurred higher on the leeward side of the pole.

Table 3: Summary of approximate mean weather conditions and Lowveld Fire Danger Index (FDI) scores with standard deviations (SD), for duration of prescribed burns at each site in the Eastern Cape, South Africa. Lowveld FDI scores were calculated according to the methods stipulated in Government Gazette Notice 1099 of 2013 for the Republic of South Africa.

Site	Date	Air Temperature ± SD (ºC)	Wind Speed (km/h)	Relative Humidity ± SD (%)	Lowveld FDI Score ± SD
1	11 Sept 2019	24 ± 0.78	4–14	60 ± 0.47	39 ± 2.7
2	17 Sept 2019	23 ± 0.71	7–14	57 ± 0.23	46 ± 3.5
3	15 Oct 2019	17 ± 1.34	2–15	55 ± 0.41	37 ± 2.7
4	16 Oct 2019	26 ± 1.2	5–14	55 ± 0.3	44 ± 3.4
5	4 Nov 2019	19 ± 0.39	8–16	49 ± 0.21	42 ± 1.1
6	8 Nov 2019	18 ± 0.54	7–21	49 ± 0.54	40 ± 2.5
7	12 Nov 2019	24 ± 0.89	13–42	51 ± 0.25	54 ± 7.2

Charring occurred on 83 of the 143 planted fence posts (~58%). Across all fire types, the flame length (y) could be accurately predicted from char height ($y = 1.42x + 0.971$; adjusted $R^2 = 0.609$), but there were differences between fire types (Figure 3). In head fires, char height showed a strong positive correlation ($r_{s(37)} = 0.807$; $P < 0.001$) with flame length. Char height in flank fires had a moderate correlation ($r_{s(25)} = 0.532$; $p < 0.005$). In contrast, char height from back fires did not show significant correlation with flame length ($r_{s(15)} < 0.15$; $p > 0.567$).

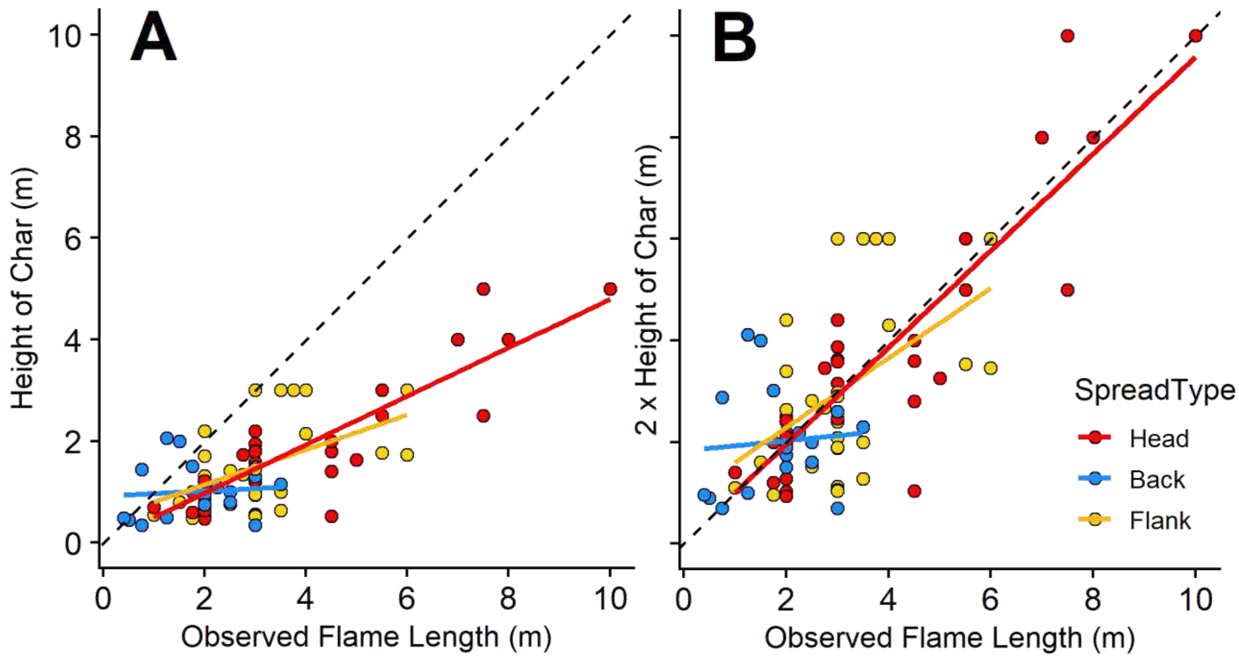

Figure 3. Observed flame lengths versus height of charring (A) & double (2x) the height of charring (B) measured on pre-planted fence posts, separated by fire spread type (head, back, or flank), for 83 monitoring plots in 7 landscape-scale fires in mesic montane grassland. Dashed lines indicate perfect agreement between observed flame lengths and char height values. Solid lines are linear regressions for each fire spread type (head, back, or flank). The regression for 2x height of charring is presented, given the pragmatic potential of this simple proxy. Linear regression for all observations in scatterplot B: $y = 0.71x + 0.971$; adjusted $R^2 = 0.609$, where y is double (2x) char height and x is the observed flame length.

Discussion and Conclusion

The results reveal a significant correlation between char height and flame length, suggesting that char height can serve as a reliable field-based indicator of fire intensity. Serendipitously, for the pragmatic application of this proxy, doubling the charring height provides a simple direct estimate of flame length in head and flank fires. The repeatability of the proxy across multiple sites and varied weather conditions suggests that the proxy may be applicable across a broad range of grassland wildfire conditions.

Williams et al. (1998) previously identified char height on pole-type fuels as a useful *post-hoc* indicator of flame length in eucalypt savannas at the Kapalga research site in Australia. Our study extends this finding to mesic montane grasslands in the Eastern Cape, South Africa, demonstrating a similar relationship (Figure 3).

It is important to note that approximately 40% of fence posts were not charred, which can be attributed to the absence of fuel within the immediate vicinity of the posts, low fire intensities, or short residence times. When applying char height as a post-fire indicator of flame length or fireline intensity, one should be cognizant of the likelihood of the absence of charring and, where possible, identify the fire type in the area.

Despite this limitation, this simple relationship has wide practical applications in southern Africa and other subtropical grassland and savanna systems. Char height provides a useful rule of thumb as a field-based method for estimating fire intensity without the need for specialized equipment. We conclude that char height on fence posts can serve as an effective *post-hoc* measure of fire behaviour, especially in areas where other fire behaviour metrics are expensive and challenging to obtain.

Mesquite (*Prosopis*) seedling responses to fire and grass production in the southern Great Plains, USA

Ansley, RJ[1]; Zhang, T[2]

[1]Oklahoma State University, Stillwater, OK USA, jim.ansley@okstate.edu; [2]Oklahoma State University, Stillwater, OK USA, tian.zhang@okstate.edu

Key Words: canopy cover; prescribed burning; shrub-grass competition; woody plant encroachment

Abstract

Prescribed fire is an economical land management practice used to mitigate the global increase in woody plant encroachment (WPE) on rangelands. For woody plants that resprout following fire, the seedling stage may be vulnerable to fire. However, we know little about long-term growth of mesquite seedlings that survive fires. We measured seedling survival and post-fire gains in canopy cover of two cohorts (seeds planted in two different years) of honey mesquite (*Prosopis glandulosa*) seedlings in response to winter or summer fires in mixed-grass (~2,000 kg/ha) or tallgrass (~7,000 kg/ha) fuel types in the Southern Great Plains, USA. Post-fire seedling survival was highest to lowest in no fire, winter fire and summer fire, respectively, in both grass types and seedling cohorts. Canopy cover in all fire treatments and both cohorts increased to a greater level in mixed-grass than tallgrass over a 20-year period. Fire treatment had little effect on post-fire canopy cover gains. Rate of cover gain in mixed-grass (3.4 percentage units per year: PU/yr) was greater than a previously reported rate of 2.2 PU/yr for mature mesquite over 20 years at the same site. Lower mesquite seedling growth in tallgrass plots was likely due to a combination of greater pre-fire mortality, greater mortality from more intense fires, and greater post-fire grass competition for resources. Results suggest that mixed-grass, which is the dominant grass type in the region, may not be sufficiently competitive to slow the rate of mesquite seedling growth even after summer fire.

Introduction

Fire was an integral part of pre-settlement grasslands and rangelands in the southern Great Plains (SGP), USA and likely suppressed the expansion of woody plants (Briggs et al. 2005, Guyette et al. 2012). After European settlement, many woody species, including the fire-resistant native woody legume, honey mesquite (*Prosopis glandulosa* Torr.), expanded in density and distribution; due in part to the reduction of fire frequency that limited mesquite seedling establishment (Archer et al. 1995, 2017). In addition, cattle consumption and fecal deposition of viable mesquite seeds enhanced distribution (Brown and Archer 1987, Ansley et al. 2017).

Adult mesquite plants resprout following top-kill and very few are root-killed by fire (Ansley et al. 2021). However, seedlings are vulnerable to fire for a brief period of time (Wright et al. 1976). Productive stands of grass can reduce growth rate of young mesquite (Brown and Archer 1989, Van Auken and Bush 1990). However, we know little about long-term growth of mesquite seedlings that survive fires. Ansley et al. (2015) quantified mortality of mesquite seedlings when burned with summer or winter fires in mixed-grass and tallgrass fuel types and found that summer fires in both grass types and winter fires in tallgrass increased seedling mortality compared to no fire. Our objective here was to quantify long-term (20-year) growth of those seedlings that survived the fire treatments.

Methods

We conducted the study within a fenced pasture on a private ranch in north Texas. We included two patches of native mixed-grass and two patches of tallgrass. Each patch was 2.7 ha in size. The mixed-grass patches were mostly comprised of Texas wintergrass (*Nassella leucotricha*) and buffalograss (*Buchloe dactyloides*), with a small proportion of C_4 mid-grasses such as sideoats grama (*Bouteloua curtipendula*) (average standing biomass ~2,000 kg/ha). The tallgrass patches consisted of introduced kleingrass (*Panicum coloratum*) planted in the 1970's (~7,000 kg/ha). All grass patches occurred on the same Tillman clay loan soil type (Ansley et al. 2015).

We hand-planted 924 mesquite seeds in each of twelve 0.125 ha plots in one mixed-grass and one tallgrass patch in April 1997 (hereafter Cohort-97), and repeated the procedure in the second of each patch in April 1998 (Cohort-98). We established three treatments (no fire, winter fire and summer fire) in each grass patch with four replicate plots per treatment. Seedlings were 17 months old during summer fires and 10 (Cohort-97) or 22 (Cohort-98) months old during winter fires. We did not apply winter fire to 10-month-old Cohort-98 seedlings due to drought and insufficient grass fuel and instead winter burned the following year. No further fires occurred after the year 2000. We excluded livestock grazing during the study period. More details are in Ansley et al. (2015).

We obtained aerial images of the plots in the years 2000, 2002, 2012 and 2019 that provided excellent contrast between mesquite and grass cover and visually estimated mesquite canopy cover in each plot each year. We analyzed canopy cover responses to fire treatments within each grass patch using the PROC MIXED procedure in SAS with fire treatment and time post-fire as main effects with four replicate plots per treatment (SAS 2013). We separated means using LSD at $P \leq 0.05$.

Results

Percent seedling survival and number of live seedlings per plot at 1 year after all fire treatments were highest in no fire, mixed-grass for both cohorts and lowest in the summer fire treatment within each cohort and grass type (Table 1).

Mesquite canopy cover of Cohort-97 in mixed-grass increased at similar rates in the three treatments and reached 65-75% by 2019 (Figure 1A). Cohort-97 cover in tallgrass increased at similar rates among the three treatments but only reached 25-33% canopy cover by 2019. Similar responses were found with Cohort-98 seedlings except that canopy cover gain in mixed-grass was slightly lower in the summer fire than the winter fire treatment by 2019, with no fire intermediate (Figure 1B).

Table 1. Mesquite seedling cohort, land patch, grass type, fire treatment season and year, seedling age at the time of fire treatment, and average percent seedling survival and number of live seedlings the first growing season after all fires were completed.

Seedling Cohort	Land Patch	Grass Type	Fire Season and Year[1]	Age when Burned (Months)	Post-fire Percent Seedling Survival	Live Seedlings Per Plot Post-Fire
Cohort-97	1	Mixed	No Fire	---	7.2	67
Cohort-97	1	Mixed	w-1998	10	5.5	51
Cohort-97	1	Mixed	s-1998	17	2.0	19

Cohort-98	4	Tallgrass	w-2000	22	3.8	35

1/ w = winter fire; s = summer fire

Discussion

Even though the fire treatments reduced the starting number of live mesquite seedlings compared to no fire, this had minimal effect on post-fire gains in canopy cover. The only exception occurred in the Cohort-98 mixed-grass patch where summer fire reduced canopy cover gain over time compared to winter fire. A spike in growth in all treatments between 2000 and 2002 was more pronounced with Cohort-97 than the 1-year younger Cohort-98 seedlings and this may have affected differences seen in 2019. Growing season precipitation was well above normal in 2002 (Ansley et al. 2021) and Cohort-97, being 1 year older, may have been able to exploit the enhanced soil moisture across all fire treatments more effectively than Cohort-98.

Largest gains in canopy cover came from Cohort-97 in the mixed-grass type. Averaged over the 3 treatments, canopy cover reached 68% over 20 years, or a rate of cover increase of 3.4 percentage units per year: PU/yr). Rate of gain for Cohort-98 in mixed-grass was similar to Cohort-97; 60% over 19 years (2000 to 2019), or 3.2 PU/yr. These rates of cover gain are greater than a previously reported rate of 2.2 PU/yr for mature mesquite over 20 years at the same site (Ansley et al. 2001). A lower rate of cover gain with mature mesquite suggests that the growth rate slows with age, but results from the current study show this decline in growth rate may not occur within the first 20 years of growth.

Slower mesquite growth in tallgrass was likely due to a combination of greater pre-fire seedling mortality due to tall grass competition (Van Auken and Bush 1990), greater mortality from more intense fires (Ansley et al. 2015), and greater post-fire grass competition for resources. Results suggest that mixed-grass stands that have degraded to lower producing species such as Texas wintergrass and buffalograss may not be sufficiently competitive to slow the rate of mesquite seedling growth even after summer fire and (in this study) under no livestock grazing pressure. However, results from the tallgrass patches suggest that mixed-grass stands that have a greater proportion of more productive C_4 mid-grass species than found in our mixed-grass stands might provide greater long-term resistance to mesquite seedling recruitment and growth.

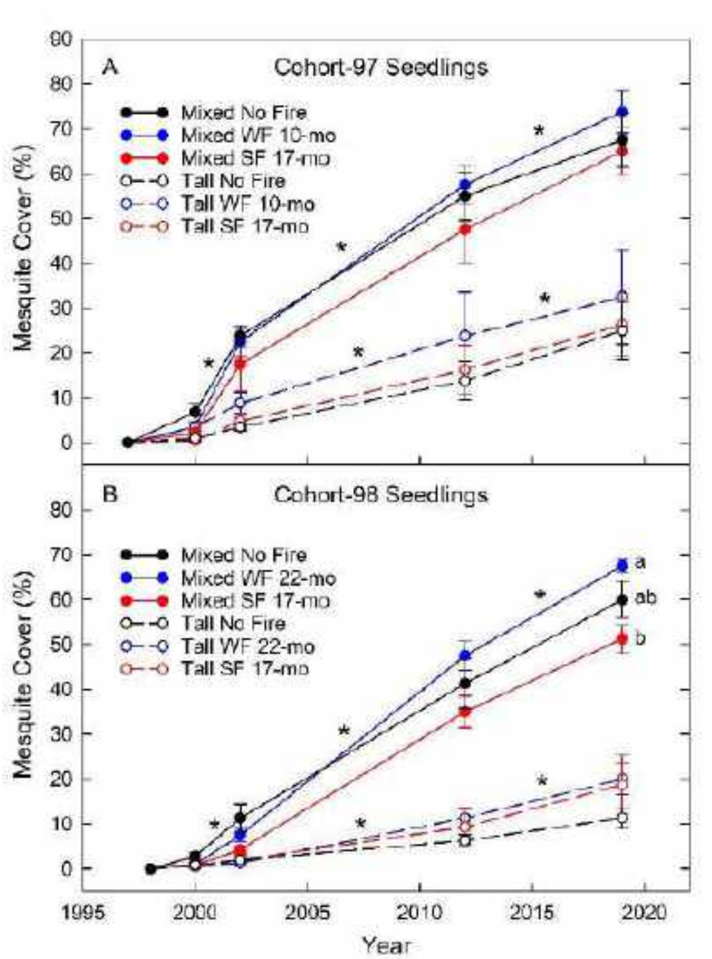

Figure 1. Change in mesquite cover from seedlings of Cohort-97 (A) or Cohort-98 (B) in mixed-grass (Mixed) and tallgrass (Tall) when exposed to no fire, winter fire (WF) at 10-months (Cohort-97) or 22-months (Cohort-98) of age, or summer fire (SF) at 17 months of age. Vertical lines are ±1 standard error. Means with similar letters within each grass type and year are not significantly different ($P \leq 0.05$). An asterisk indicates a significant ($P \leq 0.05$) difference from one time period to the next when averaged over the 3 treatments in each grass type. There were no significant differences among fire treatments within each grass type in any year.

Lessons from a 30 year burning experiment in northern Australian grazed tropical savannas

Cowley, RA[1]; Dyer, RM[2], Hearnden, MH[1]

[1] Department of Agriculture and Fisheries, Northern Territory; [2] Focus Group, Vietnam

Key words: savannas; fire; frequency; season; grazing

Abstract
Like all savannas, the semi-arid tropical savannas of northern Australia have evolved with fire. However, the presence of fire in the landscape has changed significantly with the reduction of traditional Aboriginal burning and increased control of wildfires. The incidence of fire is now greatly reduced on most land used for grazing by livestock. To address concerns about how reduced fire might influence vegetation structure and productivity, a long term fire experiment at Victoria River Research Station, also known as Kidman Springs, 400km south of Darwin in the Northern Territory began in 1993. Treatments (each with two replicates) include: season of burning (early in the dry season in June, or late in the dry season in October); fire interval (two, four and six–yearly); and four unburnt controls. The treatments are applied on a calcarosol Eucalypt woodland and on a vertosol grassland. The three decades have seen unanticipated climate driven shifts in pasture composition, and increases in woody cover in all but the most intense fire regimes and subsequent declines during a recent run of drier years. Fire prevented woody cover increases since 2009 on the grassland. On the woodland woody cover fluctuated more through time, but was at similar or lower levels in 2023 to 2009, even on unburnt controls due to drought related dieback. The herbaceous understorey is resilient to fire with perennial grasses relatively unaffected and greater diversity post fire due to increases in ephemerals. Understorey herbaceous dry matter was only negatively correlated with woody cover on the grassland. Hence, concerns about increasing woody cover leading to reduced pasture productivity may be unfounded in the woodland, but without fire native woody encroachment into the productive grasslands can change the structure from a grassland to an open woodland and may negatively impact carrying capacity for livestock. Since 2013 wet season spelling has been implemented post fire. This has improved the pasture composition on the grassland and suggests the minimum required fire interval for effective management of woody cover could be increased from four to six yearly, provided fuel loads are adequate for an effective fire. Other research at the site has investigated biocrust, mite, faunal and above and below ground carbon storage response to long term fire regimes. This is the only long term grazed fire experiment in Australia's tropical savannas. It continues to provide new insights and is open to the global research community.

Introduction
Australian savannas are well adapted to fire but not grazing, having evolved with regular fire, but only very low levels of native herbivore pressure. The incidence of fire had greatly declined on grazed pastoral land

compared to under Indigenous ownership and management due to cessation of traditional burning, reduced fuel loads due to grazing by introduced herbivores, and deliberate exclusion of fire by pastoralists to protect infrastructure and forage for livestock. There was evidence of woody encroachment into the most productive vertosol grasslands and concerns that continued lack of fire would lead to further woody encroachment and loss of carrying capacity for livestock due to competition between the woody and pasture layers. The Kidman Springs fire experiment started in 1993 and for thirty years has provided insights into the long-term impacts of regular fire regimes, and how fire can be managed in the grazed context. Combined with insights from long term grazing exclosures at the site (Bastin et al. 2003) the experiment can provide insights into the broader potential drivers of vegetation change (fire, rainfall, grazing, CO_2) in the region, answering questions that were not anticipated at its inception. This review aims to update the findings emerging from the site in the context of its beginnings.

Methods

The fire experiment is on Victoria River Research Station (VRRS) 400km south of Darwin in the Northern Territory on a calcarosol Eucalypt woodland and a vertosol grassland. 90% of the rain falls during the 'wet season' between November and March with distinct seasonally dry periods between June and October. On each site the following fire treatments (each with two replicates) include: season of burning (E-early in the dry season in June, or L-late in the dry season in October); fire interval (two, four and six–yearly); and four unburnt controls to give 16 160m x 160m plots separated by firebreaks. See Cowley et al. (2014) for full experimental design and methods. Since 2013, all plots have been rested from grazing post fire after the late dry season fires until the end of the following wet season, effectively providing a wet season spell every second year. In 2019 all two, four and six–yearly burn treatments were implemented. Tree basal area (TBA) and canopy cover were assessed using a bitterlich gauge at 19m intervals along 4 x 100m transects per 2.4 ha plot in 2009, 2017, 2019, 2021 and 2023. Total standing dry matter and species composition of the herbaceous understorey has been assessed annually from 1994 to 2001 and every two years thereafter. A linear mixed effects model in R was used to test the effect of burn interval and season of fire and for significant differences between burn treatments within year, and between years within treatments. The experiment-wise error rate was set at 0.05.

Results

The fire experiment began after an extended dry period with six of the seven years between 1986 and 1992 with below median rainfall (762mm). More recently four of the five years between 2018 and 2022 had below median rainfall (Fig. 1).

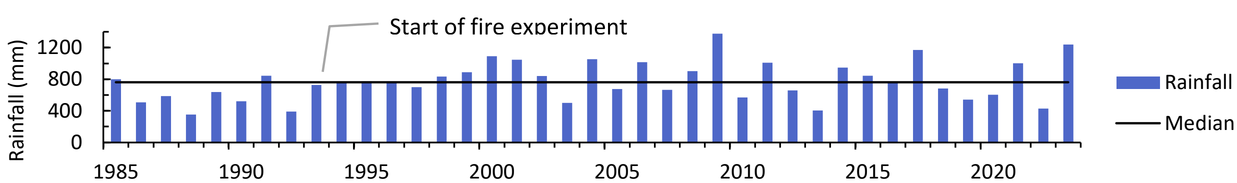

Figure 1. July to June rainfall and median rainfall (1970 - 2024) at VRRS

Pasture composition shifts in unburnt plots

Pasture composition varied through time even on unburnt controls, signalling grazing and rainfall responses. On the grassland *Iseilema* spp. declined from 19% in 1994 to 2% in 2023, while *Ophiurus exaltatus* increased from 0% to an average 18% of total yield since 2013 on the grassland control plots (Fig. 2). The proportion of *Aristida latifolia* increased at the expense of *Chrysopogon fallax* between 2003 and

2013 until the introduction of wet season spelling post burns. On the woodland the pasture shifted from arid shortgrass dominated to *Heteropogon contortus* dominated by 2001, although this subsequently declined following dry years between 2019 and 2021 (Fig. 2).

Woody cover

TBA significantly varied with year and burn interval on both the grassland (Fig. 3a) and woodland (Fig. 3b), while late dry season fires had significantly lower TBA than unburnt on the woodland, but not the grassland. The impact of 15 years of fire treatments had already influenced TBA when it was first measured in 2009, although differences were not significant. However, since then woody cover has further diverged between fire treatments, particularly on the grassland (Fig. 3a). TBA in 2023 on unburnt grassland plots was more than double 2009 levels, while TBA on the more severe fire regimes, early or late burnt every two or four years has stayed relatively stable since 2009. Late 2 had significantly lower TBA than unburnt in 2019 and 2023, and late 6 was lower than unburnt in 2023. On the woodland TBA peaked in 2019, except for the two most severe burn treatments late 2 and 4 yearly which did not vary through time. On the other woodland treatments TBA declined more with the dry years between 2019 and 2021 than on the grassland. Although by 2023 TBA was often comparable with levels in 2009, treatments had diverged enough that the unburnt woodland plots had higher TBA than all the late burnt plots and the 2 yearly early burnt treatment. The late 6 yearly burnt treatment went from having similar TBA to all other treatments in 2009 to having the lowest TBA by 2023.

In contrast to TBA, canopy cover varied significantly with treatment in all years on both the grassland and woodland. All late burnt plots and early 2 (except for the woodland in 2009) always had lower canopy cover than the unburnt plots in the woodland and grassland (Fig. 3c and 3d). Canopy cover was relatively stable on the grassland through time, except on the unburnt plots where it increased after 2009, while on the most severe burn treatment (late 2 yearly) canopy cover was lowest in 2023. Canopy cover peaked on the woodland in 2019 and was lowest in 2021.

Discussion

Cowley et al. (2014) hypothesized that the shift in composition of the woodland from arid short grass to *Heterogon contortus* was likely a response to multidecadal shifts in rainfall from drier prior to the fire experiment to wetter through the first two decades of the fire experiment. Similar increases had also been observed in grazed and ungrazed areas on the research station (Bastin et al. 2003). The subsequent decline in *H. contortus* during the recent drier years supports this. Similarly on the grassland, the replacement of the more arid adapted *Iseilema* spp with *Ophiurus exaltatus* which prefers damp conditions may also be in response to long term fluctuations in rainfall. A study of the full vegetation composition and diversity at the site in 2016 found the perennial grasses were unaffected by fire treatment, and vegetation diversity increased post fire with flushes in ephemerals (Lebbink et al. 2018).

Post fire spelling was introduced by fencing the fire experimental plots from the broader paddock in October 2013 to prevent high post fire grazing on the fire site which was contributing to a decline in pasture condition on more frequently burnt plots, particularly the early burnt plots (Cowley et al. 2014). Wet season spelling of the fire experimental plots for around six months every two years effectively reduces the average stocking rate by one quarter, compared to if continuously grazed at the same stocking rate. It also allows palatable species to establish and recover over the wet season in the absence of grazing. Within two years of wet season spelling, *Chrysopogon fallax* had recovered and *Aristida latifolia* declined to levels at the start of the experiment, although the recovery of *Dichanthium fecundum* has been much slower and has still not reached the same proportions as it was at the beginning the study on either soil type.

The impact of fire treatments on the woodland woody cover has also shifted since the introduction of post burning spelling. Before 2013 the 6 yearly and early burnt plots tended to have higher woody cover and lower fuel loads driving less effective fires. Cowley et al. (2014) concluded that fires need to be 4 yearly to manage woody cover. However, since 2013 even in dry years higher yields and more effective fires have contributed to declines in woody cover, particularly on the woodland 6 yearly late burnt plots. This suggests that provided fuel loads are suitable for effective fires, six yearly late fire may be sufficient to the manage the tree-grass balance on the woodland. On the grassland early and late 4 yearly fires were equally effective.

Although grassland woody plants were observed to be almost completely defoliated at times during the dry years, as of 2023 they had recovered to at least 2019 levels. Woody cover has remained relatively unchanged on the burnt grassland treatments, but may still be increasing on unburnt sites. This contrasts with the woodland site where declines in both TBA and canopy cover were greater and no treatments had recovered to 2019 levels by 2023. Following three dry years between 2018 and 2020 the combined impact of fire and dry years lead to the lowest canopy cover observed for the late and early 2 burn woodland treatments. Changes in canopy cover are more responsive to fluctuations in soil water deficits than tree basal area, because many of these species are semi-deciduous and regularly shed leaves in the dry season each year. Fire is more likely to cause topkill than mortality of these fire adapted species (Dyer 2001), which are exceptional resprouters. Loss of tree basal area represents woody plant death, whereas canopy cover can fluctuate rapidly without tree death. On the grassland burnt plots there are many small supressed shrubs of *Terminlia volucrens* and *Bauhinia lysiphyllum* which are vulnerable to top kill with fire. On the unburnt plots without regular fire, they have grown to trees > 2m in height, and exert competition with the understorey pasture layer (Cowley et al. 2021). In contrast there was less evidence of competition between the pasture and woody layers on the woodland, and drought led to significant tree deaths regardless of fire, as has been found previously in north eastern Australia (Fensham et al. 2019), suggesting fire could be prioritised to the more productive grasslands.

The fire experiment at VRRS continues to provide unique insights into the impacts of fire in the grazed context on the savanna vegetation, but also the less anticipated impacts of multidecadal shifts in rainfall on vegetation composition and structure. The site not only contributes to our understanding of savanna ecosystems, but also provides a visual demonstration of fire management for local land managers and has been used to determine the impact of fire on carbon storage, biodiversity and biocrusts.

Abstract
Grasslands in the northern Great Plains of North America sustain abundant plants, wildlife, and livestock but are threatened by invasive plant species. Predicted shifts toward more variable weather will challenge sustainable management of these grasslands. Effective and feasible management options need to be developed in collaboration with, and for, land managers. As part of the Long-Term Agroecosystem Research (LTAR) network, a nationwide network with 19 research sites focused on developing strategies to address current agricultural needs, we initiated an experiment in 2019 to answer whether applying fire and/or grazing can reduce the dominance of invasive Kentucky bluegrass (*Poa pratensis*) in North America's northern Great Plains ecosystems. We contrast a prevailing practice (season-long grazing at a moderate stocking rate) with four alternative practices at a half-hectare plot scale: (1) mob grazing (high intensity, short duration) by cattle, (2) multi-species grazing (mob grazing by cattle, with goats foraging at key times of the year), (3) prescribed fire, and (4) prescribed fire followed by cattle grazing. A stakeholder group was engaged in making decisions to determine alternative practices and how to apply them. Every five years, the treatment with the best overall outcomes is applied at a field scale (15 ha). We found that prescribed fire and mob grazing reduced the cover of Kentucky bluegrass and increased the cover of some native plant species. When combined, prescribed fire and grazing had the most reductions in Kentucky bluegrass and increases in native plant species. However, there are trade-offs associated with each treatment related to plant production and nutritive values, livestock weight gain, and soil compaction and infiltration. We discuss results in the context of optimizing land management based on land manager goals and current and future economic and ecosystem benefits.

Introduction
Naturally occurring fire, indigenous fire management, grazing, and soils shaped the vegetative communities on the Great Plains (Epstein et al. 1997, Fuhlendorf and Engle 2001, Lake and Christianson 2020). However, since European settlement, fire and grazing regimes on the Great Plains have been severely altered. These changes have resulted in increased abundance of invasive perennial cool-season grasses severely altering the species composition in the primarily cool-season dominated plant communities in the northern Great Plains.

Fire suppression in fire-adapted rangelands generally results in cascading ecosystem changes that not only affect the local area in which fires occur but influences the delivery of ecosystem services at landscape and watershed scales. From an ecological perspective, suppressing fire in fire-adapted ecosystems inhibits natural regulating processes and, consequently, promotes ecosystem degradation (Backer et al. 2004). From an economic perspective, ecosystem changes associated with fire suppression have led to reduced grazing land resilience, lower land productivity, changes in livestock carrying capacity, and increased risk of loss of property and life to catastrophic fires resulting from fuel load accumulation (Pyne 1984; Teague et al. 2001, Toledo et al. 2014).

Mob grazing is increasingly popular with producers, but the impacts of the practice, especially on soil and vegetative composition, are unclear. This is also true of other alternative animal practices such as multi-species grazing (Walker 1997). There is a need to evaluate and compare the impacts of alternative grazing management practices and prescribed burning on vegetation and soils.

Methods
The experiment was located on native rangeland at the Northern Great Plains Research Laboratory, USDA-ARS, which has been invaded by the perennial cool-season grass, Kentucky bluegrass. Five different land management treatments were replicated four times each in a randomized complete block design. The five treatments were (1) grazing with cattle only at a moderate stocking rate until 50% of the palatable vegetation was removed (Control); (2) use of a mob grazing technique (high intensity, short duration) for cattle only (MOBC), (3) grazing by goats and mob grazing by cattle (MOBCSR); (4) a fall prescribed fire(Fire); and (5) a fall prescribed fire that was grazed by cattle in the following spring (FireC). Each treatment was randomly assigned to a 0.5 ha plot within each block. We implemented a staggered start design, meaning that 2 experimental blocks were started in 2019, and the remaining 2 experimental blocks were started in 2020. To minimize the impact of plot size, treatment blocks were selected with care to represent the landscape and reduce potential sources of variability. Treatments were located on Loamy Ecological Sites (USDA 2024).

Vegetation sampling on each plot was conducted using the Modified Whittaker technique (Stohlgren et al. 1995; Stohlgren 2007) and the line intercept method (Herrick et al. 2005). Rangeland health assessments were performed using the Integrated Grazingland Health Assessment protocol (Toledo et al. 2016).

Soil attributes were measured in all treatments prior to treatment deployment, throughout the study, and at the end of the study. Samples were collected from depth increments of 0-0.05, 0.05-0.1, 0.1-0.2, 0.2-0.3, and 0.3-0.6 m using a hydraulic sampler and analyzed for physical, chemical, and biological attributes. Attributes included soil bulk density, water-stable aggregation (physical), soil pH, electrical conductivity, exchangeable cations, available N and P, micronutrients, total C and N, and particulate organic matter C and N, (chemical), and C mineralization, potentially mineralizable N, and phospholipid fatty acid profiles (biological). Field measurements of sorptivity, penetration resistance, and soil water content were conducted annually before and after grazing, while saturated hydraulic conductivity was measured after grazing.

Results

We found that prescribed fire and mob grazing reduced the cover of the invasive Kentucky bluegrass (Figure 1). When combined, prescribed fire and grazing had the most reductions in bluegrass. However, there were trade-offs associated with each treatment related to plant cover and livestock weight gain.

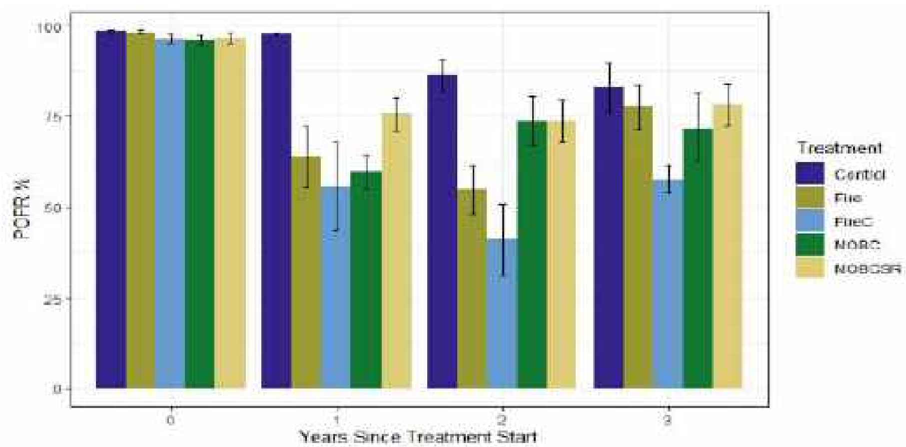

Figure 1. Percentage cover of Kentucky bluegrass (*Poa pratensis*; POPR) in treatment plots before the start of treatments and each year since treatment started. Error bars were constructed using one standard error from the mean.

Livestock weight gain differences between the control and mob grazing treatments were not significantly different in 2021 or 2023 and were only significantly different in 2022. However, there was a trend of slightly higher weight gains per hectare in the mob treatments (Figure 2). Qualitative rangeland health data (visible platy structure near the soil surface) suggest plots that were mob grazed were more compacted than plots that were grazed season-long, and the ease with which pores of a saturated soil-transmitted water was greater in the control and fire treatments than in the mob treatments but results vary by year (Figure 3).

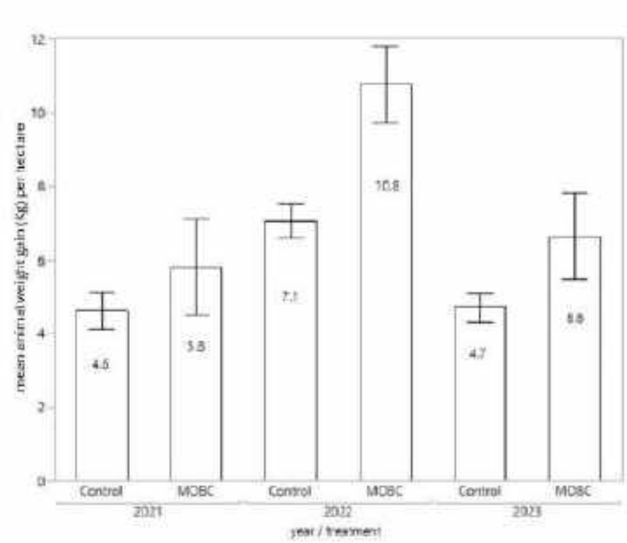

Figure 2. Twenty-eight-day mean animal weight gain (Kg) per hectare on season-long grazing (Control) and mob grazing (MOBC, alternative practice) by year. Error bar constructed using one standard error from the mean. Livestock did not graze fire treatments long enough to produce reliable weight data.

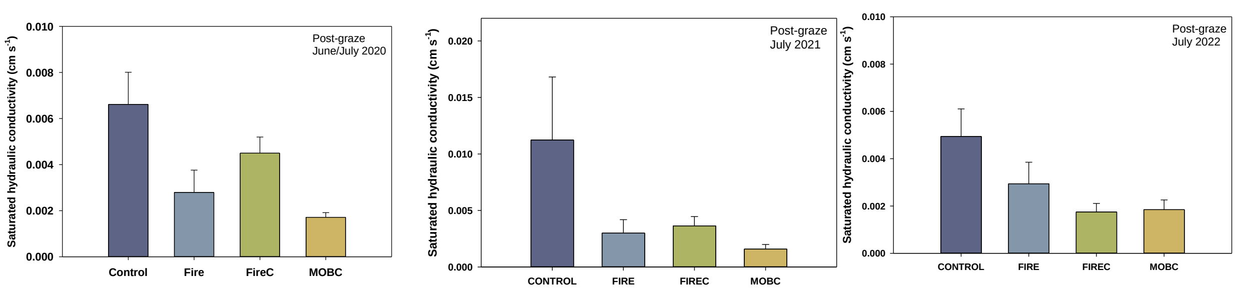

Figure 3. 2020, 2021, and 2022 post-graze saturated hydraulic conductivity of season-long grazing control (prevailing practice), fire treatment (Fire), fire treatment that was grazed by cattle (FireC), and mob grazing treatment (MOBC).

Discussion [Conclusions/Implications]

Fire treatments were more effective at reducing cover of Kentucky bluegrass than the other treatments. Mob grazing showed reductions in bluegrass and increases in weight gain per hectare compared to the control, but results were not consistently significant and were also associated with negative changes in soil physical condition. We were unable to compare weight gains of livestock in grazed fire treatments because they spent too little time on the treatments to produce reliable weight data.

Although Kentucky bluegrass is a palatable and productive grass (Toledo et al. 2014), no treatment is not an option if the goal is to maintain healthy and productive rangelands in the northern Great Plains. The combination of fire and grazing provided the most positive results in terms of Kentucky bluegrass reductions. In a region where prescribed fire is not always seen as positive, it was important for landowners who were part of the stakeholder group to see these results first-hand. Land managers need to evaluate their goals for their land and the current and future economic and ecosystem benefits and constraints of applying any of these treatments.

Effects of orientation on soil moisture, temperature, biomass production, and nutritional composition of natural grassland in the central Chile

Toro-Mujica, P[1]; Muñoz, G[2]; Lisboa, P[1]

[1]Universidad de O'Higgins, Institute of Agri-Food, Animal, and Environmental Sciences; [2]Universidad de Chile. Department of Industrial Engineering

Key words: grassland; quality; pasture; dryland

Abstract

The natural dryland grassland of Central Chile serves as the nutritional base for sheep production systems. The orientation of a hill influences solar exposure, potentially affecting soil temperature and moisture, consequently impacting the growth cycle and nutritional quality of the grassland. Therefore, this study aimed to assess the orientation's effect on biomass production and the nutritional quality of the grassland. To achieve this goal, a farm with slopes facing the four cardinal directions (N, S, E, W) was selected for the trial. Three exclusion plots were established for each orientation. Grass samples were collected monthly to measure availability (kg DM/ha), Dry Matter (DM, %), Crude Protein (CP,%), Neutral Detergent Fiber (NDF,%), and Acid Detergent Fiber (ADF,%). Soil moisture and temperature were monitored at depths of 7.5 and 12 cm using a portable TDR 350 moisture sensor, expressed as Volumetric Water Content (VWC, %) and Celsius degrees (°C), respectively. Simple and multifactorial ANOVA were employed for data analysis. Results revealed that the average soil moisture at both depths was highest on the S slope, with 9.6±7.8% at 7.5 cm and 12.2±10.1% at 12 cm. The W slope exhibited the lowest moisture; however, it was not statistically different from the N and E slopes. The higher soil moisture on the S slope corresponded with lower temperatures (24.8±6.6°C), approximately 4°C lower than other orientations. This soil moisture/temperature combination resulted in no significant differences ($p<0.05$) in biomass production between orientations until after senescence (November). Regarding nutritional quality, no orientation effect was observed on DM (%), but differences were noted in ADF, NDF, and CP. The E orientation exhibited the lowest NDF value (52.6±5.0%), the S orientation had the lowest ADF value (37.3±2.7%), and the N orientation showed the lowest CP value (9.2±1.6%). These variations suggest the potential for utilizing orientation differences to accommodate animal categories with varying nutritional requirements.

Introduction

The natural dryland grassland of Central Chile serves as the nutritional base for sheep production systems. However, changes in precipitation and temperature patterns due to global warming have altered the grasslands' growing season, affecting the availability and nutritional quality of the forage throughout the year (Liu et al. 2019). Accurate information about forage availability is essential for efficient and precise grassland management and feed planning in extensive livestock systems (Serrano et al., 2016). Unfortunately, much of the available information regarding the nutritional value and its temporal pattern is outdated, with data spanning several decades (Ruiz, 1996). In Central Chile, the effects of climate change have manifested as reduced precipitation and increased temperatures, highlighting the importance of topographical features that influence soil moisture availability. For example, the orientation of a slope affects solar exposure, which can influence soil temperature and moisture, thereby impacting the growth cycle and nutritional quality of the grassland (Cui et al. 2023). The objective of the study was to evaluate the effect of slope orientation on biomass production and the nutritional quality of the grassland, while also updating the existing information on the production and nutritional quality of natural dryland grasslands in Central Chile.

Methods

The study was conducted on a livestock farm located in the interior dryland of the Las Cabras commune, O'Higgins Region. According to the modified Köppen classification, the area has a warm temperate climate with winter rainfall (Santibañez 2017).

For the research, 12 exclusion plots, each of 100 m² (10 x 10 m), were established and distributed across the four cardinal orientations (N, S, E and W, three plot per slope). The study spanned the grassland growth period, from July to December. Samples were collected monthly using a ring with a surface area of 0.09 m². In each exclusion plot, once the grass reached a minimum height of approximately 5 cm, three grass samples were collected. Grass was clipped at ground level to ensure sampling during the early growth stages using electric hand shears. The samples were placed in plastic bags, stored in a cooler, and transported to the Animal Feed and Food Quality Laboratory at the O'Higgins University for further processing. Fresh weights were recorded, and the dry matter percentage was determined to estimate biomass availability per hectare. Nutritional composition of the samples was analyzed using a FOSS NIR DS2500, measuring the following parameters: Dry Matter (DM, %), Crude Protein (CP, %), Neutral Detergent Fiber (NDF, %), and Acid Detergent Fiber (ADF, %). Soil moisture and temperature were monitored at depths of 7.5 and 12 cm using a portable TDR 350 moisture sensor. Moisture content was expressed as Volumetric Water Content (VWC, %) and temperature as degrees Celsius (°C). In each exclusion plot, 12 measurements were taken—six per depth. Data analysis was performed using simple and multifactorial ANOVA, with month, orientation, and depth considered as factors.

Results

Grassland growth began in July; however, due to the limited grass height, sampling was not feasible. Consequently, 324 samples were collected from August to December. Although an effect of orientation and month on biomass availability was observed ($p<0.05$), significant differences were only detected in December. On the N- and W-facing slopes, maximum biomass availability was observed in October (Figure 1). In contrast, on the S- and E- facing slopes, peak biomass availability occurred in November. Subsequently, plant senescence began, resulting in a slight decrease in biomass availability.

Orientation and month also had a significant effect on the dry matter, crude protein, acid detergent fiber (ADF), and neutral detergent fiber (NDF) contents. The N-facing slope exhibited lower nutritional quality during most of the evaluated months, characterized by lower crude protein concentrations and higher NDF and ADF concentrations (Figure 2).

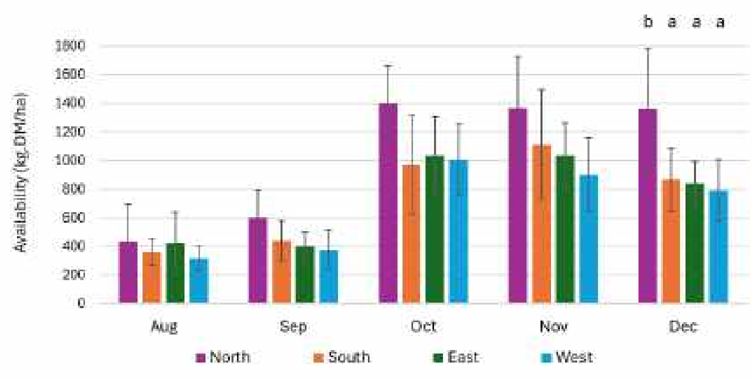

Figure 1. Effect of month and orientation on average biomass availability

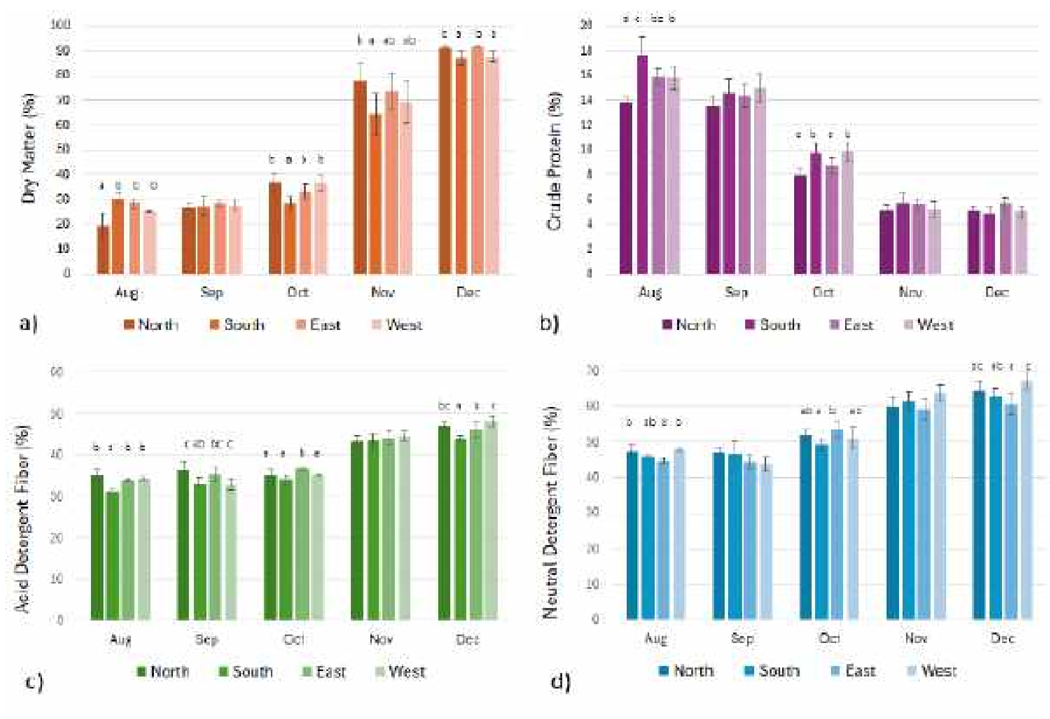

Figure 2. Monthly variation in Dry Matter content (a), Crude Protein (b), Acid Detergent Fiber (c), and Neutral Detergent Fiber (d) of the grassland.

Soil temperature and moisture variables were recorded from July to December (Figure 3). Both month and orientation significantly affected these variables at both depths (7.5 cm and 12 cm) ($p<0.05$). Depth significantly influenced soil moisture but had no effect on temperature. Soil moisture decreased rapidly from July to October, with the rate of decline slowing from October to December. From August to December, the S-facing slope consistently exhibited significantly higher soil moisture content compared to the other orientations ($p < 0.05$). At 12 cm depth, soil moisture was lower on the S- and W-facing slopes compared to measurements taken at 7.5 cm in all evaluated months. Soil temperature trends were similar across the N-, E- and W-facing slopes. On the S-facing slope, however, the temperature increase exhibited a lag of approximately two months compared to the other orientations.

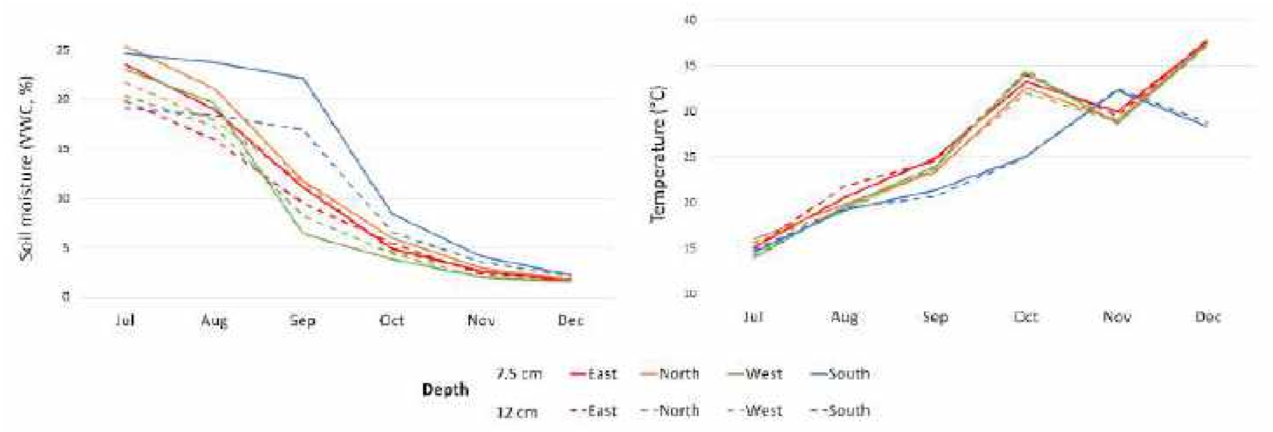

Figure 3. Effect of month, orientation, and depth on soil moisture and temperature

Discussion

Topographic factors such as slope and orientation influence the range of microclimatic conditions, including solar radiation, temperature, and soil moisture (Bennie et al.2008). These variables, which are critical for the growth of the grassland species, determine their productivity, and nutritional composition, demonstrating the potential for utilizing orientation differences to accommodate animal categories with varying nutritional requirements. In the southern hemisphere, S-facing slopes receive the least solar exposure throughout the day, resulting in lower soil temperatures (Figure 3). These lower temperatures reduce evapotranspiration, helping to maintain higher soil moisture levels and creating a greater moisture differential between the 7.5 and 12 cm depths during the wet months (Figure 3). The lower temperatures on the S-facing slopes likely delayed the onset of growth, resulting in shorter growth cycles and lower biomass availability. This growth delay contributed to lower fiber levels and higher protein content in August and September. However, as the microclimates generated by slope orientation can influence species composition, further studies are needed to identify the species present on each orientation (Zhang et al., 2022).

Structure and phenology of herbaceous forage plants in the Sahelian rangelands of Senegal during the rainy season

Sawadogo I[1, 2, 3]; Worou N[2]; Bayen P[3]; Kouassi F[1]

[1]University Félix Houphouët Boigny, B.P. 165, Abidjan 31, Cote d'Ivoire; idrissaw2017@gmail.com; [2]International Livestock Research Institute (ILRI), BP 24265 Ouakam, Dakar, Senegal; [3]University of Dédougou. BP 176 Dedougou, Burkina Faso

Abstract

This study describes the structure and phenology of Sahelian rangelands during the rainy season. It was undertaken in thorny steppe on a grazed plot and a nearby fenced plot with otherwise similar site characteristics. Measurements were taken every 10 days over two rainy seasons between July and October 2022 and between August and October 2023. The measurements included the phenological stage, the vegetative and flowering height, the foliage cover, and the phytomass. The results showed that phytomass did not systematically differ between grazed and fenced plots. Flowering started as early as mid-July, but most of the plants flowered in early October. Flowering and fruiting occurred earlier (based on the number of days after the first rain) in the late rainy season (2023) than in the early one (2022). These stages reached their peak in October; senescence began in October. Vegetative height, reproductive height, and coverage were similar between the two years. Height peaks were similar, but they were reached earlier (based on the number of days after the first rain) in the late rainy season than in the early one. Coverage peaks were similar (59.8% in the early rainy season vs. 65.8% in the late one). Vegetative height (around 30 cm), reproductive height (around 36 cm), and coverage (around 60%) reached their maximum in October, but reproductive height was greater than vegetative height. These parameters were lower at the grazed, and flowering started earlier at the grazed site. Grazing reduced cover and height, and delayed flowering. Structure and phenology were more sensitive to changes in rainfall between years. Knowing phenology helps determine the best time to harvest the phytomass, because the nutritional quality of the forage is known to decrease after fruiting.

Introduction

In the Sahelian rangelands, the main economic activity is pastoral livestock farming, which is mainly based on ephemeral vegetation. These rangelands comprises a stratum of annual herbaceous plants, mainly grasses, and a stratum of scattered woody plants dominated by the genus *Acacia* (Diawara et al., 2018). In the Sahel, the quantity of grass produced is largely determined by rainfall, which varies between years. Low rainfall caused low biomass which leads to pastoral crises.

It is therefore important to know the dynamics of the herbaceous stratum so as to adapt pastoral livestock farming to climatic constraints. However, most studies on phytomass production in the herbaceous stratum have mainly focused on variations between years and between zones, with sampling often taking place at the end of the rainy season; few studies have looked at dynamics during the season, and herbaceous plants grow very quickly during the rainy season (from June or July to October) due to the availability of soil moisture (due to rainfall) and nutrients and the impact of grazing (Habibou et al., 2018). Most studies have focused solely on biomass. However, studying other vegetation parameters over the entire life cycle of plants can provide a great deal of useful information for understanding vegetation dynamics, especially in relation to animal production.

The goal of this study was to measure the structure and phenology of the herbaceous stratum over a rainy season and to examine whether grazing had any effect on the measured parameters. Thus, phytomass, vegetative height and phenology were monitored at ten-day intervals during the rainy season, for two years, in thorny steppe at a grazed site and nearby a fenced site. These sites had otherwise similar site characteristics. The gazed site was grazed by cattle, horses, donkeys, sheep and goats at high intensity. The fenced sites excluded all herbivores from grazing. This study is innovative in that it measures parameters that are not always measured (height of inflorescences) and that were measured much more frequently than usual.

Materials and Methods

Study area

The study was conducted in the Sahelian part of Senegal named Ferlo (Fig. 1). The Ferlo, also known as the sylvopastoral zone, is the largest of Senegal's six agroecological zones. It is located between 15°21′ north and 15°28′ west. It covers an area of 54,380 km2 or 27.6% of the national territory. The physiognomy of the vegetation in Ferlo has changed from a wooded savannah to a shrubby savannah in the 1960s to a thorny steppe today (Habibou et al., 2018).

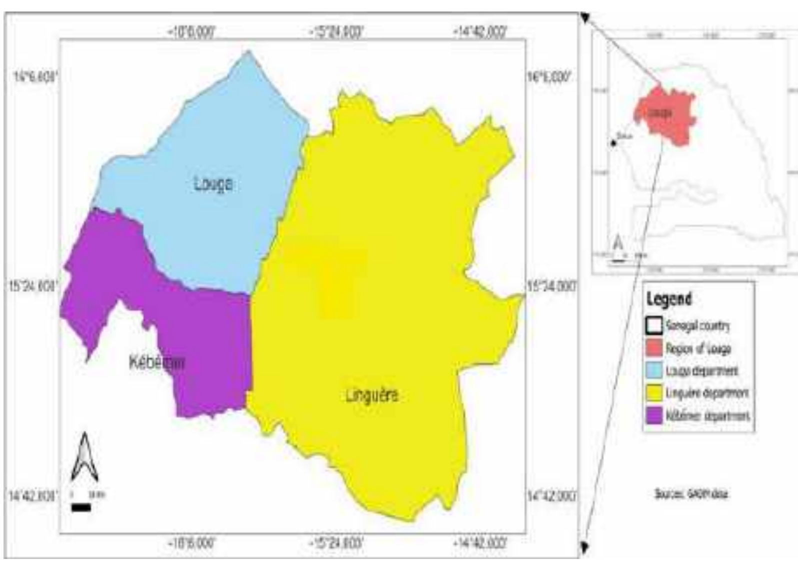

Figure 1: Study site

Data collection

Similar measurements were taken at a grazed site (g) and a fenced site (f) in the rainy season for two years to see if there were any differences between the rainy seasons and whether grazing had any effect on the parameters monitored. The measurements were carried out between July and October 2022 and between August and October 2023. Annual rainfall was 356 mm accumulated over 21 different events in 2022 and 336 mm over 20 different rainfall events in 2023. The 2022 rainy season was about 30 days earlier but was marked by long dry spells at the beginning of the season. Measurements started ten days after the first rainfall of at least 0.1 mm and were taken every ten days up to the end of the rainy season. Twenty-eight points were measured on each measurement date at each site. At each collection point, the following parameters were measured:

- Herbaceous phytomass, harvested at ground level on an area of 1 m2 was weighed fresh and placed in an oven at 65 ◦C until a constant weight was obtained before being weighed again to obtain the dry weight.
- Phenological stages: leafing, flowering, fruiting, and senescence. When a stage was present in the quadrat, the percentage of plants at that stage was estimated visually.
- Vegetative height was measured from the soil to the highest leaf.

Statistical Analysis

Student's test was used to compare parameter values across sites on each measurement date and between monitoring years.

Results

Phytomass

In contrast to 2022, where there was little variation in production between the two sites, overall phytomass production was lower at the grazed site in 2023. Maximum phytomass was reached on the same date (early October), but the peak at the grazed site (1800 kg·ha^{-1}) was less than that of the fenced site (2357 kg·ha^{-1}).

Vegetative Height

In 2018, vegetative height was equal at both sites at the beginning of the rainy season, i.e., 40 days after the first rainfall (up to early August) (Fig. 2). For the rest of the rainy season (mid-August to the end of October), it remained lower at the grazed site. This height reached a maximum of 42 cm at the fenced site and 31.3 cm at the grazed site. However, the maximums were reached on the same date, i.e., in mid-October (the 110th day after the first rainfall). In 2023, vegetative height was lower at the grazed site during the rainy season. This height reached its maximum of 48.09 cm at the fenced site slightly earlier than at the grazed site (27.4 cm) in August. This maximum height was therefore lower at the grazed site.

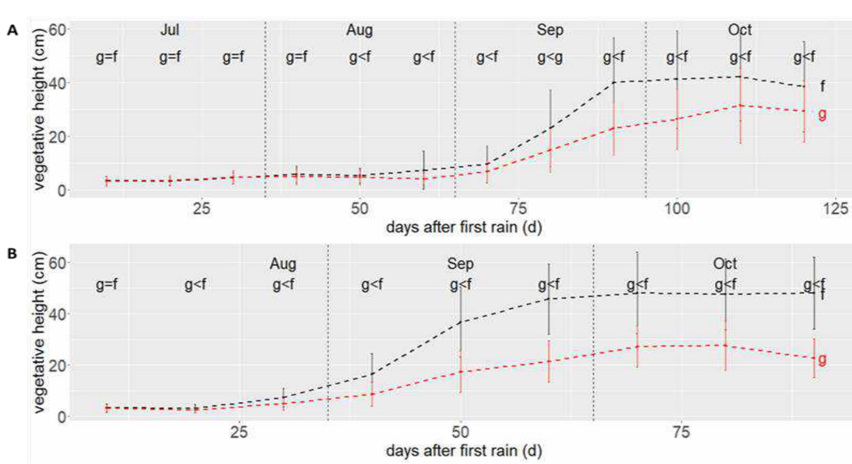

Figure 2: Vegetative height of grazed (g, red) and fenced (f, black) sites in 2022 (A) and 2023 (B).

Phenology
In 2022, the difference in phenology between the fenced site and the grazed site concerned the date flowering first appeared (Fig. 3). It occurred on the 20th day after the first rain (second ten days of July) at the grazed site and on the 30th day after the first rain (third ten days of July) at the fenced site. In 2023, flowering began 10 days after the first rain at the grazed site and 20 days after the first rain at the fenced site. In contrast, fruiting occurred earlier (40 days after the first rain) at the fenced site compared to the grazed site (50 days after the first rain). Senescence started at both sites on the same date, i.e., 80 days after the first rainfall (August). Each of the different phenological stages appeared in the same month at both sites and both years.

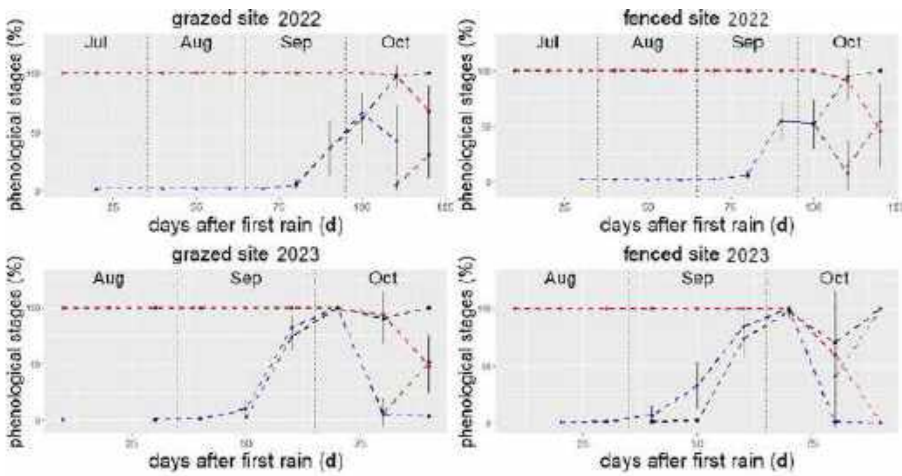

Figure 3: Phenology of grazed and fenced sites in 2022 and 2023. Red: leafing; blue: flowering; black: fruiting; brown: senescence

Discussion
The amount of phytomass was lower at the grazed site than at the fenced site, though the differences were small in 2022 throughout the season. Nevertheless, this result supports the hypothesis that grazing decreases phytomass production, which is similar to previous results in a steppe formation, even in a savanna (Diatta et al., 2023) .

Animal husbandry can cause overgrazing that reduces productivity. On the other hand, trials testing protection from cultivation, forest removal, fire, and grazing carried out in Niger (Sadoré reserve), Burkina Faso, and Senegal resulted in slightly lower herbaceous production than in the grazed control, mainly because of the greater relative importance of broadleaf weeds (Diawara et al., 2018).

Flowering and fruiting occurred earlier in a late rainy season year compared to an early rainy season year. These two stages reached their peak in October, while foliage cover started to drop. Seeding began in October for both years. The onset of flowering in mid-July indicates the existence of early-flowering species at the site. Earlier flowering was noted on pastures in Burkina Faso (Sanou et al., 2021).

Peaks in vegetative height (31 cm) and reproductive height (36 cm) were reached in October, but the reproductive height was slightly higher than the vegetative height. These figures ranged from 0.5 to 1 m (Pontanier et al., 2003) for the height at maximum vegetation and from 40 to 60 cm (Ngom, 2013) for the Ferlo area. These ranges align with other evidence that the herbaceous stratum in the typical Sahel can reach 50 cm in height on sandy dunes (Diatta et al., 2023). It is explained that even though some species continue a vegetative growth after flowering, the majority of grasses stop doing so. Grasses were the major family of the pastures studied, but most annual grasses, under the influence of the photoperiod, flower between the end of August and the beginning of September. This means that almost all species reach their maximum size and stop growing at that time.

Conclusions and Implications

The vegetative height, reproductive height, and flowering of herbaceous plants were sensitive to grazing.

The presence of early-flowering species in the area is consistent with species adaptation to the Sahelian climatic conditions, in particular to the short duration of the rainy season.

The dates of appearance of the phenological stages and the height of the herbaceous layer do not seem to depend on the date of the start of the rainy season.

When measuring the height of the canopy in grassy rangelands, it is best to measure reproductive height so as not to underestimate it.

Acknowledgements

This work was supported by the Accelerating Impacts of CGIAR Climate Research for Africa (AICCRA) project of Senegal. We also express our gratitude to the Ferlo population for their cooperation and to the people who helped collect this data.

Abstract

We established two field decomposition experiments using *Leymus chinensis* and *Stipa grandis* litter, to quantify the effect of different decomposition drivers (including microbial decomposition, abiotic photodegradation and photoacceleration) on the decomposition of different litter types (surface litter and standing dead) and age (young and old). In experiment I, the presence of photodegradation greatly enhanced the effect of microorganisms. For surface litter, microbial decomposition, abiotic photodegradation and photoacceleration reduced mass 64.4%, 18.9% and 16.7% respectively. For standing dead, microbial decomposition, abiotic photodegradation and photoacceleration reduced mass by 51.6%, 21.5% and 26.9% respectively. Solar radiation affected the decomposition of carbon only; it had no effect on nitrogen. Cellulose was less susceptible to the effect of solar radiation than lignin and hemicellulose. In experiment II, we assessed the effects of prior solar radiation on the subsequent decomposition of plant litter, and found that microbial decomposition and abiotic photodegradation decreased the mass of young litter more than that of old litter, while photoacceleration decreased the mass of young litter less than that of old litter. In conclusion, our results indicated that the impact of abiotic photodegradation tended to decrease over time, and that photoacceleration contributed more to the mass loss than the direct photo-mineralization. Our results suggest that although young and dead standing plant biomass can accelerate decomposition process, which potentially increases the carbon loss of ecosystem and decreases the accumulation of organic carbon; this may indicate a new challenge for grassland sustainability.

Introduction

Traditional models underestimate the decomposition rate in arid environments, and this is largely due to the neglect of photodegradation phenomenon. That has been studied in different ecosystems (King 2012; Wang et al. 2021). However, most of these studies evaluating the effect of solar radiation on decomposition are based on a simple comparison between blocking radiation and allowing radiation to access the litter. Furthermore, it is often difficult to separate the relative contributions of abiotic litter loss and loss due to photofacilitation. Such studies are very limited for assessing the impacts of photodegradation compared with microbial decomposition in different environments and conditions. For example, whether decomposition positions with different decomposition microenvironment (Lin and King 2014; Jacobson et al. 2015; Wang et al. 2017) will influence the contribution of photodegradation to the decomposition of litter, and whether the contribution of abiotic photodegradation and photoaccelerate on litter degradation changes with time or litter type? These questions require quantitative experiments to answer. In this study, we explore whether decomposition processes differ between different litter types, and how the different types of litter affect the contributions of microbial decomposition, photodegradation and photofacilitation to litter degradation. In addition, we also examined how our treatments influenced litter chemistry, to provide clues as to what compounds might be involved in photodegradation.

Methods

The study was carried out in an experimental grassland at the Grassland Ecosystem Research Station of Inner Mongolia University. The experiment materials were the litter of two dominant plants (*Leymus chinensis* and *Stipa grandis*). We conducted two small experiments that used a two-by-two factorial design and the same decomposition treatments, including two sunlight treatments (sun and shade) and two microbial treatments (sterilization and non-sterilization). The decomposition time both was about one year.

Experiment I: This involved litterbags (5 g litter materials). Half were laid flat on the ground (surface litter); the other half were laid upright and suspended 0.1 m above the ground to simulate the dead standing plant biomass (standing dead). Experiment II: Standing dead materials of *L. chinensis* and *S. grandis* were collected and divided into two parts; half were brought back to lab and stored in refrigerator at a low temperature (young litter), the rest were exposed to sun outside for 7 months (old litter).

Treatment implementation: (1) Sun treatment: 15 cm × 20 cm nylon net bags with a mesh size of 1 mm which passes 90% of UV radiation and photosynthetically active radiation (PAR). (2) Shade treatment: the same nylon net bags covered with two layers of black sunshade net which block 95% of UV radiation and PAR. (3) Sun+sterilization treatment: 12 cm × 17 cm solar-transparent polyethylene ziplock bags (0.08 mm, DengBi, Anhui) which passes 85% of UV radiation and PAR. (4) Shade+sterilization treatment: the same ziplock bags covered with two layers of black sunshade net. For sterilization treatment, before putting into ziplock bags, the air-dry decomposition materials entailed placing in an oven at 121℃ for 20 min (Day et al., 2015). These ziplock bags were changed regularly every two months to ensure their transmission and integrity during the experiment period.

Calculation method: where the X_0 is the initial litter mass, and X_t is the litter mass at a specific time t within the experimental duration. Litter nutrients remaining (carbon, nitrogen, hemicellulose, cellulose and lignin remaining) within a specific time-frame from 0 to t were also computed, where the C_0 and C_t respectively is the litter chemical content of at initial time point (t=0) and sampling time point (t), respectively. The formulae are:

$$Mass\ remaining = X_t / X_0 \times 100\%$$

$$Nutrients\ remaining = C_t / C_0 \times 100\%$$

$$Relative\ contribution\ to\ mass\ change_{microbial\ decomposition/abiotic\ photodegradation} = \frac{Mass\ remaining_{shade+sterilization} - Mass\ remaining_{shade/sun+sterilization}}{Mass\ remaining_{shade+sterilization} - Mass\ remaining_{sun}}$$

$$Relative\ contribution\ to\ mass\ change_{photoaccelerate} = 100 - relative\ contribution_{microbial\ decomposition} - relative\ contribution_{abiotic\ photodegradation}$$

Results

Experiment 1

Litter C loss and the contributions of different decomposition pathways

During 405-day decomposition, mass remaining gradually decreased with time (Fig. 1) and mass remaining under the four treatments were significantly different across from four kinds of decomposition materials. At the end of the experiment 1, the relative contribution of microbial decomposition, abiotic photodegradation and photoaccelerate to cumulative mass loss of *L. chinensis* and *S. grandis* surface litter is 64.4%, 18.9% and 16.7% respectively, and 51.6%, 21.5% and 26.9% respectively for their standing dead.

Litter chemistry

More N remained under the non-sterilization treatment than under the sterilization treatment. N remaining in the litter exposed to sun was usually more than that of litter under shade, while less N remained under the sun+sterilization treatment than under shade+sterilization (Fig. 2a~d). Without sterilization, N remaining in surface litter was higher than that of standing dead without enrichment process. By contrast, for both surface litter and standing dead, C remaining in litter exposed to sun was less than that of litter under shade (Fig. 2e~h).

Sunlight and sterilization treatments both significantly affected the amount of hemicellulose and lignin remaining for both *L. chinensis* and *S. grandis*, but did not significantly affect cellulose remaining (Fig. 2i~n). Only for *L. chinensis* did the litter state significantly effect lignin remaining. Sunlight significantly decreased the amount of hemicellulose and lignin remaining. Hemicellulose and cellulose remaining were slightly lower for non-sterilized surface litter, while the lignin remaining was higher.

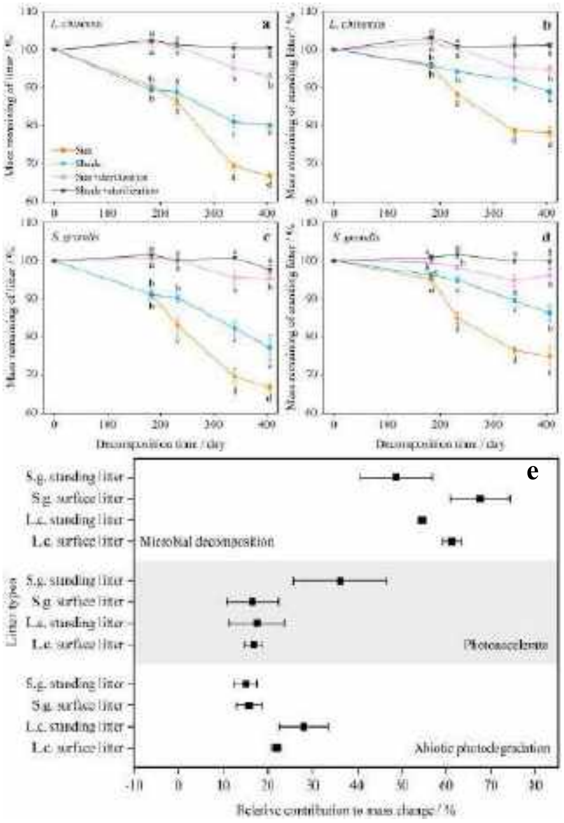

Figure 1 Mass remaining dynamics of litter at different treatment (a~d) and relative contribution of different decomposition pathway to mass change (e) over Experiment 1.

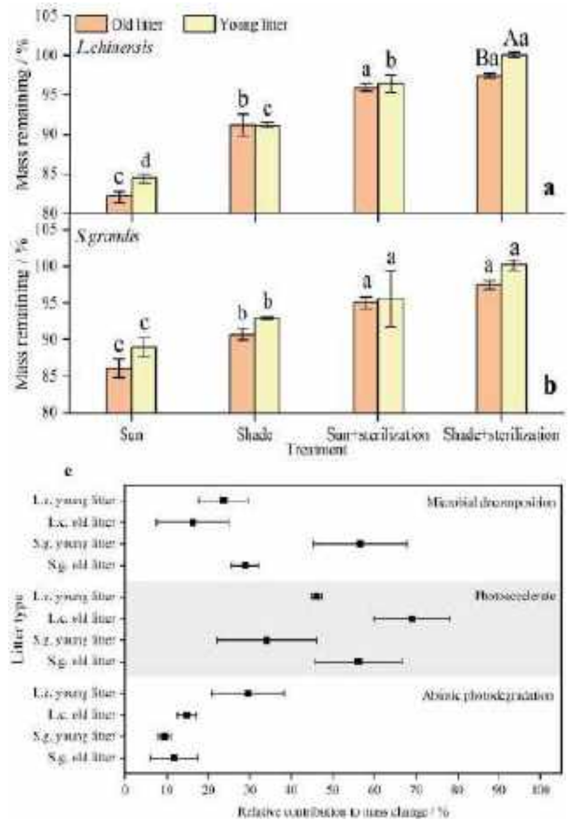

Figure 3 Mass remaining of litter at different treatment (a, b) and relative contribution of different decomposition pathway to mass change (c) over the experiment 2.

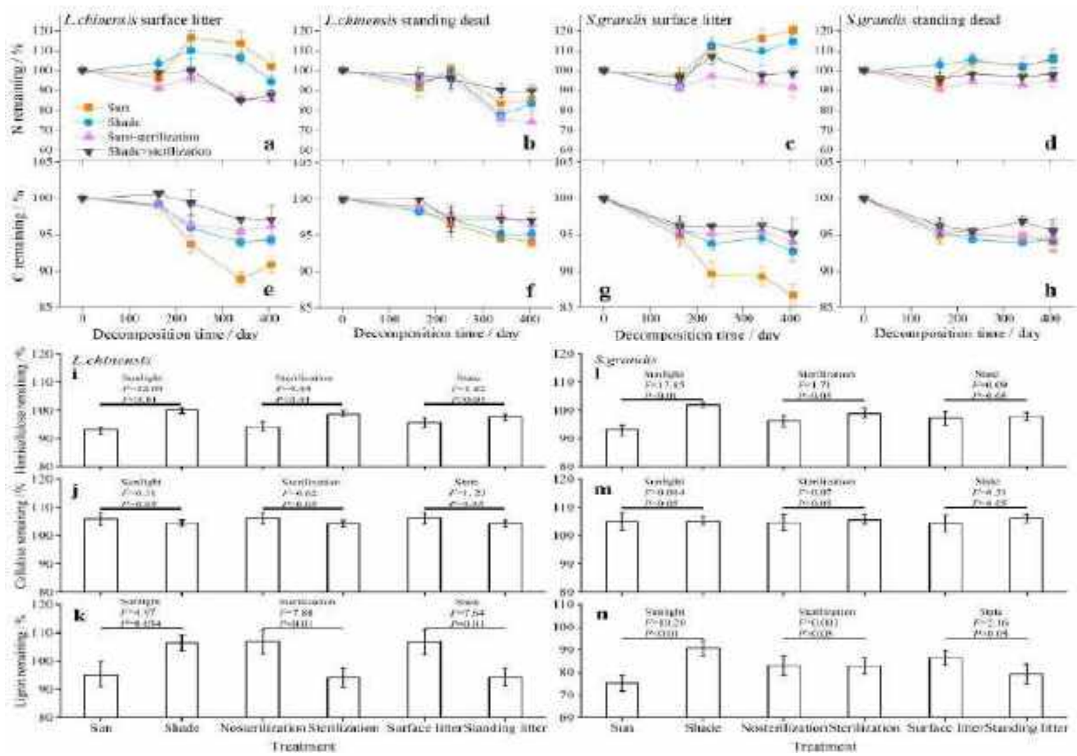

Figure 2 Dynamics of N and C remaining of different litters (*L. chinensis* surface litter (a, e), standing dead (b, f), *S. grandis* surface litter (c, g), standing dead (d, h) under all treatments, and effects of main treatment effect (sun or shade, nonsterilization or sterilization, surface litter or standing dead) on hemicellulose, cellulose and lignin remaining of *L. chinensis* (i, j, k) *and S. grandis* (l, m, n) over the Experiment 1.

Experiment 2

Litter mass remaining and the contributions of different decomposition pathways

The different treatments had significant impacts on both old and young litter. At sun treatment, mass remaining of old litter was lower than that of young litter. Moreover, for young litter, the relative contributions of microbial decomposition, photoacceleration and abiotic photodegradation were 40.1%, 40.0% and 19.5% respectively, while for old litter the relative contributions were 22.5%, 62.6% and 13.2% respectively (Fig. 3).

Discussion

Our results show that solar radiation significantly increased litter decomposition rate. This, solar radiation is a driver of litter decomposition in grassland ecosystem. Solar radiation enhances decomposition by more than 60% on average. However, the promotion effect varies between litter state types. Sunlight increases mass loss of surface litter and standing litter by 56.3% and 88.4% respectively. That means photodegadation promotes decomposition of standing litter more than surface litter. The different drivers of litter decomposition differ between litter state. photoacceleration and abiotic photodegradation have a greater effect on standing litter than on surface litter. Furthermore, there was more N remaining in surface litter, while standing litter has none, which limits microbial mineralization of carbon-based compounds. On the other hand, compared with young litter, old litter decomposed faster, perhaps because of its exposure to sun for 7 months (Angst et al. 2017). That suggests keeping litter standing and this subject to insolation will lead to faster decomposition when on the soil. Compared with the new litter, the microbial decomposition and abiotic photodegradation of the old litter is less, while photopromotion increases degradation.

Synthesizing two experiments, we conclude that the order of contribution of different decomposition pathway was: microbial decomposition (44.7%) > photoaccelerate (36.6%) > abiotic photodegradation (18.3%). No matter the litter types, microbial decomposition was always the leading pathway in the decomposition process, photoacceleration has a much larger impact photodegradation.

ABSTRACT

Napier grass (Pennisetum purpureum) is a key forage crop in Kenya. However, its yield and quality are often hindered by headsmut and stunt disease. Genetic improvement through mutation breeding, particularly using colchicine to induce polyploidy, offers a potential solution for improving Napier grass.The experiments were carried out as a factorial experiment in a complete random design (CRD). This study aimed to evaluate the response of embryogenic calli to different colchicine concentrations (0, 0.05, 0.1, and 0.2%) over 24, 48, and 72 hours duration to induce polyploidy in *South african* and *Bana* napier grass germplasms. The most suitable media for shoot regeneration was Murashige and Skoog (MS) medium supplemented with 0.2 mgL-1 Benzyl Adenine (BAP), 0.1mgL-1 dichlorophenoxyacetic acid (2, 4-D) and 0.1mgL-1 Indole-3-Butyric Acid (IBA) while media with 1mgL-1IBA, 1mgL-1 2, 4-D and 0.5mgL-1 BAP was more suitable in inducing embryogenic calli in all genotypes. Chromosome doubling was confirmed through chromosome counting and stomatal size, and number. Notably, we recommend use of flow cytometry to confirm ploidy level. Results showed that a 0.1% colchicine concentration with a 48-hour treatment was most effective for producing mutant plantlets, while higher concentrations were toxic. Significant genetic and agronomic variations were observed between the mutants and controls, indicating that the selected mutants are valuable genetic resources and recommended for characterization across representative agro-ecologies for large-scale production and used in *Penniseturm purpureum* breeding programs.

Introduction

Livestock plays a crucial role in food security, income, and employment, with global meat and milk demand expected to double by 2050(Herrero et al., 2013). In Kenya, smallholder farmers are key contributors to beef and dairy production, Napier grass (*Pennisetum purpureum*) is the primary livestock feed in Kenya, particularly in zero-grazing and semi-intensive systems (Muyekho et al., 2003; Lukuyu et al., 2011). However, continued contribution of napier grass to the livelihoods of the small-scale farmers is threatened by low growth vigor, low biomass and low feed value due to inferior germplasm (Jones et al., 2004).

Therefore, there is a need to enhance genetic diversity of pasture and forage to meet growing demand, and this is a key strategy for improving food crops resulting to enhanced plant performance (Ardabili and Zakaria, 2015). In light of the above background, this study aimed to investigate the response of embryogenic calli to different colchicine concentrations in inducing polyploidy for regeneration and selection of novel napier grass mutants.

Materials and methods

Experimental site and Plant materials

The experiment was conducted as a factorial with three factors: four levels of colchicine concentration (C0(0%), C1(0.05%), C3(0.2%) and C3(0.2%)), three levels of exposure period (T1 24, T2 48 and T3 72) and two napier grass germplasm (V1 *South africa* and V2 *Bana grass* resulting to 24 treatment combinations, that were replicated thrice using a factorial completely randomized design (CRD) resulting to 96 experimental unit. However, a pre-experiment needed to be conducted to carryout somatic embryogenesis to come up with explants to be used in the next stage of study which is colchicine treatment and acclimatization in the greenhouse. This pre-experiment was conducted as a factorial experiment in a completely randomized design(CRD) having three factors; 3 growth hormone for callus induction, 3 growth hormone for shoot regeneration and rooting and 2 germplasms of napier grass. This resulted to 18 treatment combination that were replicated six times. This resulted to 108 experimental units where the best explant that formed embryogenic calli were selected for the next stage of study. The following callus induction medium was used; GM0 as a comparative control in a hormone free media, GM1 (MS media supplemented with 0.3mg/L-1 BAP, 0.5mg/L-1 2,4-D and 0.5mg/L-1 IBA) and GM2 (MS media supplemented with 0.5mg/L-1 BAP, 1.0mg/L-1 2,4-D and 1.0mg/L-1 IBA). For Shoot regeneration, the following medium was used; SRM0 as a comparative control in a hormone free medium, SRM1 (MS media supplemented with 1mg/L-1 BAP, 0.25mg/L-1 2,4-D and 0.25mg/L-1 IBA and SRM2 (MS media supplemented with 2mg/L-1 BAP, 0.5mg/L-1 2,4-D and 0.5mg/L-1 IBA.

Embryogenic calli formation and shoot regeneration

Shoot tips from the two Napier grass genotypes were surface sterilized and prepared for tissue culture. Callus induction and shoot regeneration were achieved using Murashige and Skoog (MS) medium with specific plant growth hormones, while rooting involved transferring shoots to a medium supplemented with NAA, 2,4-D, and ascorbic acid.

Treatment with Colchicine

The impact of colchicine concentrations and treatment duration on explants survival and polyploidy induction was examined as a factorial experiment in a CRD with three replications. Explants were exposed to treatment after 134 days of culture by immersing them in filtered- sterilized colchicine solution for the designated times as stated earlier, then rinsed three times with sterile distilled water. Explants were then cultured on shoot regeneration media Ms supplemented with various concentrations of BAP (0, 1, 2 mg/L), 2, 4-D (0, 0.25, 0.05 mg/L), and IBA (0, 0.25, 0.05 mg/L). For rooting plantlets, elongated shoots were transferred to rooting medium as stated earlier.

Evaluation of induced mutants to determine ploidy level

Two months after transferring them to the greenhouse after treatment with colchicine, plants that regenerated were subjected to screening for confirmation of polyploid by measuring stomata number and size, chromosome counting and genomic DNA of mutant plants *viz* their progenitors.

Chromosome number by Karyotyping

Chromosome counting was done through karyotyping by treating leaf samples with 3% chromic acid, 20%formaldehyde, and 6% aceto-carmine, before observing them under a light microscope at X80 and X100 magnification

Stomata size and Number

Stomatal density and size were measured by applying nail polish on 35 day old leaves measuring $0.2cm^2$ and counting stomata under a microscope at X20 and X40 (Yu et at., 2009)

Phenotypic evaluations of induced mutants

Phenotypic evaluations of the induced mutants included weekly counting of tiller number and measuring plant height, and stem diameter, with stem diameter measured 10 cm from the base and height recorded from the ground to the highest point.

Results

Response of genotypes to tissue culture

The analysis revealed significant genotype effect on callus formation, necrosis, and embryogenic callus formation. After 4 weeks, all genotypes formed 97.5% calli, with no significant differences in germplasm, and no embryogenic callus formed. After week 7 and 8, The percentage of embryogenic callI after 8weeks was 68.9% and 66.2% on germplasm V1 and V2 on media with 1.0mgL-1 IBA, 1.0mgL-1 2,4-D and 0.5mgL-1 BAP while genotypes V1 and V2 on media with 0.5mgL-1 IBA, 0.5mgL-1 2,4-D and 0.3mgL-1 BAP formed 31.1% and 33.8% calli . Explants cultured on hormonal free media did not produce any sign of growth of callus or embryogenic callus, they were also 100% necrotic. V1 had the highest necrosis after 4 weeks 14.9% and 8 weeks 12.2% while V2 had the lowest case after 4 weeks 9% and 8 weeks 4% necrosis. (Table.1)

Shoot and Root regeneration
Growth of shoot was initiated after 134 days in most media, with regeneration significantly influenced by different hormone combinations. Hormone- free media resulted in no growth and 100% necrosis. The most effective media for shoot regeneration was Ms supplemented with 0.05mg/L IBA, 0.05mg/L 2,4-D, and 2mg/L BAP, achieved 43 and 40% shooting (Table 2). After 14 days, the putative mutants were transferred to the greenhouse, where rooting was successfully induced using MS medium with 1mg/L NAA and 150mg/L ascorbic acid (Table 2, Fig 1)

Table 2. Growth hormone combination effects on shoot induction derived from shoot tillers of two genotypes of *Penniseturm purpureum*

Growth Media	Genotype	No. of regenerated clumps (%)	No. of regenerated shoots (%)

Effect of different colchicine concentrations on survival of explants and ploidy induction
Explants from two germplasm were treated with different colchicine concentrations on solid media. The percentage (%) survival rate differed depending on colchicine concentration, exposure duration and

temperature. Higher concentrations and longer exposure time led to severe toxicity and reduce callus survival, however, it increased octoploidy induction. The optimal condition for inducing polyploidy was 0.1% colchicine with a 48 hours exposure, resulting to 48% polyploidy. Putative mutants exhibited shorter height, increased tillering, and reduced stem diameter compared to their progenitors. Chromosome counting and stomata size and number confirmed successful polyploidy induction (Fig 2)

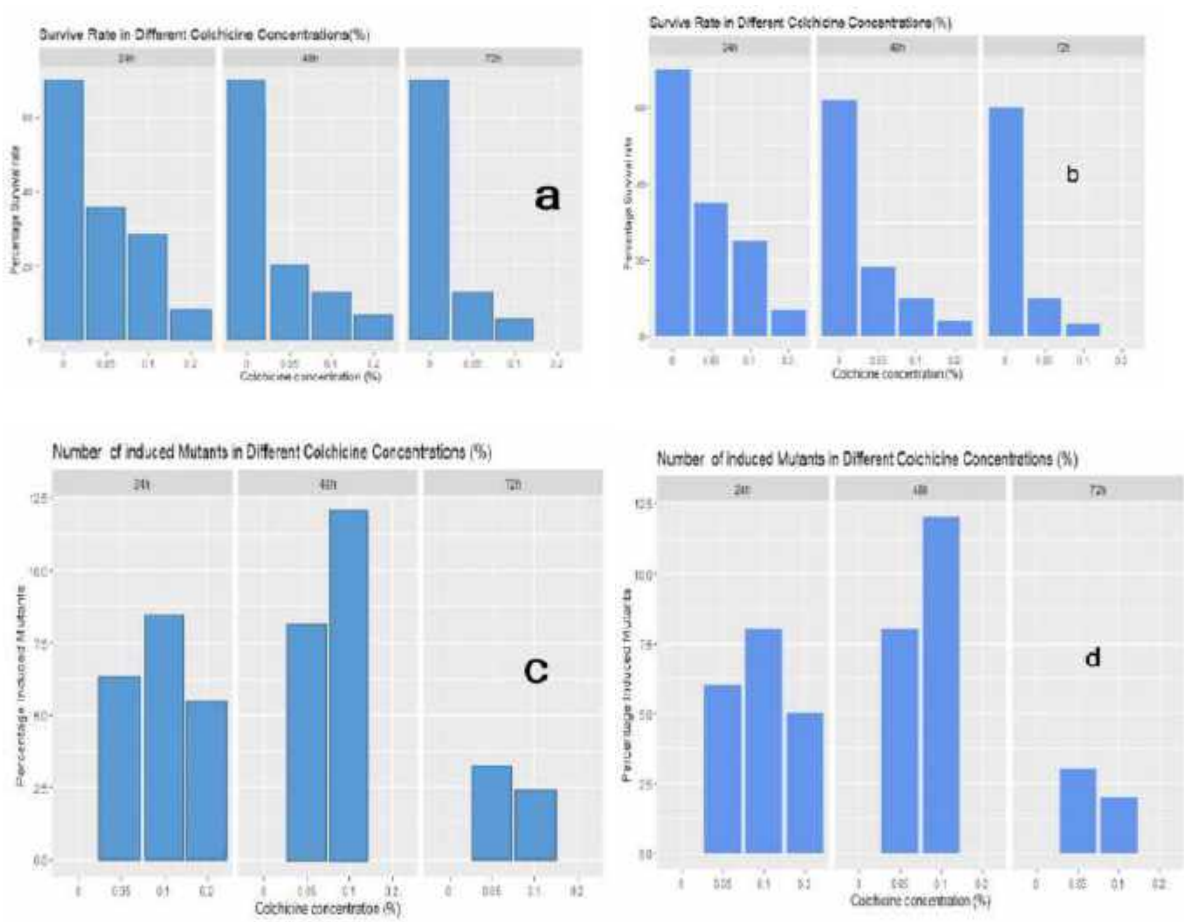

Fig 2 Different letters shows differences at ($p \leq 0.05$)

Score as abc shows variation in No. of induced mutant where a=2-5 %, b=6-8% and c=12%

Phenotypic effect on leaf characteristics

Induced mutants stomata size and number was significantly different from their progenitors. Mutants exhibited larger stomata with stomatal length of 20 or more (>120um) than their progenitors, however, they had lower stomatals density (Table 3, Fig 3). Similarly, analysis of variance detected high significance in tillering ability after 6 weeks of establishment in the greenhouse where induced mutants were the first to produce tillers but after 8 weeks, there was a high significance in number of tillers between induced mutants with their progenitors (Table 3,Fig. 4). Induced plants had slow growth rate as a result of chromosome abbreviation (deletion, duplication, inversion and translocation), physiological and toxic effect which presumably reduced cell survival (Table 3, Fig. 4). The mean stem diameter of synthetic induced mutants was slightly smaller compared to their progenitors (Table 3, Fig 4)

Table 3. Quantitative and qualitative characteristics in *Penniseturm purpureum* induced mutant's.

Germplasm	stomata number (per mm^2)	Stomata size (mm^2)	Plant height (cm)	No. of Tillers after 6 weeks	No. of Tillers after 8 weeks	Stem diameter after 8 weeks (cm)

E, F G and H shows abnormalities several weeks after establishment. E shows chromosome incompatibility that result to death of plants. F and D shows leaf chlorosis of new leaf whole that is dying off. G and H shows new leaf whole emerging with vigor immediately former dying off.

Discussion

This study reports the first successful creation of octoploids plants from selected tetraploid *Pennisetum purpureum* germplasms through in vitro polyploidy induction using colchicine.Two germplasms, *South africa* and *Bana grass*, were used to produce synthetic mutants. The process involved optimizing a tissue culture method where shoot tillers were cultured on Murashige and Skoog (MS) media with varying concentrations of plant growth hormones (Unami et al., 2012). The most effective media for inducing embryogenic calli and subsequent shoot regeneration was MS supplemented with low levels of BAP, IBA, and 2,4-D (Unami et al, 2012). The study also highlighted the challenges of colchicine use, such as toxicity at higher concentrations, which reduced calli survival and resulted in deformed plants. However, a concentration of 0.1% colchicine over two days proved optimal for inducing polyploidy (Mba et al., 2009) The study observed significant morphological and genetic changes in the induced mutants, such as increased stomatal size, decreased stomatal density, and variations in plant height, tillering, and chlorophyll expression (Queensenberry et al., 2010). These traits are crucial for selecting superior mutants for breeding programs.

In conclusion, this study successfully advanced napier grass breeding by regenerating polyploidy mutant plantlets through chromosome doubling and somatic embryogenesis, with confirmation of polyploidy via chromosome counting, stomata size and number, Genomic DNA and other morphological characteristics. However, flow cytometry is recommended for further ploidy level confirmation. The superior mutant plantlets can be selected and recommended for characterization across representative agro-ecologies for large-scale production and used in *Penniseturm purpureum* breeding program in Kenya and its environs.

Key words: carbon concentration; lignin; photodegradation; standing litter

Abstract

In grassland ecosystems, many plants gradually senesce in autumn, forming standing dead material (standing litter) that remains through the winter rather than immediately falling to the ground as litter. However, limited research has focused on the decomposition of standing litter during winter and its subsequent effects on decomposition after being shed in the following spring. We conducted a one-year experiment in the typical steppe of Inner Mongolia, China, to investigate the decomposition processes of litter from the dominant plant *Leymus chinensis* and *Stipa grandis* litter in autumn and spring. During the experiment, autumn-shed litter was placed directly on the soil surface, while spring-shed litter remained suspended above the soil surface for the first seven months of winter until it detached and fell to the ground. The results showed that throughout the study, the decomposition rate of spring-shed litter was consistently faster than that of autumn-shed litter. Notably, the lignin content in spring litter decreased significantly during the winter standing period, while no such change was observed in autumn litter. This suggests that photodegradation played a crucial role in lignin decomposition during the winter, facilitating the subsequent breakdown of plant litter. These findings highlight the significant differences in decomposition rates between litter shed in autumn and spring.

Introduction

Litter decomposition is crucial for nutrient cycling, soil fertility, and carbon dynamics, with decomposition rates largely determined by litter quality and microbial communities (Bradford et al. 2016). The state of plant material, whether standing dead or detached on the soil surface, significantly influences decomposition (Lin and King 2014). In grasslands, plants often retain dead material as standing dead for extended periods, exposing it to harsh environmental conditions that inhibit microbial activity (Wang et al. 2017). However, the role of the standing-dead phase in decomposition, especially processes like lignin photodegradation, remains underexplored. Understanding these dynamics is critical for comprehending nutrient cycling, particularly in grazed grasslands, where management practices influence the standing-dead phase.

Microorganisms in soil and vegetation are vital to litter decomposition, but those attached to litter often face drier conditions and greater temperature fluctuations, which reduce their activity and slow decomposition (Lin and King, 2014; Wang et al. 2017). In addition to microbial decomposition, abiotic processes such as leaching, physical fragmentation, and lignin photodegradation also play important roles (Rahman et al. 2013; Yanni et al. 2015). Solar radiation promotes photodegradation, making lignin more accessible to microbes for further decomposition (Lin et al. 2015; Austin et al. 2016). In sunlit areas, photodegradation dominates, while microbial decomposition is more significant in shaded regions (Lin and King 2014). For example, in semi-arid grasslands and alpine meadows, suspended litter decomposes faster than litter on the soil surface (Wang et al. 2021; Lin and King 2014). Although photodegradation is not the only factor, its contribution to litter decomposition is significant.

The natural grasslands of northern China, covering 2.82 million square kilometers, play a crucial role in supporting pastoral activities and maintaining ecological stability (Li et al. 2019). These grasslands are predominantly dominated by species like *Leymus chinensis* and *Stipa grandis*, which have tall, erect stems that persist long after senescence in autumn (Giese et al. 2009; Peng et al. 2014). The region's land use practices include grazing, mowing, and fencing, with grazing, especially rotational and continuous grazing, being the most common management strategy (Li 1989; Baoyin et al. 2014; Zhang et al. 2020). During the non-growing season, grazing and trampling accelerate litter accumulation and shorten the standing-dead phase (Mor-Mussery et al. 2021). Consequently, in grazed grasslands, dead plants bypass the standing-dead phase and fall directly to the soil surface. In contrast, ungrazed grasslands may see dead plants remain standing through the winter and fall in the spring or summer when grazed. This highlights the significant role of trampling in litter decomposition, as it accelerates litter burial and promotes the formation of a soil-litter interface (Liu et al. 2018; Wei et al. 2021).

To explore the effects of the standing-dead phase on litter decomposition, we conducted a one-year experiment in central Inner Mongolia, comparing the decomposition of litter from *Leymus chinensis* and *Stipa grandis* shed in autumn and spring. We hypothesized that: (1) plant residues that undergo the standing-dead phase decompose more slowly during this period than those that fall directly to the soil surface after senescence; and (2) residues that experience the standing-dead phase, due to changes in lignin content, are more readily degradable and decompose more rapidly than fresh litter.

Methods

The study was conducted at the Grassland Ecosystem Research Station of Inner Mongolia University, located 60 km northeast of Xilinhot, Inner Mongolia, China (116°31′E, 44°15′N, elevation 1146 m). The region has a temperate semi-arid climate, with an average annual temperature of 2.8°C and precipitation ranging from 280 to 350 mm, mostly occurring from May to September. The native steppe is dominated by *L. chinensis* and *S.* grandis.

The experiment was conducted in a 50 m × 50 m grassland plot, which had been used for grazing but had remained ungrazed for six years prior to the study in 2018. In November 2017, we collected senescent leaves and stems from two dominant grass species, *L. chinensis* and *S. grandis*. The collected litter was air-dried at room temperature, then portioned into 10 g samples and placed in nylon mesh bags (15 cm × 20 cm, with a 1 mm mesh size). The bags were divided into two groups to simulate the decomposition processes of autumn and spring litter. The first group, termed "surface litter" consisted of material placed directly on the soil surface, representing the decomposition of autumn litter. The second group, referred to as "standing litter," was initially suspended 0.1 meters above the ground for seven months over the winter before being placed on the soil surface to simulate the spring decomposition process, following the standing-dead phase. Litter samples were collected at the 7th and 12th months of decomposition. This study involved placing both autumn and spring litter from all species in five replicates, using a fully random design. This resulted in a total of 40 litterbags, calculated as: 2 plant species (*L. chinensis* and *S. grandis*) × 2 litter types (autumn *vs.* spring) × 2 sampling points（7months and 12 months） × 5 replicates. The concentrations of nitrogen (N%) were quantified using an elemental analyzer (Vario MACRO cube, Elementar, Germany). Neutral detergent fiber content (NDF%) and acid detergent fiber content (ADF%) were measured using an ANKOM 2000 Automated Fiber Analyzer (A2000i, Fiber Analyzer, American). The digestion of acid detergent lignin (ADL%) in 72% H_2SO_4 solution, obtained by the lignin sulfate method, was used to analyze the lignin content of ADF fractions (Trofymow et al. 2002).

Results

Changes in plant litter mass

For both species (*L. chinensis* and *S. grandis*), the mass of both spring and autumn litter decreased significantly during decomposition. In the first 7 months, the remaining mass of spring litter from *L. chinensis* was significantly higher than that of autumn litter (P<0.05), while no significant difference was observed between spring and autumn litter for *S. grandis* (P>0.05). By the 12th month, the remaining mass of spring litter from *L. chinensis* was significantly lower than that of autumn litter, while no significant difference was observed between the spring and autumn litter of *S. grandis* (P>0.05).

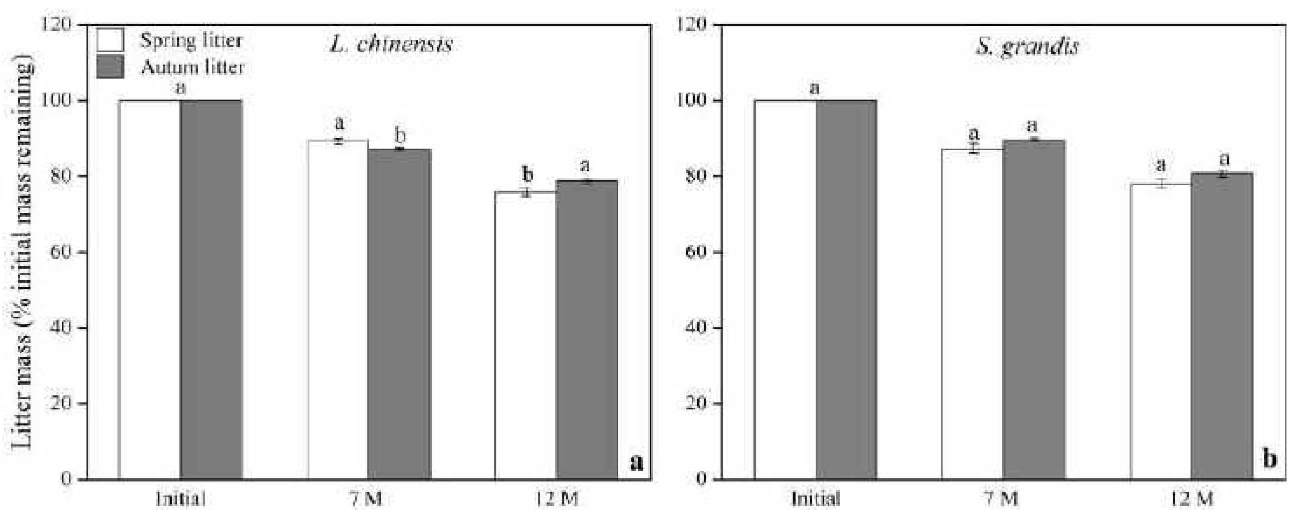

Fig. 1. Remaining litter mass (RM) of *L. chinensis* (a) and *S. grandis* (b) over the one-year experimental period. Bars represent means, and error bars indicate standard error. The spring litter was suspended as standing dead for the first 7 months (winter) under ambient conditions (7M) before being placed on the soil surface for the remainder of the one-year period, whereas the autumn litter was directly placed on the soil surface for the entire decomposition period. Different lowercase letters indicate significant differences between spring and autumn litter within the same period at P < 0.05.

Changes in litter quality

In the first 7 months, nitrogen content in spring litter of *L. chinensis* and *S. grandis* significantly decreased (P<0.05), while nitrogen content in autumn litter showed an increasing trend. After one year of decomposition, nitrogen content in all litter types significantly increased (P<0.05) (Table 1). Meanwhile, hemicellulose and cellulose contents in both spring and autumn litter continuously declined over the course of decomposition. Additionally, during the first 7 months of the standing-dead phase and the subsequent surface litter phase, lignin content in spring litter of both *L. chinensis* and *S. grandi*s significantly decreased (P<0.05). In contrast, lignin content in autumn litter of *L. chinensis* significantly increased throughout the decomposition period. After one year of decomposition, lignin content in spring litter was significantly lower than that in autumn litter (P<0.05) (Table 1).

Discussion [Conclusions/Implications]

The decomposition rate of litter varies significantly across different ecosystems, influenced by litter quality, decomposer communities, and environmental conditions (Bradford et al. 2016). Numerous studies have highlighted the impact of lignin content on the decomposition rate of litter (Liao et al. 2022). Our results show a significant positive correlation between litter decomposition rates and the contents of hemicellulose, cellulose, and lignin, which is consistent with previous studies (Duan et al. 2018; Wang et al. 2022).

Table 1 Nitrogen (N) content, hemicellulose, cellulose, and lignin content in initial litter (Initial) and subsequent treatments of *L. chinensis* and *S. grandis*. Values are means ± standard error. Different letters within a row indicate significant differences (P < 0.05).

Relationships of litter decomposition rate with litter quality

The remaining mass of litter showed significantly positively correlated with the contents of hemicellulose, cellulose and lignin (P<0.05), but it was no significant correlation with nitrogen content (P>0.05) (Fig. 2).

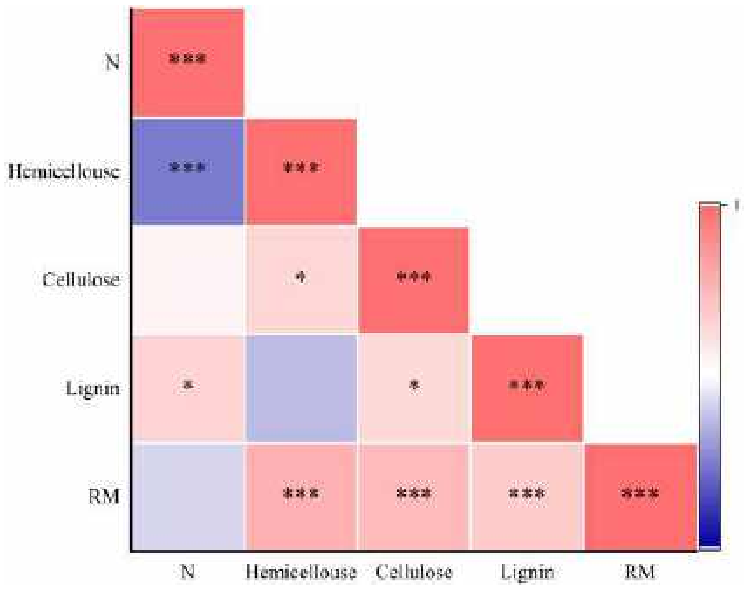

Fig. 2. Heatmap of the correlation between litter mass remaining and litter quality

In addition to soil microbial communities, solar radiation also plays a significant role in litter decomposition (Wang et al. 2021; Jiang et al. 2022). We found that after 7 months of exposure, spring litter experienced greater mass loss than autumn litter, both at the 12th and 17th months. This indicates that spring litter, having undergone the standing-dead phase, decomposed faster than autumn litter, which had not. This result is in line with previous studies, which suggest that the retention of standing-dead biomass promotes subsequent decomposition in the soil surface (Day et al. 2015; Angst et al. 2017). Moreover, after 7 months of winter exposure to sunlight, spring litter decomposed more rapidly than autumn litter, likely due to photodegradation. Lignin, a key component of plant cell walls, is difficult to biodegrade (Huang et al. 2022), but it is highly susceptible to photodegradation when exposed to UV and blue-green light, promoting subsequent microbial decomposition (King et al. 2012; Austin et al. 2016). Our data show that after 7 months of exposure, the lignin concentration in spring litter decreased, whereas in autumn litter, lignin concentration increased. A similar trend was observed in the decomposition of *S. grandis* litter. This suggests that the significant breakdown of lignin enhances microbial decomposition, leading to a faster decomposition rate in spring litter than in autumn litter.

Our study suggests that the enhanced photodegradation of refractory structures in standing litter, compared to that in litter lying on the ground, likely explains why the standing-dead phase contributes to overall faster decomposition. Our findings highlight the importance of considering litter status (standing dead or lying on the soil surface) and factors like grazing that alter this status when modelling or calculating litter decomposition in semi-arid grassland ecosystems.

Restoration techniques of rangelands in the hyper-arid area of central Saudi Arabia

Weijerman, M[1]; Al-Harigi, TA[1]; Al-Shlash, KS[1]; Al-Zahrani, AM[1]

[1]Imam Abdulaziz bin Mohammed Royal Reserve Development Authority, Riyadh, Saudi Arabia

Key words: Reintroduction; assisted regeneration; rainwater harvesting; tilling

Abstract
Restoration efforts are influenced by previous human use and management actions which have contributed to different levels of habitat degradation and biodiversity loss. We discuss the monitoring and evaluation of restoration activities tailored to study sites in two adjacent Royal Reserves located in the hyper-arid desert area of central Saudi Arabia. One reserve has been fenced for over 40 years with limited public use. The other was open to life stock grazing until recently and has over one million visitors each year in the winter. Ecological assessments in both reserves identified the extent and scale of degradation which informed restoration priorities. Planned restoration techniques were based on nature-based solutions suitable for these areas. In the more ecological intact reserve, restoring the ecological dynamics was the main focus through the reintroduction of native grazers, i.e. gazelles and oryx. Restoration activities of native flora included rainwater harvesting on an experimental scale. In the open reserve, restoration primarily focuses on restoring the floristic composition. Here we implemented a pilot study to assess if tilling the compacted top crust facilitated germination and establishment of plants. Monitoring the impacts of restoration efforts is crucial to be able to evaluate if targets are met. We implemented various monitoring techniques to assess changes in vegetation structure and composition, and spatial abundance and presence of newborns of reintroduced animals. Results were used to evaluate if reintroduced animals established themselves and if assisted regeneration led to the germination and growth of plants in the pilot studies. This paper highlights the preliminary empirical assessments of these different restoration techniques for rangelands in hyper-arid areas.

Introduction
In the current Anthropocene era, unsustainable use, habitat destruction, introduction of invasive species and overexploitation has led to the alarming loss of biodiversity and reduced ecosystem services (Díaz et al., 2019). Safeguarding habitats is one of the most effective conservation strategies for combatting this biodiversity crisis and desertification (Barth, 1999). Typically, habitat restoration efforts focus on the re-establishment of plant communities. Restoration efforts should, however, integrate the restoration of both key plant and animal groups, especially those animals that change habitat directly, such as herbivores, and

indirectly, such as carnivores (Suraci et al., 2016). Re-establishing plant-animal interaction and trophic complexity is crucial to achieving all the ecosystem services nature provides, including nutrient cycling, soil formation, pollination, and seed dispersal that rely on the plant-animal dynamics.

Hyper-arid, arid, and semi-arid lands form about one third of the Earth's terrestrial surface. These lands contain unique biological and cultural diversity, and biodiversity loss can have a disproportionate impact on these ecosystems due to low redundancy and a high risk of trophic cascades (Zhang et al., 2023). The Kingdom of Saudi Arabia hosts 32.5% of the global hyper-arid areas and hence plays a significant role in the conservation of biodiversity in these ecosystems (Keith et al., 2022). In recent years, contributing to global commitments, large areas have been established as protected areas in Saudi Arabia with the aim to have 30% of its terrestrial area protected by 2030. Two adjacent protected areas established in 2018 are the King Khalid Royal Reserve (KKRR) and the Imam Abdulaziz bin Mohammed Royal Reserve (IARR). They are located in central Saudi Arabia, and the area is characterised by low rainfall, high diurnal and seasonal fluctuating temperatures with predominantly sandy, gravelly soil and low levels of nutrients. Rangeland vegetations consist of slow growing perennials and ephemeral plants with long-lived soil seed banks. Understanding the full complexity and integrity of the ecosystem as well as the sources of degradation (prior land use) and implemented restoration practices will enhance the success of habitat restoration efforts (Atkinson et al., 2022). An ecological assessment using the Recovery Wheel and a 5-star scale assessment approach (Mcdonald et al., 2016), is a widely used tool and was implemented in each reserve to assess the integrity of the ecosystem and to prioritize restoration efforts (IARDA internal report).

In this study, we highlight different restoration strategies in the two reserves. In KKRR we discuss the reintroducing of key herbivores and in both reserves we conducted a pilot study to increase the native plant community through assisted regeneration (McDonald et al., 2019). Specifically, in KKRR we assessed if the reintroduced ungulates remained close to the release site and if they produced offspring, two indicators for establishment success. Additionally, we assessed if rainwater harvesting pits increased the germination of annuals from the seed bank. In IARR, we assessed if tilling the compacted top crust resulted in the initial growth of annuals and the subsequent establishment of perennials.

Methods

The study areas are within KKRR and IARR, approximately 100 km northeast of Riyadh. KKRR is 1,160 km^2 and has four main habitats, the pediplain, plateau, wadi (valley) and catchment. The pediplain is about 250 km^2 and contains numerous catchment areas. It is bordered by the escarpment of the Urumah Mountain plateau to the east and at all other sides by roads and has been fenced for over 40 years. This area was used to reintroduce 242 native ungulates between 2021 and December 2024. The rainwater harvesting (RWH) pilot study of 4.35 ha was also located in this pediplain, on a slightly sloping surface at the foothills of the escarpment with pits of ~ 1 x 1.5 m and 10-15 cm deep. IARR is 11,300 km^2 and has six main habitats, the pediplain, plateau, wadi, catchment, sand plain, and sand dune. This reserve harbours 13 catchment areas with Rawdhat Khuraym being the largest with eight main wadis draining into it and is a very popular destination for people in the winter. Adjacent to Rawdhat Khuraym, was the experimental tilling area of 680 ha.

In total nine Arabian oryx, one sand gazelle and two Arabian gazelles were deployed with satellite-based GPS collars to assess site fidelity. The collars were programmed to drop off after one year. Camera traps were positioned at 53 locations in the pediplain next to water sources, burrows, and on wildlife trails to estimate newborn animals and relative occupancy. Relative occupancy was calculated as the number of locations with species-specific observations divided by the total number of camera locations. Since water is a limiting resource, locations next to water sources likely attract animals and are therefore not representative of capture rates and were excluded from the relative occupancy calculations. Newborn individuals were identified by the distinctive brown collar for oryx and absence of horns for gazelles. The monthly maximum number of newborns at each location was recorded.

The succession of plants in the RWH pits was monitored by recording the percentage cover and species abundance every two months at 60 randomly selected pits and adjacent control sites from November 2023 to July 2024. For the tilling experiment in IARR, we collected data using the line-intercept method along a 100-m transect placed in the furrows at five sample sites in each of the three experimental plots (tilling to 5, 10 and 15 cm in plot A, B, and C resp.) and three sample sites in a nearby control plot. The first transect location was randomly selected as being the 10th furrow from the eastern edge. The following four sample sites were approximately five furrows to the west. All germinated plants were recorded under and to 10 cm left and right of the transect line from January 2023 to June 2024. Observed species in both pilot studies were classified to the highest taxon possible and into their life span as annual or perennial.

Results

Establishment of reintroduced ungulates in KKRR

Based on the GPS data from the collars, the three gazelles predominantly stayed in the catchment areas of approximately 60 km^2 close to the release site with the one sand gazelle travelling a maximum distance of 10 km and the male Arabian gazelle moving in and out of KKRR to the adjacent IARR but staying within a few km from the border of KKRR. Of the nine tracked Arabian oryx, four individuals climbed up the escarpment and left KKRR, they followed the wadi into IARR, three of them died in IARR. Three other individuals also climbed up the escarpment but stayed in the wadis on the plateau of KKRR, and one died. The other two individuals predominantly stayed within 50 km^2 along the escarpment just north of the release site (Fig 1).

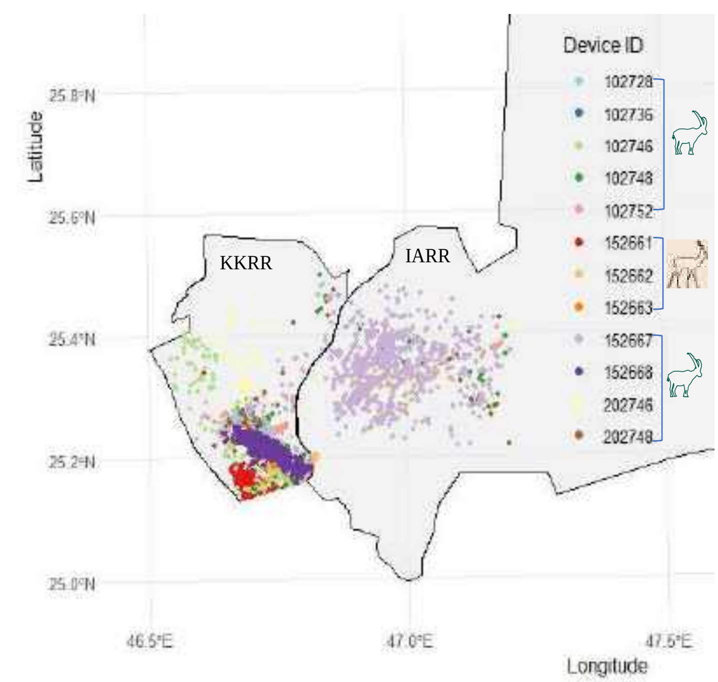

Figure 1. Movement patterns derived from GPS data of 12 tracked individuals for one year. Device ID 15661 is a sand gazelle, 152662 and 15663 is Arabian gazelle and the other nine are Arabian oryx.

Spatial occupancy data from the camera trap data showed that oryx and sand gazelles roamed widely but the Arabian gazelle was most restricted in its relative occupancy (Table 1). Camera trap data showed newborns of all species.

Table 1. Relative occupancy (rel. occ.) and demographics per species for the period 2021-2024

Characteristic	Arabian oryx	Sand gazelle	Arabian gazelle
Reintroduced	45	120	11
No of cameras with observations (rel, occ.)	19 (56%)	17 (50%)	3 (9%)
No of newborn	9-14	40-48	1
No of mortalities	4	11	5*

*4 assumed, 1 confirmed

Rainwater harvesting in KKRR

Creating a shallow pit to collect rainwater had a positive effect on the germination of predominantly annuals (Fig. 2). The mean cover of plants increased from approximately 3% at the start of the experiment in November 2023 to 21% in the following four months, then slightly decreased to 19% in May and then decreased sharply to 6% in July when most remaining plants were dry. The control area never showed more than 1% cover. The abundance had a slightly different pattern as it steeply increased from 5 plants to 40.6 plants in January but only 8% were perennials. Afterwards, abundance steadily decreased to 32.4 plants in March, 17.0 in May, and finally dropped to 4.5 in July of which 100% were perennials predominantly *Zygophyllum indicum*.

Figure 2. Succession of plants in the rainwater harvesting pits

Tilling in IARR

Tilling the top crust led to germination and growth of various species of plants including perennial plants. The number of unique species recorded was 39, about three times higher compared to the control with just 12 species. The great majority of the observed species (84%) were herbaceous plants, 10% were shrubs and 6% grasses. No seedlings of trees were observed. The vegetation was dominated by annual plants of which *Malva neglecta* was most represented both in abundance and cover (Fig. 3). The perennial shrub *Zilla spinosa* was the second most represented. Tilling to a depth of 15 cm (plot C) resulted in the highest cover and abundance. The species *Erucaria hispanica* and *Zilla spinosa* were responsible for the high cover in May. Both species were still present in June but had partially died off in plot B resulting in the subsequent decline in cover. However, in plot C they did establish and flourished to at least double their cover in June (Fig.2). A year later, the same trend in cover is still present with C having the highest cover and abundance, but the composition has changed to only perennials in all plots.

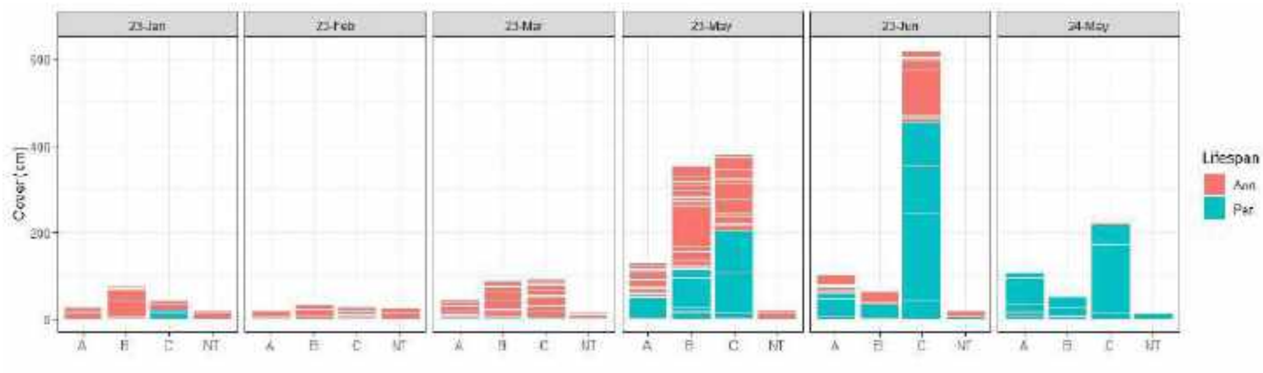

Figure 3. Trend in vegetation cover by lifespan and per treated plot (NT=No Treatment and is the control area)

Discussion

Monitoring and evaluation are essential to determine whether restoration projects are successful so that we achieve the intended benefits (Otiendo, 2019). These assessments also help to ensure that project and program resources are used efficiently and effectively. Using complementary monitoring techniques can provide a more comprehensive evaluation as the GPS tracking devices in combination with the camera traps demonstrated for the assessment of indicators of establishment of reintroduced animals in this study. The data showed newborn of all reintroduced species indicating that KKRR can sustain pregnancies. Additionally, results showed the high site fidelity of gazelles but less so for oryx as they did move out of the pediplain. These roaming oryxes either established them on the plateau of KKRR or followed the wadi to the adjacent IARR, underscoring the importance of safe wildlife corridors between the reserves. This roaming behaviour could indicate that space was a limiting factor in retaining animals at release sites since food resources were plentiful (IARDA Carrying Capacity internal report). With the many reintroduction programs currently on-going in the Kingdom of Saudi Arabia (Alatawi, 2022), we believe these results can inform other programs of the benefits of monitoring using different techniques to evaluate success.

Natural generation is a preferred restoration method as it mimics nature and leads to a sustainable establishment of plants following the natural succession processes after external threats (grazing, logging, off-roading) are removed. However, natural generation is only possible when the ecosystem is intact and fully functional. In our study sites, assisted regeneration was implemented and monitored for 6 months to 1 year. Both pilot studies showed rapid germination of annuals after rainfall with the establishment of some perennials indicating the presence of viable seeds in the seedbank and the outset of restoring native vegetation. Other factors could also have contributed to this success, such as the closeness to surrounding vegetation and topography. Also, the rougher surface that resulted from the tilling and the creation of shallow pits could have trapped more windblown seeds which could explain the higher germination in both pilot studies. Conducting pilot studies to evaluate the appropriateness of the used technique is an important step before implementing it on a large scale.

Ecological regeneration in a low rainfall environment using long-rest grazing management

Kerr, JG[1]

[1] Buckleboo Station, Kimba, South Australia

Key words: Drought; resilience; sustainability

Abstract
In 2020, after 3 years of severe drought which heavily impacted the productivity of Buckleboo Station, we commissioned the design of a detailed 5-year Ecologically Sustainable Rangelands Management (ESRM) Environment Plan.

Buckleboo Station has fast-tracked the ESRM Environment Plan, with the added benefits of producing more lamb in a shorter timeframe and championing innovative and industry-leading regenerative grazing practices. The station has changed from set stocking to long-rest grazing. The dorper ewes are now running in one mob. The station is sub-divided into 6 grazing areas of approximately 40,000 acres, each area being grazed for 3 months followed by 15 months complete rest. Every watering point has a trap yard around it. More watering points are being prepared to ensure even grazing of each area.

Badly degraded and scalded country has been treated with a crocodile seeder, to divot the surface, aiming to slow down the flow of water and re-hydrate the soil. These areas will be closely monitored to determine if the native grasses return.

New technology has been adopted for key project outcomes: Ceres satellite tags for livestock movement monitoring, NDVI satellite monitoring, satellite monitoring of water storage tanks, and soil probes to measure moisture available to plants in a range of different soil types. Twelve monitoring sites are being constructed across the station to monitor the changes in vegetation.

In October 2021, the Emissions Reduction Fund (ERF) approved a large carbon project (over a million tonnes of carbon sequestered) for Buckleboo Station. This project is managed by Australian Integrated Carbon. More fencing will be constructed in the future to control the grazing of livestock. Our key action is managing the carbon project with long-rest grazing and not destocking the carbon project areas.

Introduction
Buckleboo Station endured a severe three-year drought 2018 – 2020, that heavily impacted the station's ability to efficiently and sustainably produce dorper lambs. In early 2019, management decided to urgently

address these issues by improving long term sustainability through regenerative grazing, improved water management, improved monitoring and drought resilience activities. Buckleboo Station commissioned the design of a detailed 5-year Ecologically Sustainable Rangelands Management (ESRM) Environment Plan through Contour Environmental and Agricultural Consulting. The Buckleboo Station ESRM Environment Plan is based on the ESRM project tool that follows the principles of regenerative grazing to maximise the restoration of biodiversity, water and nutrient cycling and energy efficiency within the local ecosystem. The ESRM methodology was selected for the following reasons:

• Involvement of a rangeland ecologist to build a better understanding of how different actions would impact the environment.

• The process aligns the goals for the property and the business with the capability of the land.

• Proven track record of success in Western Australia with pastoralists and mining companies.

In 2020, Buckleboo Station engaged the services of Contour Consulting to prepare a detailed ESRM Environment Plan in conjunction with the existing business plan. This is a new way of planning as far as the pastoral industry is concerned. Contour Consulting has used satellite imagery and GPS mapping to locate key problem areas across the station and develop strategies to address them. Additionally, as part of the initial commencement of the ESRM Environment Plan, we used an innovative mapping process to locate deep underground water using electromagnetic data sets. The concept of long-rest grazing on a pastoral property is quite innovative in South Australia.

Sustainability improvements on Buckleboo will be achieved through activities that will:

• Increase ground cover from 20% to 70%. Ground cover of 70% will reduce water and wind erosion to almost nil. The increased ground cover also has significant production advantages due to increased water infiltration, good microbial activity, improved soil structure and buffering from extreme temperatures. We anticipate that it will take several years to reach such levels of groundcover in an arid environment.

• Regenerate the grasslands which have been badly degraded due to overstocking and under grazing by sheep and kangaroos. These grasslands are essential in the dietary mix for our sheep so once the higher quality and more palatable native grasses return this will provide better quality feed. Sheep require the correct amount of protein and energy in their diet to maximise production. The chenopod shrubland is very high in protein and the grasses provide the energy component. Historically the grasses have been overgrazed leaving an imbalance in the diet which has caused low production.

• Re-generate the Chenopod shrublands. The rest period (approx. 15 months) will allow these bushes to re-foliate and recover much more quickly. The areas around watering points require close monitoring as they have been badly affected due to the long-term effects of heavy grazing pressure. It is important to keep the chenopod shrublands healthy as these plants are a tremendous feed reserve through dry times and also help protect the landscape from wind erosion in dry periods.

• Introduce and install more watering points so that a much larger area of land can be grazed, allowing the flock to grow by a predicted 60%, and ensuring the grazing areas will be grazed more evenly.

• Provide opportunities for Carbon Farming. Vegetation assists the retention or accumulation of soil carbon. There is significant interest in the potential for soil carbon projects across the Australian rangelands. While sequestration rates are generally low, there is a large area available, providing the opportunity for substantial abatement. Unfortunately, at this time, the significant cost of establishing projects, undertaking the required soil sampling at a suitable scale and monitoring project delivery and change require further developments before a methodology can be adopted in pastoral or rangeland areas. We will be in a good position to immediately apply this methodology once it has been established.

Methods

The ESRM process works closely with pastoralists to develop an ecologically sustainable, profitable and respected pastoral community. It enables land lessees to receive support to develop whole of property plans that include mechanisms for reporting on rangeland condition, implementing rehabilitation works, managing threats, and coordinating landscape and catchment approaches to maintain and improve vegetation cover. ESRM planning at Buckleboo Station incorporated grazing and fire management with erosion mapping and erosion control works to improve the rangeland condition of the property. A desktop analysis of Buckleboo was carried out using data from the South Australian Government, Australian Government, Trove and the Rainman Streamflow software package. Available information was used to undertake a preliminary landscape function assessment, characterise the flora, fauna and vegetation present, and to understand the context of management history and previous work carried out on Buckleboo and in the surrounding area. Maps of infrastructure, land systems and satellite imagery were prepared for use in discussions during a station visit which occurred between the 24th – 27th October 2020. It was attended by James Kerr and James Wright (Paroo Pastoral) and facilitated by Richard Marver (Contour Consulting). During the visit, detailed discussions around the prepared maps provided the framework for the infrastructure development plan. A preliminary assessment of the condition of Buckleboo Station and areas of interest was made based on discussions with the property owner. Participants were asked to identify these areas on a map, and to document their own knowledge and observations regarding the environmental condition of the station. Targeted on-ground and aerial surveys (using an Unmanned Aerial Vehicle or drone) of areas of interest and proposed areas of infrastructure development were then conducted.

The proposed grazing strategy for Buckleboo is to have six secure paddocks with reliable (12 month) water supply that encompass the entire station area. To achieve this, dams will be supplemented with tanks and troughs supplied by several bores and a pipeline. The paddocks are created by subdividing the current infrastructure to create paddocks that encompass similar land types. The paddocks will be grazed under a rest-based system giving each paddock approximately 3 months grazing with 15 months rest. A more intensive rotation may be implemented in the future dependent on the success of the proposed 6-paddock rotation in encouraging pasture regeneration, and how well it fits into the management schedule for the station.

Two grassland regeneration paddocks will be created which will exclude kangaroos and wallabies and which, after being rested for a season, will be grazed conservatively during lambing (May/June). The existing paddocks near the homestead will be strategically grazed with sale/young stock that will provide them with a short graze, followed by a longer rest period. Any mechanical regeneration works that are carried out within the paddocks will have a greater chance of success if they are rested from grazing until vegetation has colonised the area. Resting these historically heavily utilised areas will speed their recovery. A rest-based grazing system will provide the most amount of benefit to the highly productive grassland areas of the lease. A short, heavy graze period applies the same level of grazing pressure to an area as a long, light graze period, while maximising the length of the rest period. This will result in a healthier root system, and a more resilient tussock that has a better chance of surviving long dry spells.

As part of the ongoing project, we will be using the following new technology:

- NDVI satellite monitoring; we have engaged CIBO Labs to monitor the increase in biomass using NDVI technology.
- Ceres satellite tags: These tags are the world's first real time satellite tracking ear tags for livestock. The tags not only indicate the location of animals and allow lifetime traceability but also provide health information such as temperature and elevated heart rate. Livestock movement data will help us understand the movement/concentration of sheep in a grazing cell in line with our objective to encourage more even utilisation of the available grasslands and Chenopod shrublands by provision of additional water points.
- Satellite water monitoring of storage tanks: These monitors are designed to improve productivity and efficiency on pastoral stations. The daily reporting enables the station manager to monitor the amount of water stored and to identify issues such as major leaks in the system very quickly. Monitors also increase productivity as there is no need to drive around watering points every day.
- Soil probes: Soil probes inserted 1 m into the ground enable us to understand the amount of moisture that is available to the plants in a range of different soil types.

Results

The changes to the landscape biomass are observed with satellite images from Cibo Labs (Figure 1). These images are acquired in January each year. 2020 was the end of a three-year drought, 2021 was an average rainfall year, however, the recovery was slow due to low levels of biomass, 2022 was a higher-than-average rainfall year with 485mm, 2023 was another average rainfall year, however, the good rainfall in 2022 is reflected in the satellite image, 2024 was a very dry year with 175mm recorded. The biomass continued to improve and the image for January 2025 is the evidence of the significant increase in biomass since 2020.

Evidence of the success of the program to date is provided by the following observations on landscape changes by James Thiessen and Kylie Moritz (Australian Integrated Carbon) and Richard Marver (Contour Consulting) in 2022.

James Thiessen and Kylie Moritz:

- Traditionally, trees and shrubs that are not observed regenerating on pastoral stations were observed - notably
  - Western myall *(Acacia apyrocarpa)* estimated to only regenerate 5 times per century – after massive rainfall. Readily grazed by sheep and rabbits. Young recruits were observed
  - Pin bush (*Acacia burkittii*) – in the book Acacia's of South Australia (D.J.E Whibley & D.E Symon 1980) the authors predicted that within a century A. burkittii will be close to extinction where both rabbits and sheep occur together. So, it was great to see this species regenerating at multiple sites across the station
  - Bullock Bush *(Alectryon oleifolius)* – new growth shoots observed suckering off old established trees – Bullock Bush is a favoured plant by all herbivores
  - Other notable species regenerating at various sites were the native apricot (*Pittosporum angustifolium*), Black Oak *(Casuarina pauper),* Sheep Bush *(Geijera linearifolia)*, Sugarwood (*Myoporum platycarpum*)

- Buckleboo's road to recovery after being heavily grazed last century is looking very promising. Planned and well executed rotational grazing is enabling the regeneration of many trees and shrubs. This was observed alongside a very healthy ground cover full of grasses, forbs and an amazing-looking soil crust.

Figure 1. Increase in biomass using CIBO Lab, NDVI technology

Richard Marver:
"Since my first visit to Buckleboo I have been privileged to be able to witness the amazing recovery and transformation of the landscape through the implementation of a regenerative management plan. The plan has allowed the station to capitalise on the recent good seasons. The aspects of the improvement that I have been most pleased to see are the recruitment and establishment of the palatable saltbush species within the lake country, and the universal improvement in groundcover due to increased abundance of perennial grasses, particularly in the naturally Spear Grass dominated vegetation areas. With continued regenerative management I expect this recovery to result in a far improved landscape resilience through the next dry season".

Ecohydrological resilience of sagebrush rangelands following tree encroachment

Williams, CJ[1]; Phelps, EL[2]; Johnson, JC[3]; Polyakov, VO[4]; Rutherford, WA[4]

[1]United States Department of Agriculture, Agricultural Research Service, Northwest Watershed Research Center, 251 E Front St., Suite 400, Boise, ID 83702, USA, jason.williams@usda.gov; [2]University of Arizona, School of Natural Resources and the Environment, 1064 E Lowell St, Tucson, AZ 85721, USA; [3]N3B Los Alamos, 1200 Trinity Dr, Suite 150, Los Alamos, NM 87544, USA; [4]United States Department of Agriculture, Agricultural Research Service, Southwest Watershed Research Center, 2000 E Allen Rd, Tucson, AZ 85719, USA; [5]United States Department of Agriculture, Agricultural Research Service, Southwest Watershed Research Center, 2000 E Allen Rd, Tucson, AZ 85719, USA

Key words: Erosion; Juniper; Pinyon; Runoff; Woody Plant Encroachment.

Abstract

The expansion and contraction of pinyon (*Pinus* spp.) and juniper (*Juniperus* spp.) woodlands in the western US is a broadly occurring phenomenon. The sagebrush (*Artemisia* spp.) vegetation type is vulnerable to woodland encroachment and much of the western US sagebrush domain has transitioned to PJ woodlands. These ecological state changes alter plant community structure and function and delivery of ecosystem services. This study applied a set of vegetation, soil, and rainfall simulation experiments over a range of scales (point to hillslope) to evaluate the ecohydrologic and erosion impacts of a shrubland-to-woodland ecological state transition on sagebrush rangelands on coarse-textured soils. The transition shifted the plant community from a fine to coarse structure and increased the connections between bare areas. Declines in shrub and herbaceous covers associated with pinyon and juniper woodland-encroachment increased the connectivity of runoff and sediment sources. Bare patches in the woodland contributed ample runoff and sediment at the fine spatial scale (0.5 m^2) that facilitated flow paths and erosion over the hillslope scale. Overall, the shrubland-to-woodland transition marked substantive declines in cover and enhanced connectivity of runoff and sediment sources.

Introduction

Pinyon (*Pinus* spp.) and juniper (*Juniperus* spp.) [PJ] woodlands substantially increased in density and distribution throughout much of the western US after European settlement, and continue to expand into rangeland plant communities due to intensive land use, historic fire exclusion, and atmospheric CO_2 enrichment. The encroachment of sagebrush shrublands by pinyon and juniper is commonly associated with degradation of understory vegetation and groundcover (Miller et al., 2000), impaired hydrologic function

(Williams et al., 2014, 2022), and amplified soil loss (Pierson et al., 2007, 2010; Roundy et al., 2017). The extensive conversion of sagebrush rangelands to PJ woodlands throughout the western US merits a fundamental understanding of key ecological processes regulating these ecosystems. A primary tenant in pinyon and juniper removal to restore sagebrush vegetation is to implement treatments in the early stages of woodland encroachment, while sagebrush and native perennials remain the dominant vegetation (Miller et al., 2014; Roundy et al., 2014). Further, treatment implementation should target sites where specific objectives such as sagebrush and perennial grass retention/recruitment and reduced runoff and erosion risks are plausible. Decisions on implementing sagebrush restoration treatments to reduce pinyon and juniper require baseline data and understanding on the structure and function of these communities across the diverse landscapes in which they occur.

The purpose of this study was to evaluate the ecohydrologic and erosion impacts of shrubland-to-woodland plant community transitions on sagebrush rangelands on coarse-textured soils. The primary objectives were to quantify (1) vegetation and ground cover conditions at the hillslope scale (990 m^2 plots) and (2) vegetation and ground cover, soil properties, runoff rates, and sediment delivery at the fine spatial scale (0.5 m^2 plots) at a site dominated by sagebrush shrubs (Fig. 1a) and at an immediately adjacent site dominated by pinyon and juniper trees (Fig. 1b). The study sites represent different ecological states (sagebrush shrubland and PJ woodland) of the same ecological site.

Methods

Study area and experimental design

Experiments were conducted at a sagebrush shrubland (Sagebrush Site) and a PJ woodland (Woodland Site) located (~39.8227°N latitude, -114.014°W longitude) at 1850 m elevation approximately 40 km northeast of Kanab, UT, USA. The sites are immediately adjacent to one another on an Upland Loam (Mountain Big Sagebrush) Ecological Site (Site id: R035XY308UT; NRCS, 2024). The sites receive approximately 400 mm of precipitation annually and have an average annual air temperature of 9.9°C. The sites are on S to SE facing aspects with gentle sloping terrain (6-8% slope). Hillslope-scale vegetation and ground cover at each site were measured on three 33 m × 30 m rectangular site characterization plots. Fine-scale plots were randomly located to occur on interspace (areas between shrub and tree canopies), shrub, and tree microsites (Pierson et al., 2010; Williams et al., 2014). Eight interspace and nine shrub fine-scale plots were installed and sampled at the Sagebrush Site. Twelve interspace, six shrub, and six tree fine-scale plots were installed and sampled at the Woodland Site.

Vegetation and ground surface measurements

Hillslope-scale overstory tree cover and understory vegetation and ground cover at each site were sampled on the aforementioned 990 m^2 site characterization plots using a set of tree measures and line-point intercept methods consistent with hillslope-scale methods in Williams et al. (2020a). Foliar and ground cover on each site characterization plot were recorded for 60 points with 50 cm spacing along each of five line–point transects 30 m in length and spaced 5-8 m apart, for a total of 300 sample points per plot. Foliar cover and ground cover were measured on fine-scale plots using point frame methods described by Williams et al. (2020a). Foliar and ground cover on each fine-scale plot were recorded at 7 points with 10 cm spacing along each of 15 evenly spaced (5 cm apart) transects oriented perpendicular (downslope) to the hillslope contour, for a total of 105 points per plot. Litter depth on each plot was measured to the nearest 1 mm at four evenly spaced points (~15-cm spacing) along the outside edge of each of the two plot borders located perpendicular to the hillslope contour.

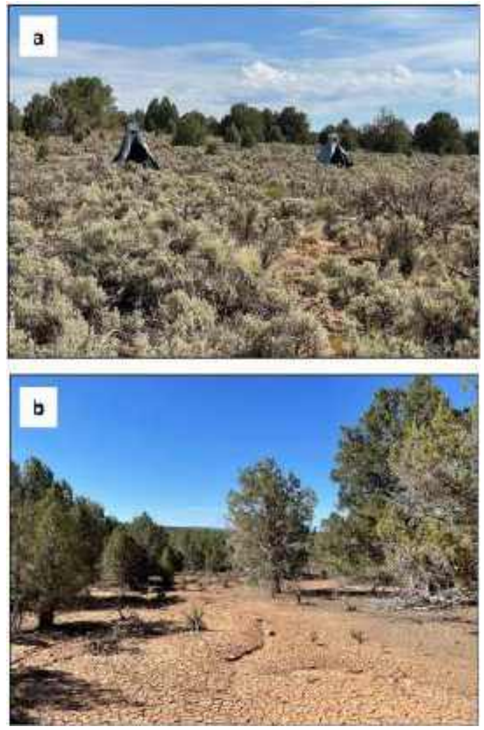

Fig. 1. Photographs of (a) the Sagebrush (*Artemisia* spp.) Site showing rainfall simulators, minimal tree cover, ample understory vegetation, and limited erosion features and (b) the Woodland Site showing an extensive bare intercanopy between tree islands and with visible overland flow paths and erosion features.

Soil characterization and soil property measurements
Soils for each fine-scale plot were characterized using a suite of sampling methods. Three surface soil grab samples (with litter, duff, and biological soil crust removed) were obtained adjacent to each fine-scale plot and transported to the lab in sealed bags for subsequent soil texture analyses. Soil bulk density was sampled immediately adjacent (≈ 15 cm distance) to each fine-scale plot using a 4.8 cm diameter metal core inserted 5 cm into the soil (litter and duff removed). Bulk density for each soil core sample was calculated in the lab as the oven dried (105˚C) soil mass divided by the core cylinder volume (90.5 cm^3). The persistence of soil water repellency (SWR) was quantified immediately adjacent to each fine-scale plot under dry antecedent soil moisture conditions using the water drop penetration time (WDPT) test as described by Williams et al. (2020b). Soils were classified as wettable where WDPT < 5 s, slightly water repellent when WDPT ranged 5 s to 60 s, and strongly water repellent when WDPT > 60 s.

Rainfall simulations
Rainfall simulations were conducted to quantify fine-scale runoff and erosion processes using methods and simulators described by Williams et al. (2020a). Two separate, but sequential 45-min rainfall simulation experimental runs were conducted on each fine-scale plot. The Dry Run applied rainfall at an intensity of 64 mm h^{-1} on dry antecedent soil moisture conditions. The Wet Run applied rainfall at an intensity of 100 mm h^{-1} on wet soil conditions approximately 15 min following the Dry Run. The mean rainfall intensity and cumulative rainfall applied by run type were similar ($P > 0.05$) across all plots. Actual rainfall applied for 45 min simulations averaged 48 mm and 75 mm for the Dry and Wet Runs, respectively. Timed samples of runoff were collected over 1-min to 5-min intervals throughout each 45-min rainfall simulation and were analyzed in the laboratory for runoff volume and sediment concentration as described by Williams et al. (2020a).

Statistical analyses
Data comparisons for hillslope-scale experiments were conducted using two-sample *t* tests. Assumptions of normality and homogeneity of variance were assessed, and transformations were applied where necessary to address deviances. The Mann-Whitney U test was used for comparisons where transformations were ineffective. Comparisons for fine-scale data were conducted via one-way analysis of variance. Post hoc pairwise comparisons were made using Tukey's honestly significant difference test. Assumptions of normality and homogeneity of variance between groups were assessed and addressed through data transformations. The Kruskal-Wallis method was applied for fine-scale comparisons in cases where normality was not achieved through data transformation. All significant effects were assessed at the $P < 0.05$ level.

Results
Vegetation cover assessed in summer 2022 quantified the contrasting cover conditions for the two sites. The Sagebrush Site had minimal tree cover (Fig. 1a) and understory foliar cover of 29% shrub, 9% herbaceous (grasses and forbs), and 8% standing dead covers. Litter (45%) and moss (13%) were the dominant ground covers and bare soil was 36%. The Woodland Site had approximately 32% overstory tree canopy cover and about 68% of the area as sparsely-vegetated intercanopy between trees (Fig. 1b). Total understory foliar cover at the Woodland site was 6% and consisted of minor amounts of shrub (2%), grass (1%), and standing dead (2%) covers. Litter cover and bare soil both approached 40%. Most of the litter occurred underneath tree canopies. Incised flow paths and erosion features were common throughout the intercanopy at the Woodland Site (Fig. 1b).

For the fine-scale, shrub microsites at the Sagebrush Site averaged about two-folder greater shrub foliar (64%) cover relative to shrub microsites at the Woodland Site (33%). The ground surface underneath shrubs at the Sagebrush Site was covered by litter (76% cover) and some moss (10%), woody dead debris (5%), and basal plant (4%) covers. The ground surface under shrubs at the Woodland Site had only 41% litter cover and 34% moss and biocrust, 3% woody dead, and 2% basal plant covers. Litter depth averaged 3-5 mm on shrub plots across both sites. Bare soil on shrub microsites averaged 3% at the Sagebrush Site and 19% at the Woodland Site. Interspaces at the Woodland Site had minimal foliar cover, whereas, interspaces at the Sagebrush Site had 9% total foliar cover. At the Sagebrush Site, interspaces were mostly bare (74% bare soil) at the ground surface but had some litter (11%), mosses and biocrusts (10%), woody dead debris (2%), and plant bases (1%). Interspaces at the Woodland Site were also mostly bare (55% bare soil) but had 36% biocrust cover and 7% litter cover. Litter depths were minimal (1-2 mm) in interspaces at both sites. Tree microsites sampled at the Woodland Site had only 4% total foliar cover but were 100% covered by a nearly 50 mm thick accumulation of litter and woody debris.

Soils were generally similar across the study sites, but bulk density and soil water repellency exhibited microsite-specific patterns at each site. Soils across both sites had a loamy sand texture at the surface (0-5 cm depth). Soil bulk density was 1.69-1.73 g m^{-3} across all shrub plots and woodland interspace plots, lowest for tree plots at the Woodland Site (1.45 g m^{-3}), and highest for interspace plots at the Sagebrush Site (1.99 g m^{-3}). The mineral soil surface was strongly water repellent directly under sagebrush canopies at the Sagebrush Site and under tree canopies at the Woodland Site, but soils were wettable in interspaces at both sites.

Table 1. Mean response variables for rainfall simulations (Wet Run, 0.5 m^2 plots) on wet soil conditions at the Sagebrush (*Artemisia* spp.) and Woodland study sites. Means within a row followed by different lowercase letters are significantly different ($p < 0.05$).

	Sagebrush Site		**Woodland Site**		
	Inter-space	**Shrub**	**Inter-space**	**Shrub**	**Tree**
Wet Run (100 mm h^{-1}, 45 min)					
Antecedent soil moisture (%)	26 a	21 a	26 a	22 a	18 a
Post-simulation soil moisture (%)	33 a	34 a	32 a	34 a	29 a
Mean runoff rate (mm h^{-1})	34 b	5 a	23 b	2 a	19 b
Cumulative runoff (mm)	26 b	4 a	17 b	2 a	15 b
Cumulative sediment (g m^{-2})	104 b	8 a	85 b	10 a	22 ab
Percent of plots with runoff	100%	89%	92%	50%	100%

Few plots generated runoff for the Dry Run overall, therefore rainfall simulation results are restricted to the Wet Run experiments. The Wet Run results showed interspaces as the primary source of runoff and sediment delivery at both sites (Table 1) and that repellency effects persisted even with soil moisture contents approaching 20%. Across the sites, runoff rates and sediment yields were high for interspaces (23-34 mm h^{-1}, 85-104 g m^{-2}), moderate for tree plots (19 mm h^{-1}, 22 g m^{-2}), and low for all shrub plots (2-5 mm h^{-1}, 8-10 g m^{-2}) (Table 1). Runoff rates typically peaked early for water repellent tree and shrub plots and then declined throughout the remainder of rainfall simulation. Litter and moss covers showed variable effectiveness in limiting runoff from water repellent tree and shrub plots.

Discussion and Conclusions

The preponderance of evidence across spatial scales shows pinyon and juniper encroachment into the sagebrush vegetation type in the study area has altered plant community physiognomy and hydrologic function. The Woodland Site intercanopy (68% of area) was mostly devoid of understory vegetation and the ground surface there was mostly bare or covered by biocrusts (Fig. 1b). Shrub and herbaceous covers were well distributed and bare ground was isolated at the Sagebrush Site (Fig. 1a). For the Sagebrush Site, the fine vegetation structure buffered the effects of high runoff rates and sediment discharge from isolated interspaces and the formation of concentrated overland flow, as evident by limited erosion features at that site (Fig. 1a). At the Woodland Site, extensive sparsely vegetated intercanopy areas facilitated connectivity of runoff and sediment sources from contiguous interspaces (Fig. 1b), as evidenced by the presence of numerous water flow and erosion features (Fig. 1b). Consistent with other woody plant transition studies (Pierson et al., 2007, 2010; Williams et al., 2014; Roundy et al., 2017), our experimental results demonstrate how coarsening of the community structure with sagebrush-to-woodland conversions increases hydrologic vulnerability and soil loss through expanded connections of runoff and sediment sources along hillslopes. This study documents the impacts of PJ woodland encroachment into sagebrush steppe on vegetation cover and hydrologic and erosion processes. Studies documenting vegetation, soils, and hydrologic functioning commonly focus on either the sagebrush ecological state or, more often, the PJ woodland state, with encroachment effects inferred. This study is unique in capturing intact sagebrush state attributes and those of the PJ woodland state for the same ecological site. The results contribute to conceptualizing and predicting ecological and hydrological responses for similar ecological state transitions in other ecosystems.

Abstract

Mediterranean biotic and abiotic conditions, with severe drought, high temperatures, decreasing rainfall and increasing human disturbances are expected to have negative impacts on vegetation. Functional traits can be used to understand the relationship between plants and the environmental conditions, including grazing, under which they grow. Plant traits of *Stipa tenacissima* L., the most abundant and multi-used species in North African montane arid rangeland, are studied under three grazing regimes (full exclusion, seasonal and continuous grazing). Results confirmed that *S. tenacissima* traits are strongly affected by the grazing regimes. Leaf water content, bio-volume (the volume occupied by the above ground biomass) and the specific contribution of *Stipa* (the proportion of the species among the total plants founded) are higher under seasonal grazing. Hence this last management is recommended for the sustainability of both plant and rangelands.

Introduction

The functional traits of species are the resulting evolutionary and adaptive responses to the specific conditions of their environment (Reich et al. 2003). Climate change and human disturbances, particularly grazing, are considered among the most challenges confronting our world (Mikhaylov et al. 2020). They affect key habitat elements critical for the maintenance of species (Krichen et al. 2019). To evaluate vegetation behaviour and highlight adaptation to grazing and climate change, it is important to understand the plant's responses through their functional traits such as those associated with their colonization, survival, growth, and mortality (Reich et al. 2003).

Stipa tenacissima L. is a dominant perennial Poaceae in southern Tunisia, particularly in the montane rangeland chain of Matmata. It is subject to a wide range of climate and soil stresses. *Stipa* helps to prevent soil erosion by its developed root system and its adaptability to environmental shifts (Yang et al. 2024). *Stipa* constitutes an integral part of local economies according to its multiple uses as artefacts (baskets, strings, shoes) and for livestock feeding in summer (Ben Salem 2012).

Methods

Study area

Three sites located in the region of Toujane (south-east Tunisia) in the Matmata Mountain Chain are studied (Fig. 1). The mean annual precipitation is approximately 150 mm. The three sites have similar soil substratum, topography and geology, but differ in altitudinal range and grazing regime. Zmerten (33°26′07.20″ N, 10°07′29.02″ E, 3000 ha)) has been protected from grazing for 44 years. Its natural vegetation is dominated by *Juniperus phoenicea* L., *S. tenacissima* and *Rosmarinus officinalis* L. Brighith (33°29′23.40″ N, 10°12′02.88″ E, 100 ha) is dominated by *S. tenacissima* and is devoted to seasonal grazing. The control (33°29′14.95″ N, 10°11′58.24″ E) is dominated by *S. tenacissima* and continuously open to grazing.

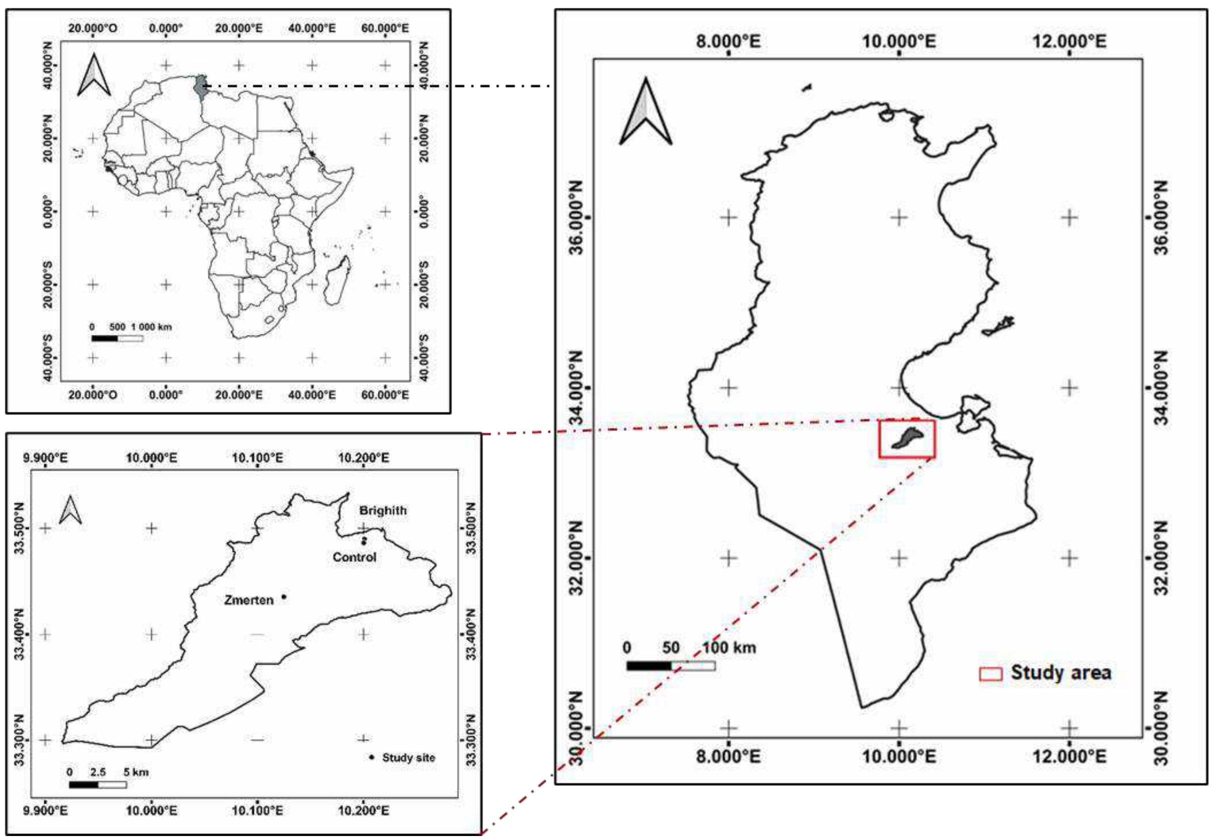

Fig. 1 Geographical location of the three study sites.

Methodology

At each site, nine tufts of different sizes (three big, three medium and three small) are measured in each altitude (low, medium and high) and aspect (south and north expositions to sunlight). The methodological approach is a pseudo replicated-nested design, with the three grazing treatments confounded with site. In total, 54 measurements are made within each site. Five leaves are collected from each tuft to measure the leaf traits. They were placed in moistened paper, and put in a refrigerator to prevent dehydration. In the laboratory, the leaves were weighed (to obtain their fresh matter (FM)), flattened, fixed and photographed. The photos are then analyzed using ‘Image J’ software to calculate the leaf area (LA). The sampled leaves are then oven dried for 48 hours at 60°C to obtain their dry matter content (DM). The leaf water content

(LWC), as a percentage of FM, was then calculated. The leaf dry matter content (LDMC), in mg g^{-1} FM, is DM/FM. Specific leaf area (SLA), in cm^2 g^{-1} DM, is LA/DM. The biovolume (in m^3) is calculated as BV = $((4/3)\,\pi r^3)/2$, where r is the average radius of the tuft and it is obtained as $r = ((D/2) + (d/2) + h)/3$, with: D is the largest diameter, d is the smallest diameter and h is the height of tuft. The canopy cover (CC in m^2) is the area covered by the aerial organs of *S. tenacissima* and it is calculated as CC = πr^2.

To characterize the whole plant community of the sites, three 20 m line-transects, 100 m apart, are installed at each level and aspect (in total, 18 lines per site). Data are collected using the quadrat point method. A metal fine pin is entered vertically into the vegetation every 20 cm along the transect (100 hits per line). The plant species touching pin are recorded. The total vegetation cover (Vc in %) is calculated as: Vc = $(n/N) \times 100$ where n is number of points where the vegetation is present and N is the total number of the measured points along the line.

The specific contribution (Sc in %) reflects the proportion of the species in the vegetation cover and was calculated as $Sc_i = FS_i / \Sigma FS \times 100$, where FS_i is the specific cover of the species and ΣFS the sum of the cover of all species. All these measurements are taken during the springs of 2019, 2020 and 2021.

Results

To summarize and investigate the patterns of the studied functional traits, a principal component analysis (PCA) is used (Fig. 2). PCA showed two principal components explained together 76.27% of the total variance. PC1 explained 53.36% of variation, while PC2 explained 22.91%. PC1 displayed a high positive association with BV, CC, Vc, Sc and LWC while it had high negative association with LDMC, SLA and LA. PC1 indicated a grouping of sites that exhibited high BV, CC, Vc and LWC. PC2 showed a positive loading with LDMC and a negative one with SLA, LA and LWC.

As showed in Figure 2, three site-groups are identified according to the hierarchical clustering. The first group included ZN1, ZS1, ZS2, ZS3, CS1 and CS2. Higher LDMC characterizes this group. The second one contained ZN2, ZN3, CN1, CN2, CN3, CS3. It is distinguished by a high LA and SLA. The last group contained all the seasonally grazed sites (BN1, BN2, BN3, BS1, BS2 and BS3) and it is characterized by a higher BV, CC, Vc, Sc and LWC. This distribution clearly proved the positive correlation of seasonal grazing on both functional traits of *Stipa* (BV, CC, Sc and LWC) and on the whole community (Vc).

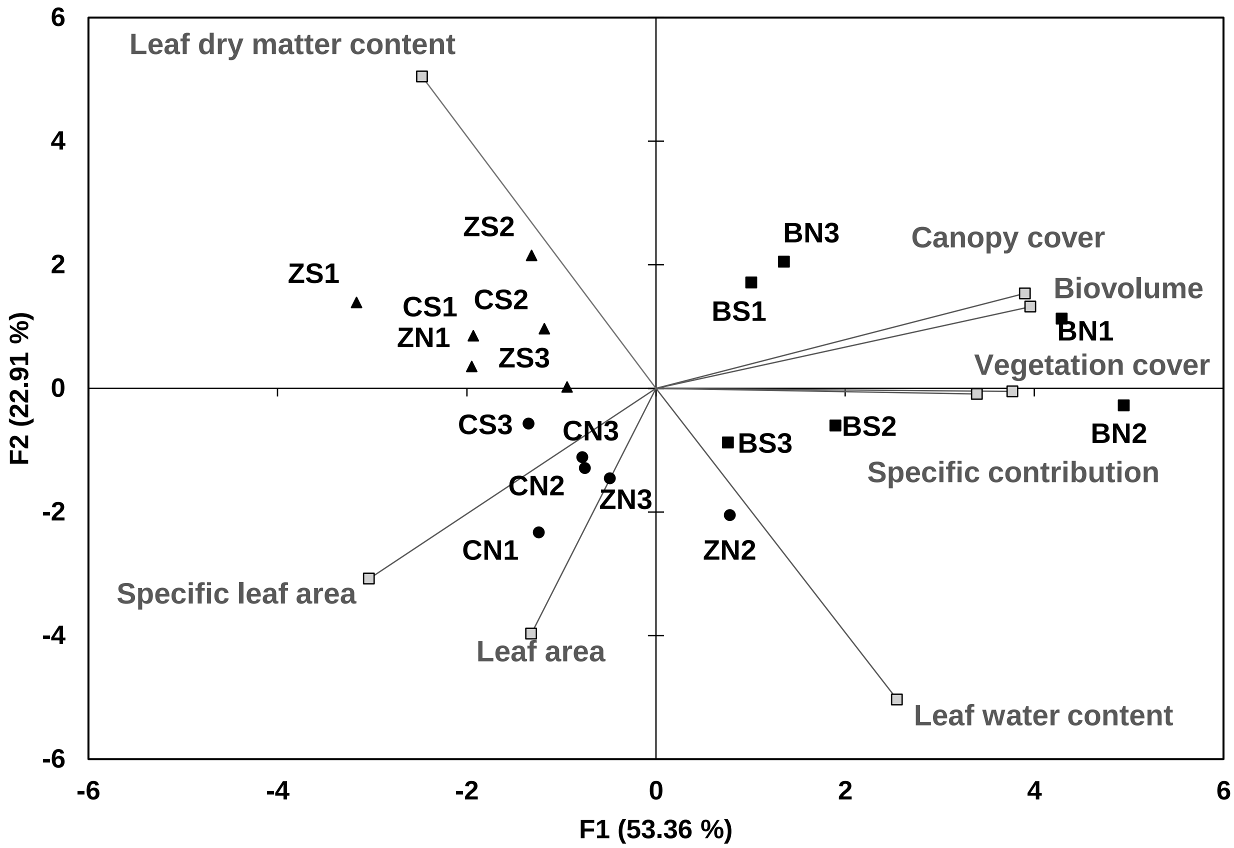

Fig. 2. Principal component analysis applied on the data of eight variables in 18 locations, meaned over the springs of 2019, 2020 and 2021. B: Brighith (seasonally grazed), C: control (continuously grazed) and Z: Zmerten (Livestock exclusion). N: northern aspect, S: southern aspect, 1: low elevation, 2: medium elevation, and 3: high elevation. For example: BN1 is Brighith North, low elevation.

Discussion

The CC, BV and Sc at the site under seasonal grazing are higher than those of the fenced and control sites. These may relate to improvements in soil characteristics. Seasonal grazing with controlled animal numbers has increased soil organic matter content and improved its physical and chemical conditions in Argentina (Vecchio et al. 2018).

Leaves are the most appropriate indicators of plant water status (Hamdani et al. 2019). SLA and LWC are closely linked to the productivity and water status of plant (Chirino et al. 2017). Hence, the low SLA with high LWC in the seasonal grazing site shows the adaptive capacity of *Stipa* to moderate grazing compared with the fenced and continuously grazed plants.

The Vc in the protected site is lower than the one in seasonal grazing. Thus, short grazing periods alternated with fencing during the growing season, seems better than strict protection (Msadek et al. 2021). Some grazing will temporarily decrease the aerial organs and allow the root systems to revitalize the remaining plant materials. Thus, individual plants are reinvigorated and vegetation cover increases (Louhaichi et al. 2012).

In conclusion, these experiments, revealed that seasonal grazing, with a controlled animal charge, is more beneficial for species and plant communities than grazing exclusion and continuous grazing. Seasonal grazing is rehabilitating degraded rangelands using selected local plants adapted to different biotic and abiotic constraints.

Local flora for ecological restoration: the flore project

Carita, T.[1]; Simões, N.[1]; Carneiro, J.P. [1]; Reis, P. [2]

[1] National Institute of Agricultural and Veterinary Reseache - Elvas, Ap 6, 7351-901 Elvas, Portugal; [2] National Institute of Agricultural and Veterinary Reseache - Oeiras, Av. da República, Quinta do Marquês, 2780-157 Oeiras, Portugal

Key words: native seeds; restoring nature; Mediterranean region

Abstract

The territories of south-western Europe are still recognised as a biodiversity hotspot. However, it is very much subject to the dangerous consequences of the intensification of human activities, climate change, wild fires and the abandonment of the agricultural and forestry activities in marginal land areas, with the consequent degradation of the land, vegetation and the ecosystems. There, the Interreg SUDOE FLoRE project, started in January 2024, is being implemented to test, analyse and scale-up the implementation of different ecological restoration solutions based on native and locally sourced herbaceous plant seeds. We develop: a) practical tools adapted to the current needs of the target groups; b) create a network of pilot projects in sites with diverse environments and land degradation (due to wildfires, overgrazing, mining, invasive vegetation); and c) lead a multi-stakeholder participatory process to design and test new models of economic cooperation, aimed at the self-production of seeds by users or the supply of products and services to sector players. The project will engage public authorities, non-profit private organization and private companies with the ambition of introduce this type of species into their restoration processes and organise dissemination days for the general public.

Three working groups (WG) were created: WG1 - Operationalise and disseminate existing knowledge on ecological restoration using local seeds, to facilitate the information and learning process by stakeholders, and encourage their commitment and the implementation of good practices.; WG2-Test, monitor and evaluate different ecological restoration solutions from local seeds; and WG3-Develop a strategy to involve all the stakeholders in large-scale actions to support the sustainability of the ecological restoration solutions tested, and formulate recommendations for professionals and decision-makers on the different means of action available to them.

Introduction

Our lives depend on nature, but we are degrading it, and it is imperative that we reverse this trend. A number of factors are putting pressure on ecosystems and species populations, including: pollution, climate change, habitat loss and invasive species (80% of habitats are in poor condition, 10% of bee and butterfly species are in risk of extinction and 70% of soils are in an unhealthy state) (European Council 2024). Soil degradation represents a major threat to ecosystem services and biodiversity conservation. In addition, degradation processes are continuing and worsening (EC 2023).

The semi-enclosed nature of the Mediterranean Sea and the complex topography result in unique physiographic and ecological features. The latest IPCC results show an increasingly arid future for the Mediterranean, with less rainfall and more frequent and longer heat waves (Ali et al. 2022). Some of the consequences of climate change are: reduction of river low flows and annual runoff by 5-70%; yields of rainfed crops may decrease by 64% in some places; desertification will affect more areas, especially in the south and south-east.

The EU Environmental Council adopted the Nature Restoration Law (NRL). They intend to intervene in at least 20 per cent of the EU's land and sea areas by 2030. Restoration plans are intended to cover the period up to 2050. One of the measures envisaged is to restore of at least 30% of the habitats that are in poor condition.

In this context, the FLoRE project was created as part of the INTERREG-SUDOE programme, which aims to consolidate South-West Europe as an area of territorial cooperation in the of innovation, competitiveness and environmental protection. The major challenge of the FLoRE project is to ensure the preservation of the quality of life and the attractiveness of rural areas by demonstrating the economic and organisational viability of scale-change in the implementation of various ecological restoration techniques aimed at valuing native and local wild herbaceous species.

Project Workplan

The Interreg SUDOE FLoRE project, started in January 2024 and will finish in December 2026. The consortium is made up of eight partners (three in France: Conservatoire d'Espaces Naturels d'Occitanie (project leader), FAB'LIM - Le Labo des Territoires Alimentaires Méditerranéens, Conservatoire d'espaces naturels d'Auvergne; three in Spain: Comunidad Autónoma de la Región de Murcia, Asociación Forestal de Soria, Cámara Oficial de Comercio, Industria y Servicios de Badajoz and two in Portugal: National Institute of Agricultural and Veterinary Research, MORE CoLAB on mountain regions. Three groups of tasks were drawn up into three working groups (WG 1, WG 2 and WG 3); all the beneficiaries will take part in each WG, but one beneficiary is responsible for coordinating each WG.

WG 1 - Operationalisation and dissemination of existing knowledge on ecological restoration

Here, the focus is disseminating and applying existing knowledge on ecological restoration techniques using native and locally sourced wild herbaceous species, to facilitate their use by stakeholders (professionals in the sector, landowners, managers, national bodies), in order to encourage their involvement in changing practices and identify the remaining gaps in technical and socio-economic knowledge. To do this, we will update the current state of knowledge on initiatives, scientific publications and public policies aimed at supporting ecological restoration. Then, to facilitate access to information, the most frequently asked questions by stakeholders will be identified and answered, along with other types of dissemination actions. The deficits and gaps in knowledge identified will be revealed and addressed at a later stage of the project. (INIAV is the responsible beneficiary).

WG 2 - Experimentation and evaluation of different solutions for seed production and ecological restoration

A network of demonstration sites is being set up in different environments to publicise different solutions (including different restoration and seed multiplication techniques). Most of our pilot sites are already in place and are located in:

- Occitanie: representing altered agricultural systems and highly anthropized environments and Auvergne: representative of wetlands, meadows and pastures in Auvergne (France)

- Soria: captures truffle farms, recently cleared environments and forest environments and Murcia: degraded natural spaces and eroded areas (Spain)
- Serra da Estrela: I an example of mountain burnt areas in the centre of Portugal and the left bank of the Guadiana river- south-east Portugal represent grasslands (Portugal). This last pilot site is the responsibility of INIAV.

Based on the mapping of grasslands of ecological interest carried out, different techniques for obtaining and recovering seeds will be developed (brushing, mowing, hay transfer). Transnational co-operation will enable us to provide a range of restoration solutions adapted to the regulatory contexts of each country and the realities of each territory, given the diversity of environments representative of the SUDOE area[5]. The experiments carried out and their monitoring (based on indicators developed by the consortium) will make it possible to consolidate protocols and identify the relevant adaptations to be made depending on the contexts and restoration objectives. We will also measure the real benefit or added value, as well as the possible impacts of the restoration operations carried out. (*Asociación Forestal de Soria* is the responsible beneficiary)

WG 3 - Development of a strategy to involve stakeholders in a large-scale action

A medium/long-term strategy (from three to eight years) will be developed jointly based on the sharing of results from the multi-stakeholder group animation work at a transnational level, i.e., from the workshops involving different types of stakeholders (from scientific researchers and public decision-makers to seed vendors and farmers) from various countries, specifically from the SUDOE European region (southwest of France, Spain, and Portugal). Its main objective will be to guide professionals (landscapers, consultants, public and private buyers, scientists, local development associations, site managers) and decision makers (elected representatives, company managers, etc.) towards the means of action available to them supporting long-term viability of the technical solutions tested during the project (collection, planting and monitoring of native and locally sourced wild herbaceous species, etc.). This strategy will define realistic objectives (taking into account the constraints of these stakeholders) but ambitious enough to support the development of the proposed solutions. This may be broken down into several action plans, tailored to each type of public concerned and their respective areas of competence. We will identify a number of economic and public policy levers that can support this strategy. To facilitate its implementation, the strategy will be accompanied by a number of resources available in open access e.g. training modules for field workers and decision makers, awareness-raising content, a letter of engagement, feedback from multi-stakeholder groups, etc. (*FAB'LIM* is the responsible beneficiary).

Goals to be achieved

By carrying out the different tasks (WG1-3), we aim to achieve the following goals:

-1.Obtain commitment from: (i) the managers of the pilot ecological restoration fields to guarantee the sustainability of the solutions tested, (ii) the professionals to collectively implement the economic and organisational models co-constructed in accordance with the initial ethics, (iii) the beneficiaries of the multiplied seeds for use in projects of collective interest and (iv) the communities and companies to introduce this type of seed in their ecological restoration processes in favour of biodiversity.

[5] Interreg Sudoe is a European Union funding programme to support regional development and cohesion in the regions of south-west Europe.

-2.Training organisations that adopt the tested solutions to manage them independently over time.

Key words: reintroduction; site fidelity; home range; IUCN Red List

Abstract

The global biodiversity crisis has manifested itself on the Arabian Peninsula with wildlife population declines and extinctions particularly of the large iconic mammals. Protected areas are increasingly being established to provide refuge, enhance wildlife populations, and reintroduce missing keystone species. Since 2018, eight royal reserves have been established in Saudia Arabia, two in the hyper-arid central region. Understanding current species occurrence, richness, abundance, and diversity is crucial to targeting management and reintroduction efforts. Due to the scarcity of data on wildlife presence and spatial abundance in the region, we utilized camera traps placed on trails, at water stations, and at burrows, as non-intrusive tools for baseline biodiversity assessment in these protected areas. These camera traps revealed the presence of 12 species listed as threatened on the IUCN Red List, underscoring the regional and global importance of these areas. Additionally, these findings contribute valuable information on species distributions in hyper-arid areas for global assessments. The data on the spatial abundance of top predators and meso-predators is crucial for designing feasibility studies for reintroduction programs and can guide spatial management strategies that will enhance biodiversity.

Introduction

Biodiversity has shown an alarming downward trend in the last decades (Díaz et al., 2019). Effective ecological structure and functioning of ecosystems requires the full trophic network of wildlife species to be present. Large predators have cascading trophic effects through predator avoidance by herbivores (Suraci et al., 2016), resulting in spatial variation in vegetation communities in areas these grazers avoid (Boyce, 2018). The presence of large herbivores increases plant diversity through selective browsing (Cook-Patton et al., 2014; Olff & Ritchie, 1998) and the improvement of soil fertility through dung and urine deposits (van der Waal et al., 2011). Birds and small mammals facilitate regeneration through seed dispersal (Kellner et al., 2016). And insects are not only food for many animals, but they are also very important for nutrient recycling. Therefore, an ecosystem with a diverse and abundant wildlife population can enhance the natural regeneration and diversity of the vegetation which in turn supports wildlife communities.

Various species of large mammals used to roam the desert ecosystems of Saudi Arabia, having adapted to the harsh climate conditions. However, most have now disappeared from the wild. These include the

Arabian oryx (*Oryx leucoryx*) which is deemed extinct from the wild since the early 1970s (Henderson, 1974), and the sand gazelle (*Gazella marica*), the mountain gazelle (*Gazella arabica*), and the Arabian grey wolf (*Canis lupus arabs*) are currently only present in small remnant populations in Saudi Arabia (Habibi & Grainger, 1990; Ross et al., 2019, 2020). Overhunting and habitat degradation have resulted in their population decline (Alatawi, 2022) and these species are currently listed on the IUCN Red List as vulnerable to extinction (Mallon et al., 2023). Protected areas are a key component in global biodiversity conservation management and have shown to be effective in conserving terrestrial mammals (Chen et al., 2022). To support the Saudi Vision 2030 and in aligned with international treaties, particularly the Convention of Biological Diversity, the Saudi government has pledged to have 30% of its terrestrial and marine areas protected by 2030. Since 2018, eight royal reserves have been established, covering 13.5% of the total terrestrial land. Two reserves are located in the central hyper-arid desert, the King Khalid Royal Reserve (KKRR) and the Imam Abdulaziz bin Mohammed Royal Reserve (IARR). No studies on the presence and abundance of wildlife have been published for these areas. Monitoring wildlife to assess diversity using camera traps, especially for elusive and nocturnal animals, is now a standard method (Palencia et al., 2021). We used camera traps as point-based sampling units to increase our understanding of wildlife species' occurrence, richness, and relative abundance at two study sites in the recently protected areas.

Methods

The study areas are within KKRR and IARR, approximately 100 km northeast of Riyadh. KKRR is 1,162 km^2 and has four main habitats, the pediplain, plateau, wadi (valley) and catchment. The pediplain is about 250 km^2 and contains numerous catchment areas. It is bordered by the escarpment of the Urumah Mountain plateau to the east and at all other sides by roads and has been fenced for over 40 years allowing the vegetation to regenerate (Al-Harigi et al., 2023). Between 2021 and 2024, 45 Arabian oryx (*Oryx leucoryx*), 120 sand gazelles (*Gazella marica*), 11 Arabian gazelle (*Gazella arabica*), and 15 Asian houbara (*Chlamydotis macqueenii*) have been reintroduced in this pediplain. IARR is 11,300 km^2 and has six main habitats, the pediplain, plateau, wadi, catchment, sand plain, and sand dune. This reserve harbours 13 catchment areas with Rawdhat Khuraym being the largest, with eight main wadis draining into it and a popular destination for people in the winter; Kasr Almuzayri is the second largest catchment. Ten Asian houbara were reintroduced in Rawdhat Khuraym in 2023.

In KKRR, camera traps were positioned at 53 locations, predominantly in the fenced pediplain. In IARR, 11 cameras were placed in Rawdhat Khuraym and 2 in Kasr Almuzayri. To increase the observations of diverse animal assemblages we placed cameras next to water sources (50-60 cm height), burrows (10-15 cm height), and on wildlife trails (50-60 cm height). Photos that were taken two minutes or less apart were combined into a single continuous sequence and reported as a single observation. Species richness was based on the incidence of rare species (Chao et al., 2014; Hsieh et al., 2016). We used Hill numbers to quantify community diversity with q representing species richness (q = 0), Shannon diversity (q = 1), and (1-) Simpson diversity (q = 2). The widely used Relative Abundance Index (RAI), calculated as the ratio of photographic captures to camera trapping effort, provides a baseline species abundance for unmarked populations at each feature type (Rovero and Marshall, 2009; Tanwar et al., 2021).

Results

Species Richness

In total, 59 vertebrate species were observed, 35 birds, 17 mammals (of which 3 were domestic) and 7 reptiles. Of these species, 12 are listed on the IUCN Red List: 2 as Endangered (steppe eagle, Egyptian vulture); 8 as Vulnerable (Eastern imperial eagle, Arabian wolf, sand cat, Egyptian spiny-tailed lizard, and the reintroduced Asian houbara, Arabian gazelle, sand gazelle, and Arabian oryx); and 2 as Near-threatened

(Arabian wildcat, honey badger). Placing cameras at different features resulted in slightly different species assemblages (Fig.1 left panel) with, as can be expected, burrowing animals (*Meriones libycus, Jaculus jaculus, Uromastyx aegyptiae*) being pervasive at burrows; pigeons, domestic cats (*Felix catus*), and raptors (e.g. the steppe eagle, *Aquila nipalensis*, Egyptian vulture, *Neophron percnopterus*) at water sources; and on trails the wolf (*Canis lupus arabs*), Arabian gazelle and oryx were frequently captured. However, overlap in species assemblages was quite large.

Species diversity indices showed similar values for richness among feature types (Fig. 1 right panel), suggesting a similar number of species in each habitat. However, the Shannon and Simpson diversity indices, which account for both species richness and evenness, are lower at wildlife trails. This is likely driven by the occurrence of rare species, such as the rarely observed honey badger, Indian crested porcupine, false cobra, sand skink, and the Arabian babbler. The slightly higher Shannon and Simpson diversity indices at burrows, despite overlapping standard errors with water sources, suggest a more even distribution of species resulting from the frequent observations of burrowing animals.

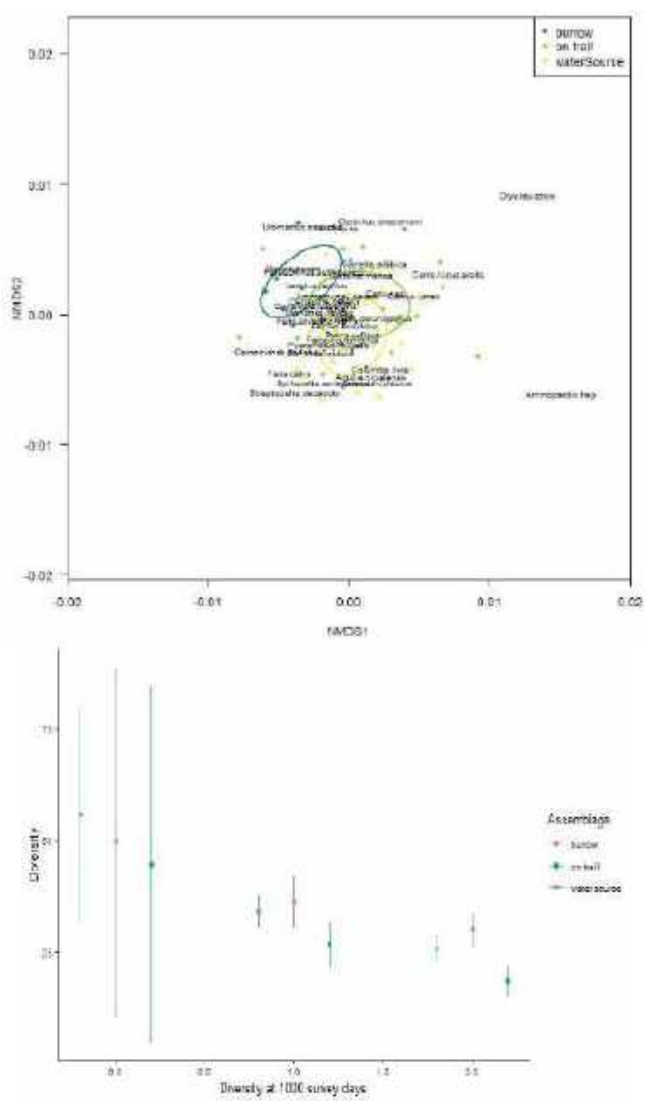

Figure 1. *Left panel*: Non-Metric Multi-Dimensional Scaling (NMDS) plot of species encountered at burrows, water sources or along wildlife trails. *Right panel*: Predicted diversity indices with 0 = species richness, 1 = Shannon diversity, and 2 1-Simpson diversity

Relative Abundance Index (RAI)

Most species had a higher RAI at water sources compared to the other features with only the burrowing species being restricted to observations at burrows (Fig. 2). In KKRR, the reintroduced sand gazelle was the most prominent species at water sources, followed by foxes (*Vulpes*), pigeons, ravens (*Corvus*), and stray dogs (*Canis lupus familiaris*). In IARR, no large herbivores have been reintroduced, and the most abundant species were pigeons, white-eared bulbuls (*Pycnonotus leucotis*), house sparrows (*Passer domesticus*), and feral cats (*Felis catus*) that were all attracted to water sources.

Discussion

Our study demonstrated that the recently established protected areas hold both regional and global significance, as 20% of the observed species are listed as threatened on the IUCN Red List. Providing a refuge for these animals will enhance their survival chances. Water provision also proved crucial for these threatened species, including migrating raptors and native gazelles and oryx. These observations are valuable for biodiversity restoration efforts through reintroduction and wildlife species enhancement programs.

Interestingly, the diversity at water sources, which attracted a high abundance of animals, showed similar species richness with considerable overlap in species assemblages compared to trails and burrows. Only burrowing animals were almost exclusively seen at their burrows, while species mostly associated with urbanized areas (pigeons, sparrows, stray cats, and stray dogs) were predominantly observed at water sources. This was especially notable in Rawdhat Khuraym, which experiences high levels of disturbance in the winter due to thousands of visitors from surrounding areas. Restoring wildlife biodiversity in this area will depend on the restoration of the currently degraded habitat. As a first step the native vegetation, including palatable species for native ungulates and reptiles, will need to be restored and natural regeneration needs to be stimulated. After the successful establishment of these plants for food and shelter, it is expected that wildlife will reoccupy the area from its surrounding and missing keystone species can be reintroduced, increasing the biodiversity.

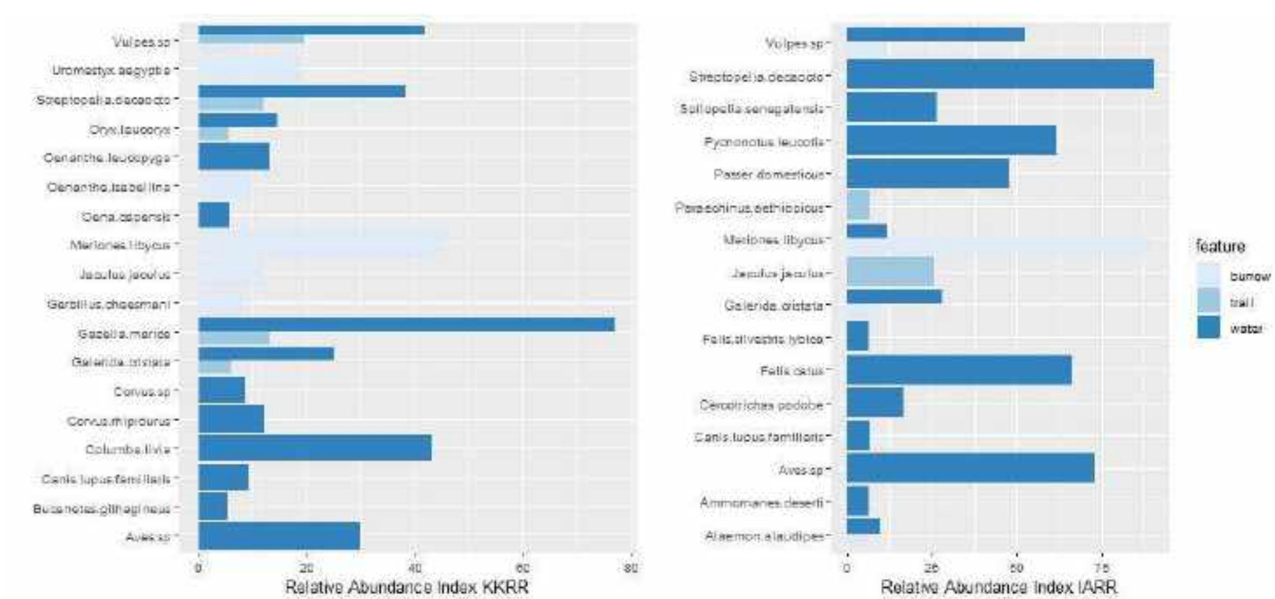

Figure 2. Relative Abundance Index of species frequently encountered (i.e., RAI >5)

For the success of reintroduction programs, it is important to understand the spatial abundance of potential predators near release sites. For example, releasing Asian houbara in areas with low predator abundance (foxes, wild cats, honey badgers) will increase their survival rate, especially after a hard release when they still need to find suitable habitat for shelter. Equally important for species conservation is identifying the locations of stray cats and dogs, as they not only compete for resources with wild cats and wolves but also pose a risk of interbreeding, which can lower genetic integrity. Additionally, dogs can prey on small gazelles or even attack oryx when in packs, and could outcompete the remnant wolves.

Results from our study provide insights into the spatial occupancy of predator and prey animals and highlighted areas of high abundance. Furthermore, they offer crucial information on the spatial abundance of threatened species, which can inform spatial management strategies to effectively protect and conserve these animals.

Grazing management and low-stress herding to prevent livestock predation by grizzly/brown bears: a case study in the Rocky Mountains, USA

Barnes, MK[1,2]

[1] Reintegrating Wildness, a project of the Northern Rockies Conservation Cooperative, Jackson, Wyoming 83001-2705, USA (matt@shininghorizons.com); [2] At the time of the field work, Field and Research Coordinator with People and Carnivores, Bozeman, Montana 59771-6733, USA

Key words: depredation; livestock-carnivore coexistence; low-stress livestock handling; range riding; stockmanship

Abstract

Low-stress herding is a method to apply strategic grazing management, and possibly to reduce vulnerability to predation by rekindling herd instinct and increasing effective stocking density, facilitating collective anti-predator behaviour—similar to the group-size effect in wild prey species (Barnes 2015a,b).

We collaborated with ranchers and agency partners on a grazing allotment in the Wind River Range of northwestern Wyoming, USA, where permittees were having difficulty implementing a grazing rotation without cross-fences, and cattle had been lost to grizzly bears (North American brown bears; *Ursus arctos*) and other predators including gray wolves (*Canis lupus*). For 3 years, we hosted workshops on low-stress livestock handling, including hands-on practice in the field, and we attempted a grazing rotation through 7-9 mostly unfenced units, with at least one rider on the allotment most days.

In the 3 years prior to the project (minimal grazing management), cattle tended to scatter, and the ranchers lost 0.8-19.1% of calves per year, as well as a few yearlings and adult cattle, to all causes during the summer grazing season. In the year of highest losses, one rancher lost 19.1% of calves, and bear predation accounted for 6.7% of calves (about 1 of every 3 deaths). During the 3 years of the project (rotation by low-stress herding) the cattle self-organized into larger groups, although never a single large group: a modest improvement over previous years (but not all that is possible with low-stress herding). Losses to all causes were 2.8-7.7% of calves per herd per year, as well as a few yearlings and adult cattle, with 0 confirmed predation losses. This reduction in both total and predation losses followed a modest improvement in handling skill, herd instinct, and effective stock density. While we cannot conclusively attribute causality, this result continued for the 3 years of the project.

Introduction

Livestock producers may be able to reduce vulnerability to predation by managing herds in ways similar to the group size effect (prey aggregation), a well-known anti-predator behaviour in wild prey, through strategic grazing management that involves increased stock density and movement around the landscape (Barnes 2015a,b). Low-stress livestock handling (LSLH) techniques have many benefits including rekindling the herd instinct (Cote 2004; Hibbard and Barnes 2016), which when applied to herding (low-stress herding; LSH) can facilitate strategic grazing management (Barnes 2015b; Barnes and Hibbard 2016) and possibly reduce predation, as theorized by Barnes (2015a). Other LSH practitioners have noted that their methods appear to reduce predation losses through associated behavioural changes (Zaranek 2016) and are transferrable (Louchouarn and Treves 2023), and thus are important practices for range riders where potential predators, especially species of conservation concern such as grizzly bears and wolves, are present.

Methods

We collaborated with ranchers and agency partners on a summer grazing allotment on the Shoshone National Forest in the Wind River Range of northwestern Wyoming, USA, where before the project, the two ranches (permittees) who shared the allotment were having difficulty implementing a grazing rotation without cross-fences, and cattle had been lost to grizzly bears and likely other predators including gray wolves. During the project, for 3 years (2014-2016), we hosted workshops on LSLH, including hands-on practice in the field, and we attempted a grazing rotation through 7-9 subunits (with only one cross-fence separating two of the subunits), with at least one rider on the allotment most days.

Ranches differed in initial livestock handling and adoption of the methods. Ranch A believed they were already practicing LSLH, though their methods were more accurately described as relatively skilled conventional handling; one of several individuals from the ranch attended the workshops, and may have made modest improvements in handling, but overall ranch A did not make major changes. Ranch B had practiced conventional handling; both of two individuals attended the workshops and did their best to adopt LSLH. Thus this case study has a design similar to before-after-control-impact (BACI), but more accurately a non-equivalent groups design where ranches A and B are not replicates, and ranch A is not strictly a control treatment, but rather ranch A had a lower level of treatment or impact than ranch B. Before the project, grazing management was relatively extensive and handling was conventional; during the three-year project, grazing management intensified somewhat, and became more low-stress, albeit less so for ranch A than ranch B.

At least one individual from one or both ranches functioned as a range rider on most but not all days, and attempted to combine smaller groups of cattle into larger groups—ideally (but rarely) a single large group—and attempted to follow the grazing rotation to the best of their ability.

To assess the effect of these management changes, we compared livestock loss data from the three years before the project (2011-2013) to the three years during the project (2014-2016), for the herds from ranches A and B (herds A and B). Losses were obtained from U.S. Forest Service (USFS) 'Actual Use' forms submitted by each permittee each year, and were categorized as: confirmed grizzly; suspected predator (possibly grizzly, wolf, black bear, or mountain lion, but not confirmed); sickness or other (including poisonous plants); and unknown (including missing). Confirmation was determined by the Wyoming Game and Fish Department. In one year, missing cattle were recorded by the permittee as suspected predation, but because there was no evidence these were recategorized as unknown.

The project was considered to end after 2016 because of personnel turnover at the conservation organization, one of the ranches, and the USFS.

Results

Grazing management

We were modestly successful at improving grazing management. Before the project, herd A had been more cohesive than herd B. During the project, overall, the cattle tended to be in fewer, larger groups, and there was more mixing of the cattle from the two herds, but they did not form a single socially-cohesive herd. More but not all of the cattle were in the appropriate subunit as intended in the planned rotation. Overall utilization was light and rangeland health was good, with two small areas used slightly more than desired, one by each base herd (M. Buzalsky, USFS, pers. comment). Herd A behaved mostly similarly to before the project. Commensurate with the greater degree of adoption of LSLH on ranch B, herd B made more improvement, in terms of cattle being in larger groups and more often with cattle from herd A.

Livestock losses

Most livestock losses were to sickness or unknown causes, rather than confirmed or suspected predation, both before and during the project. Losses to confirmed grizzly bear predation and suspected predation were substantial before the project, but stopped completely during the project, while losses to sickness and unknown causes continued. (Fig.1)

Before the project, all confirmed predation was in herd B; suspected predation was more prevalent in herd A. herd A had suspected predation of mean 2.1% (range 0-5.0%). Herd B had confirmed predation of mean 2.6% (range 0-6.7%), and confirmed plus suspected predation of mean 2.8% (range 0.6-6.7%).

Total losses were initially lower in herd A than herd B; they increased slightly in herd A, while they decreased substantially in herd B. Before the project, across both herds, total losses were from 0.8-19.1% of calves per herd per year; and lower in herd A (mean 3.2%, range 0.8-5.0%) than herd B (mean 10.6%, range 5.8-19.1%). During the project, total losses were 2.8-7.7% per herd per year; similar in herd A (mean 4.8%, range 2.8-7.7%) and herd B (mean 4.3%, range 3.2-6.0%).

Discussion

We provided training in LSLH, so that two ranches could practice LSH to implement a rotation and possibly reduce vulnerability to predation. One of two ranches (A) made slight improvements, while the other (B) embraced LSLH. Even with imperfect implementation, the two ranches eliminated confirmed (herd B) and suspected (herd A) predation by grizzly bears and other potential predators. It is possible that some of the unknown losses before and during the project were to predation. The herd (B) that had all of the confirmed predation before the project, and whose operators made greater management changes, also experienced reduced total losses to about the level of the other herd (A), while the herd (A) whose operators mostly continued previous practices had a slight increase in total (likely non-predation) losses.

These results are consistent with the hypothesis that LSLH, particularly when used in the form of LSH to increase stock density or group size and facilitate strategic grazing management (Cote 2004; Barnes 2015b; Hibbard and Barnes 2016), can reduce vulnerability to predation, and should be considered an important aspect of range riding in predator habitat (Barnes 2015a; Zaranek 2016; Louchouarn and Treves 2023). In this case study, we cannot conclusively attribute causality, but the results are compelling. Future studies should employ rigorous experimental or quasi-experimental design (e.g., BACI), if feasible given the challenges of field conditions.

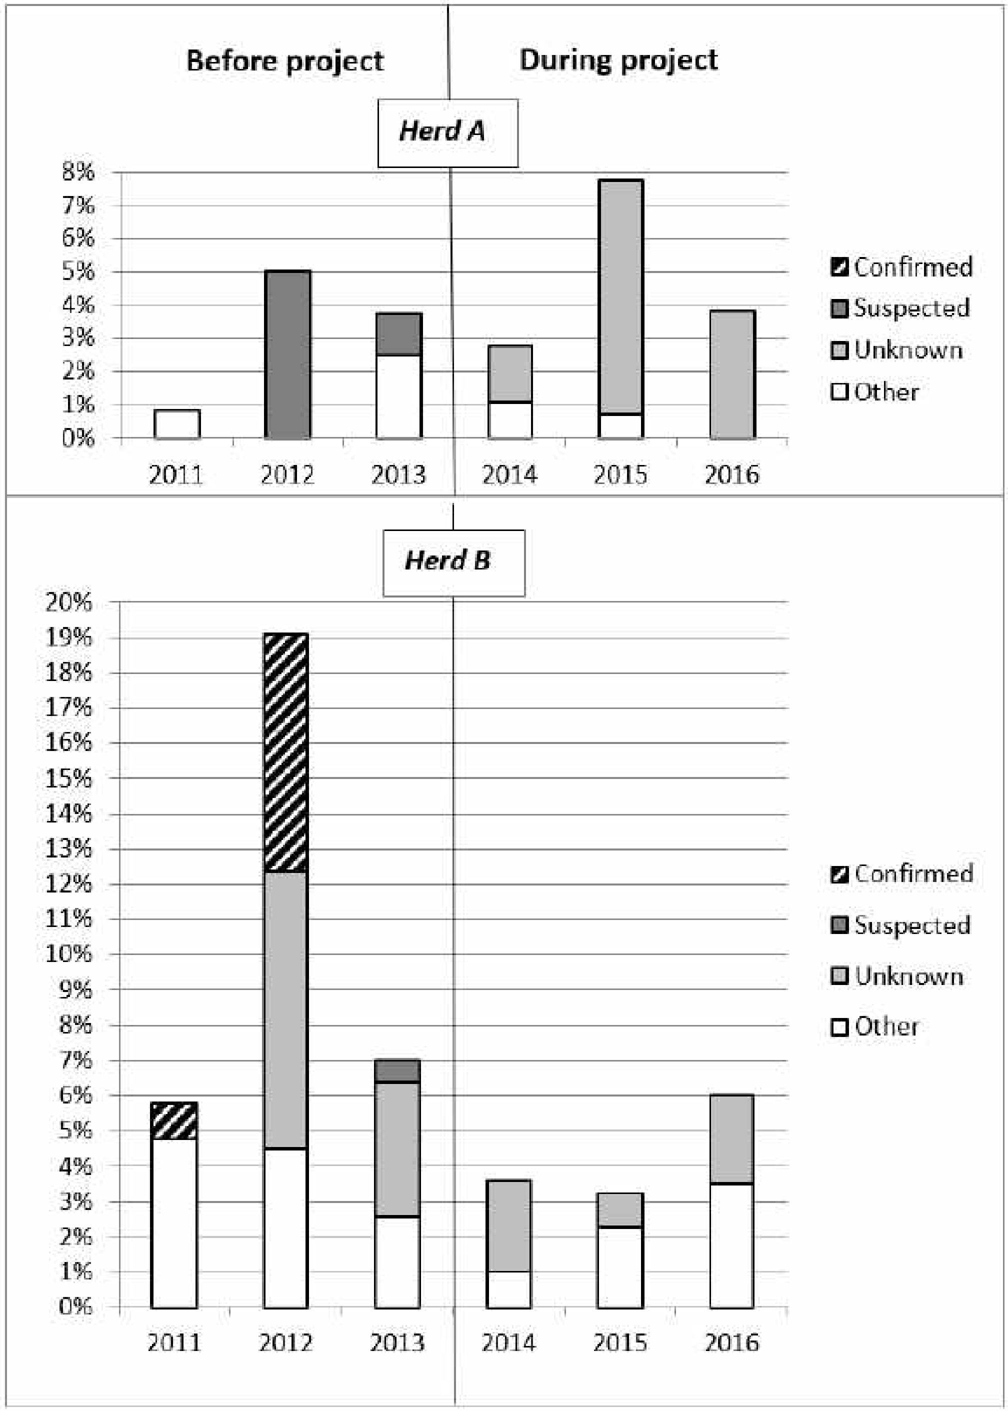

Fig.1. Cattle loss to confirmed (grizzly bear) and probable (bear, wolf, or cougar) predation, unknown causes, and other known losses (sickness), before and during a herding project, in two herds (A, B) that shared an allotment. Operators of both herds received training in low-stress livestock handling, but the methods were more fully adopted by the operators of herd B.

Acknowledgements
I thank the ranch personnel, who as usual did the vast majority of the work; the LSLH consultants who provided training, W. Hibbard and S. Cote; the USFS range staff, B. Russell and M. Buzalsky; and my former colleagues at People and Carnivores, especially L. Upson, H. Rasker, and S. Primm.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Fencing the future: enhancing livestock management and wildlife conservation with virtual fencing

Bennett, DE[1]; Berman, C[1]; Brammer, T[2]

[1]Haub School of Environment and Natural Resources, University of Wyoming, Laramie, WY USA; [2]Property and Environment Research Center (PERC), Bozeman, MT, USA

Key words: fencing; technology; ecosystem health; human-wildlife conflict

Abstract
Virtual fencing technology presents a potentially transformative approach to livestock management across extensive rangeland systems with significant implications for wildlife conservation. Virtual fencing enables remote and dynamic management of livestock movement, offering solutions to mitigate the adverse impacts of traditional physical fencing on landscape connectivity, reduce wildlife-livestock conflicts, and exclude grazing in sensitive habitat areas. In this paper, we present a framework outlining the diverse applications of virtual fencing to conservation efforts and present insights from several pilot case studies from the North American Great Plains and Greater Yellowstone Ecosystem, USA. We examine the operational approaches, and adaptive strategies employed to integrate virtual fencing into existing rangeland management practices, and their potential impact in achieving wildlife conservation goals as part of a working livestock operation. Despite the promising potential of virtual fencing, pilot applications have encountered a range of technological, social, and policy barriers. The findings from the case studies underscore the necessity for continued innovation, stakeholder engagement, and policy reform to harness the full potential of virtual fencing. We argue that, by addressing these considerations, virtual fencing technology can substantially contribute to the co-objectives of livestock production and wildlife conservation. By enhancing landscape connectivity, reducing human-wildlife conflicts, and minimizing habitat impacts, virtual fencing represents a pivotal step towards more sustainable rangeland management.

Introduction

Livestock grazing is the most extensive land use globally, occupying approximately 25% of the Earth's terrestrial surface (Asner et al., 2004). Physical fencing is a key grazing management tool to control the spatiotemporal distribution of livestock (Bailey, 2004) and plays a large role in human socio-ecological interactions worldwide (Xu and Huntsinger 2022). While nearly universally associated with grazing, traditional fencing has only recently received widespread conservation attention (McInturff et al., 2020), including the recognition that fencing can have considerable ecological and economic drawbacks.

Traditional fencing can create social conflicts by reducing human mobility and weakening social relationships, fragment landscapes that reduce wildlife mobility, cause direct mortality due to collision and entanglement, facilitate the spread of invasive species, and reduce native plant diversity, leading to potential widespread ecological consequences (Harrington and Conover, 2006, Jakes et al., 2018, McInturff et al., 2020, Xu et al., 2021, Xu and Huntsinger 2022). From an economic perspective, fencing is a major input and expense for livestock producers. For instance, new fencing in the western USA can be upwards of $25,000/mile and requires significant physical and financial maintenance once erected. Given these challenges, there is a need and demand for new ways to contain livestock while offsetting some of the potential negative effects of traditional fence.

There is a growing interest in technological solutions that can meet the needs of livestock management while minimizing negative ecological impacts and reducing costs for producers. Virtual fencing provides a potential win-win solution that can enhance livestock operations while providing significant conservation benefits that extend beyond simply reducing physical fencing. Below, we provide an overview of emerging virtual fencing technology, detail the specific functions virtual fencing can provide to realize conservation benefits, and provide insights from initial pilot applications.

Methods

We employed two complementary approaches to identify conservation opportunities and implementation challenges associated with virtual fencing technology: an expert stakeholder workshop and semi-structured interviews with key stakeholders involved in pilot projects. In June 2024, we convened a three-day workshop in Bozeman, Montana, that brought together over 40 experts from across technology, agriculture, government, and conservation sectors. Expert workshops have been shown to be effective for synthesizing diverse knowledge and identifying priorities in conservation planning (Sutherland et al., 2011). The workshop, co-hosted by the Property and Environment Research Center and the Beyond Yellowstone Program, with support from multiple conservation organizations, focused on understanding the current state of virtual fencing technology, evaluating its conservation potential, and identifying barriers to adoption. Participants included virtual fencing technology developers, ranchers with direct experience implementing the technology, conservation professionals, researchers, and government agency representatives. Through facilitated discussions and working sessions, participants identified key functions of virtual fencing that enable conservation benefits and developed strategies for scaling adoption.

To complement the workshop findings, we conducted 15 semi-structured interviews with key stakeholders involved in four pilot projects implementing virtual fencing technology for conservation benefits (Young et al., 2018). Interview subjects included ranchers operating the technology and conservation professionals involved in project implementation. Semi-structured interviews are particularly valuable for understanding complex social-ecological systems and documenting stakeholder experiences with new conservation technologies. These interviews explored practical challenges encountered during implementation, documented early conservation outcomes, and identified opportunities for improving virtual fencing applications. The interviews provided detailed insights into the real-world application of virtual fencing technology and helped validate the functions and challenges identified during the expert workshop. Together, these methods provided a comprehensive understanding of both the theoretical potential and practical realities of using virtual fencing to achieve conservation outcomes.

Results

Key Functions and Potential Conservation Benefits

Based on the expert workshop, we identified five key functions of virtual fencing that provide significant conservation benefits. First, virtual fencing can reduce the need for physical infrastructure, helping restore landscape connectivity by removing barriers that fragment habitats, impede wildlife movement, and cause wildlife mortalities through entanglement and collisions (Jakes et al., 2018; Harrington and Conover, 2006). Second, virtual fencing enables precise livestock exclusion from sensitive areas through dynamic, remotely adjustable boundaries. This capability allows managers to protect critical habitats such as riparian zones (Belsky et al., 1999), breeding areas, and post-fire restoration sites (Boyd et al., 2022), with the flexibility to modify exclusion zones based on seasonal needs or changing environmental conditions.

The third function involves the strategic concentration of livestock, which can serve multiple conservation purposes. Operators can focus grazing pressure to control invasive species, create fuel breaks for wildfire management (Boyd et al., 2022), and reduce predation risk by grouping cattle away from areas that provide cover for predators (Kluever et al., 2009). The fourth function utilizes the technology's precise livestock tracking capabilities to aid in predator conflict mitigation. Real-time monitoring can detect abnormal herd movements indicating predator presence and enable rapid carcass removal to reduce predator attractants (Morehouse and Boyce, 2011).

Finally, virtual fencing provides unprecedented flexibility in timing grazing rotations, enabling sophisticated management strategies such as high-density, short-duration grazing. This approach can create habitat heterogeneity that benefits various wildlife species (Fuhlendorf et al., 2010; Krausman et al., 2009) while allowing for more strategic rest periods that promote ecosystem recovery (Briske et al., 2008). The technology's adaptability is particularly valuable in the context of climate change, as managers can rapidly adjust grazing patterns in response to changing environmental conditions, contributing to the overall resilience of grazed landscapes.

Challenges and Promise in Pilot Efforts

Based on the interviews with stakeholders involved in pilot virtual fencing projects, we identified several implementation challenges during early adoption phases. Initial efforts were often more ambitious than what could be realistically achieved in the first few years of deployment, with participants encountering technical obstacles such as collar retention issues and limited battery life. The learning curve for adopting the technology proved steeper than anticipated, requiring significant time investment from operators to become proficient with the system. Additionally, effective communication between conservation organizations and ranchers emerged as a critical factor for success. In one pilot project, misaligned expectations regarding timelines, funding arrangements, and technology deployment created challenges that could have been avoided through more structured communication protocols.

Despite these initial obstacles, stakeholders universally expressed optimism about the technology's potential and demonstrated strong commitment to continuing their virtual fencing programs. While documented conservation benefits have been limited thus far, largely due to implementation challenges that shifted focus away from specific conservation objectives, participants identified numerous promising applications for future deployment. Stakeholders emphasized that achieving conservation outcomes would require patience as operators progress through the learning curve and technical improvements enhance system reliability. The need for more durable collar designs was consistently highlighted as a priority for advancing the technology's effectiveness. As these pilot projects mature, participants plan to expand their focus on specific conservation applications, building on the operational experience gained during initial implementation phases.

Discussion and Conclusions

Virtual fencing represents a transformative technology for both livestock management and conservation, but realizing its full potential requires addressing several key challenges. While innovative producers are successfully implementing virtual fencing systems across large operations, widespread adoption faces three primary barriers. First, ongoing technological improvements are needed, particularly in areas of battery life, collar retention, and system reliability across diverse landscapes. Second, the significant learning curve for both operators and livestock requires substantial time investment and may initially disrupt established routines. Third, cost remains a critical factor, especially where existing physical infrastructure is functional. Although virtual fencing can be cost-competitive when compared to new fence installation or intensive range riding operations, the initial investment and ongoing maintenance costs can be prohibitive for many operators without external support or clear evidence of return on investment (Umstatter, 2011).

Conservation organizations can play a crucial role in accelerating adoption of virtual fencing technology through strategic partnerships and targeted support. Cost-share programs focused on critical conservation areas, such as migration corridors or sensitive habitats, could help overcome financial barriers while ensuring implementation achieves meaningful conservation outcomes. The success of such programs is evident in existing conservation initiatives, such as the USDA's investment of over $290 million in wildlife-friendly fence modifications since 2014 (USDA-NRCS, 2021). Similar programs could be adapted or developed specifically for virtual fencing adoption. However, these initiatives must be coupled with research to demonstrate conservation effectiveness and identify best practices for implementation.

Looking forward, the implications of successful virtual fencing adoption extend beyond individual ranch operations to landscape-scale conservation outcomes. The technology's ability to create dynamic, adaptable boundaries while reducing physical barriers could fundamentally reshape how we approach grazing management and wildlife conservation in working landscapes. However, realizing these benefits requires proactive engagement with the agricultural community and careful attention to both technical and social aspects of adoption. Strategic partnerships between conservation organizations and livestock operators, supported by targeted research and policy initiatives, will be essential for capitalizing on virtual fencing's potential to advance both agricultural productivity and biodiversity conservation goals.

Acknowledgements

We thank the Alumbra Innovations Foundation for the financial support that made this research possible. We expend our gratitude to the Property and Environment Research Center and the Beyond Yellowstone Program for their partnership in hosting the workshop and supporting the research.

Frequency distribution, species richness and egg per gram of gastrointestinal parasites in free-ranging Papio Ursinus species in a semi-arid savanna ecosystem of Zimbabwe

Banda, A[1]; Moyo, DZ[1]; Ncube, N[1]; Utete, E[2]; Gandiwa, E[3]

[1]Centre for Wildlife conservation and research, Gwanda State University, P.O Box 30, Filabusi, Zimbabwe; [2]Department of Mathematics and Statistics, Faculty of Computational Sciences, Gwanda State University, P.O Box 30 Filabusi, Zimbabwe; [3]Scientific Services, Zimbabwe Parks and Wildlife Management Authority, P.O Box CY 140, Causeway, Harare, Zimbabwe

Keywords: baboons, wildlife-livestock interface, zoonosis

Abstract:
A cross-sectional study of the free-ranging baboon (*Papio ursinus*) troops was undertaken at the Epoch Mine campus, Insiza district, Zimbabwe with the objective of investigating the frequency distribution, species richness and eggs per gram (EPG) of gastrointestinal parasites among three baboon troops. Baboons are general feeders and have been observed to interact with both livestock and humans at Epochmine campus this can lead to cross exchange of parasites among these organisms. One hundred and twenty (120) fresh faecal samples were collected from February 2023 to September 2023. Floatation technique was utilised to process the faecal samples, thereafter samples were placed in Mcmaster slides and viewed under a microscope. Parasite ova were identified based on morphological features like size and shape. There was significant difference in the parasite frequencies among the troops (P=0.041). No significant difference (P = 0.311) was observed in parasite species richness. There was significant differences in egg per gram among the three troops (P=0.00193). The high frequency and EPG of gastrointestinal parasites among the three troops can be attributed to eating less of fortified food among peoples' resident bins and limited use of natural herbs. The high species richness among the baboons can be attributed to larger baboon home range thereby resulting in acquisition of many different gastrointestinal parasites along the way. The observed research outputs calls for active surveillance of gastrointestinal disease outbreaks among humans and livestock since the baboons carry potential zoonotic parasites.

Introduction
Parasites are a common threat in natural animal populations impacting the health of wild animals. The most prevalent of these parasites are the gastrointestinal (GIT) (Obanda *et al*. 2019). Parasites weaken the physical health of the host thereby affecting its ability to forage and consequently being fatal in some instances (Mason *et al*. 2022). Baboons are known to host parasites including those of zoonotic importance (Banda *et al*. 2024). Papio species easily adapt to different environments and interact often with humans

and livestock in the human-wildlife-livestock interfaces making baboons, humans and livestock prone to cross-species disease transmission (Ebbert *et al*. 2013). About 68-70% of the known primate parasites have been reported as multi-host species (Pedersen *et al*. 2005). Close interactions in wildlife-livestock interfaces due to sharing resources like grazing land and water sources can facilitate parasite spill over, spillback and species hybridization (Khanyari *et al*. 2022).

Zoonotic diseases of parasitic origins affect the health and behaviour of baboons and livestock which in turn impacts foraging patterns, vegetation patterns, range land biodiversity and poses a risk to livestock productivity and wildlife conservation (Talukdar *et al*. 2020). Understanding baboon-parasite dynamics and parasite epidemiology across multi-use rangelands is imperative to conservation strategies and mitigation of emerging parasitic diseases (VanderWaal *et al*. 2014). Parasite species richness is another metric often used in primate studies to understand parasite-host dynamics (Deere *et al*. 2021). In light of the foregoing, the study aimed to test the null hypothesis that frequency distribution and parasite species richness would be similar among the three troops present at the Gwanda State University, Epoch Mine campus where wild animals interact with livestock and humans. Especially more often the baboons interact with livestock, eating the animal feed, goat kids if unattended and drinking from livestock water points. This association will likely lead to cross exchange of parasites between baboons and livestock.

Materials and methods

Study site

The study was done at Gwanda State University, Epoch Mine campus, Filabusi, Insiza district. Insiza district is situated in Zimbabwe's natural agro-ecological region 4, which receives mean annual rainfall of 350mm and has mean temperature ranges from 9.93°C to 33.8°C (Chisadza *et al*. 2023). Other primates present in the study area were Vervet monkeys (*Chlorocebus pygerythrus*) (Banda *et al*. 2024).

Sample collection and analysis

Using a descriptive and analytical cross-section design (Larbi *et al*. 2020), the study was undertaken to investigate the frequency distribution, species richness and egg per gram (EPG) of gastrointestinal parasites among three free-ranging baboon troops. One hundred and twenty (120) fresh faecal samples were collected from February 2023 to September 2023. The troops were trailed and fresh faecal samples were randomly collected immediately after defecation or when the baboons had left the immediate vicinity (Banda *et al.* 2024). Collected faecal samples were immediately preserved in 10% formalin. Analysis of samples was done at the Bulawayo Provincial Veterinary Laboratory using the centrifugal floatation technique to process the faecal samples (Hansen and Perry 1990). Thereafter the McMaster technique was used to quantify the observed parasite ova using a compound light microscope (Optika brand, Italy) at x100 magnification (Zajac *et al*. 2021). Parasite ova were identified based on morphological features like size and shape (Taylor *et al*. 2015). Identification was done to suborder and genus level.

Data analysis

Frequency distribution was analysed graphically and a Chi-square test was used to determine if there was significant difference among the troops (Fowler et al. 2013). Margalef index (D_Mg) was used to measure parasite species richness (Aslam 2009). A Kruskall-Wallis test was conducted to test for significant differences among troops. Egg per gram was counted using the McMaster egg counting technique. A Kruskall-Wallis test was conducted to test for significant differences among troops. Analysis was done using the R Studio package version 4.3.2 (R Core Team, 2022).

Results

Six parasite taxa were observed (Figure 1). Troop 1 had the highest number of samples infected with one or more parasite taxa. *Strongylid* nematodes had the highest frequency across the three troops followed by *Schistosoma* spp.

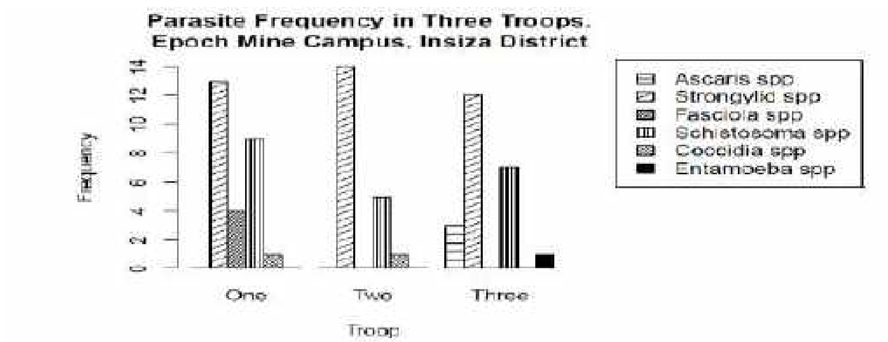

Figure 1 Frequency of parasites in three *Papio ursinus* troops at the Epoch Mine campus, Zimbabwe

A Kruskall-Wallis test indicated significant differences among the troops frequencies (*P*= 0.041). Furthermore, pairwise comparison using Dunn's test (post-hoc analysis) showed no significant differences (*P*= 0.541) between Troop 2 and Troop 3 troops frequencies. However, Troop 1 significantly differed from Troop 2 troops (*P*= 0.026) and Troop 3 (*P*= 0.012) frequencies.

Parasite Species Richness

The Margalef Index (D_Mg) indicated that Troop 3 had the highest parasite species richness (D_Mg =1.361) followed by Troop 1 (D_Mg =1.315), whilst troop 2 had the lowest (D_Mg =1.038) However, there was no significant difference in parasite species richness among the three troops (*P* = 0.311).

Egg per gram

Schistosoma spp. in troop 2 had the highest average EPG among all three troops across all species. The average EPG for Strongylid was the highest in troop 2 (303.85 EPG), while lowest in troop 3 (195.83 EPG). *Coccidia* spp and *Entamoeba* spp had the same and the least average epg. There was a significant difference in average epg among the three troops (Kruskal-Wallis, *P*= 0.00193). A pairwise comparison indicated that troop 1 significantly differed from both troop 2 and 3 (Dunn's test, *P*=0.037; *P*=0.002, respectively), however troop 2 and 3 are not significantly different (Dunn's test, *P*= 0.145).

Discussion

The study observed four helminths and two protozoa taxa. There was a significant difference among the troop frequencies. Strongylid nematodes are common parasites of baboons and they co-occurred in all troops with high frequency (Obanda 2015). Strongylid nematodes have been observed to cause severe diarrhoea; weight loss leading to death if left untreated; affect the respiratory and the gut system in livestock (Income *et al*. 2021). Schistosomiasis caused by *Schistosoma spp* is a neglected tropical disease infecting primates, livestock and humans (Jones *et al*. 2011). Schistosoma species have been found to hybridise, this suggests the probability of exponential growth in emerging zoonotic parasites which might be of public health and veterinary importance (Tober *et al*. 2021). Despite *Coccidia spp* and *Entamoeba spp* being asymptomatic and recording low frequencies in the study, there is a need for further research on the pathogenicity of such species (N'da *et al*. 2022).

The parasite species richness in this study included six species, which is comparable within the range of most parasite species richness observed in most baboon populations of five to eight species (Obanda 2015). No significant differences were noted in parasite species richness among the troops which may be attributed to similar intermediate host ecology in the study area and parasite migration which may occur due to a new individual joining another troop after being chased away from their own troop (Ebbert *et al*. 2013). Five of the taxa have been well-documented in primate studies except for *Fasciola* spp. which was observed in troop 1 only (Banda *et al*. 2024). Further research on spill over and transmission of parasites from baboons to domestic, wildlife species and humans in the study area is imperative. Parasites of zoonotic potential observed in this study highlight the necessity for caution regarding monitoring emerging, re-emerging infections and conservation efforts (Hahn *et al*. 2003). The significant differences in average EPG among different troops may be due to variations in the troops foraging areas. Some troops may be eating more of fortified food from human dustbins, while others forage where livestock graze, thus exposing them to high risk of parasites from livestock (Ryan *et al*. 2012).

Conclusion

The presence of gastrointestinal parasites in baboons suggests future health and livestock productivity implications due to disease emergence and re-emergence. The study highlights the need for active surveillance system to be put in place so as to curb public health and veterinary diseases. Further on, a wider scope/area coverage study is needed as this is a study in a University campus which may differ from the real situation in the country. Strongylid nematodes were not identified to species level hence it is difficult to conclude whether the high frequency observed was a result of a single species or mixed infection of Strongylid nematodes (Ryan *et al*. 2012). This underscores the need for molecular analysis of parasites to the species level to ascertain the potential health implications.

Soils and rare plant habitat in the Colorado Plateau

Boettinger, JL[1]; Schupp, EW[2]

[1] Department of Plants, Soils, and Climate, Utah State University; 4820 Old Main Hill, Logan, UT, 84322, USA, janis.boettinger@usu.edu; [2] Department of Wildland Resources, Utah State University, 5230 Old Main Hill, Logan, UT, 84322, eugene.schupp@usu.edu

Key words: endemic plant, soil depth, species conservation, rangeland planning

Abstract

It is common for botanists and plant ecologists to study the soil of rare plants by sampling the soil surface horizon and analyzing pH and a few other chemical properties, often looking for a "silver bullet" to explain rare plant distribution. It is rare in these studies to investigate the whole soil in a landscape context. However, multiple pedological studies of rare plants in the arid and semiarid climate of western North America's Colorado Plateau reveal a unique soil physical habitat where few other plants exist. These rare, endemic plants adapted and survived in soil environments and edaphic conditions that most plants are unable to survive in, effectively creating a competition-free zone. Shrubby reed-mustard (*Schoenocrambe suffrutescens*), Jones' waxy dogbane (*Cycladenia humilis* var. *jonesii*), Parachute beardtongue (*Penstemon debilis*), and Debeque phacelia (*Phacelia submutica*) all occur in shallow soils in distinct sedimentary rock strata. In the case of *Schoenocrambe suffrutescens*, the habitat was successfully modelled using remotely sensed and topographic data in order to locate new occurrences, and we believe there is potential for modelling potential habitat for the other species. In some cases, the harsh soil physical environment was also associated with one or more chemical properties that are challenging for most common plants. Understanding where these rare endemic plants occur and how they persist facilitates rangeland planning decisions.

Introduction

It is common for botanists and plant ecologists to study the soil of rare plants by sampling the soil surface horizon and analyzing pH and a few other chemical properties, often looking for a "silver bullet" to explain rare plant distribution. It is rare in these studies to investigate the whole soil in a landscape context. There is a relatively high concentration of rare endemic plants in the Colorado Plateau known only to occur in small, specific geographic areas, generally fragmented into smaller subpopulations.

The Colorado Plateau was a basin subject to more than 300 million years of sediment deposition. About 20 million years before present, the region began uplifting and continues to uplift today, reaching elevations of more than 3000 m. The region of 390,000 km^2, centered at the four corners where the states of Utah Arizona, New Mexico and Colorado meet, was dissected by the Colorado River and its tributaries, resulting in tablelands, plateaus, mesas. The elevation ranges from 750 to 3840, the mean elevation is 1936 m, and the climate is mainly arid to semiarid.

We hypothesize that the uplift and dissection of the Colorado Plateau over 20 million years has led to genetic isolation and speciation of plants. The objective of this study was to determine the soil and landscape habitat of four rare endemic plant species in the Colorado Plateau to develop concepts that can help guide rangeland planning that is compatible with conservation efforts.

Methods

Three of the plant species, *Penstemon debilis*, *Cycladenia humilis* var. *jonesii*, and *Phacelia submutica* are listed by the US Fish and Wildlife Service (USFWS) as "Threatened" and one, *Schoenocrambe suffrutescens*, is listed as "Endangered" (USFWS, 2024). *Penstemon debilis*, commonly known as Parachute beardtongue and thought to tolerate toxic trace elements, is a mat-forming perennial that was reported to occur only in the Parachute Creek member of the Green River Formation in western Colorado (McMullen, 1998). *Cycladenia humilis* var. *jonesii*, commonly known as Jones' waxy dogbane and reported to be a gypsophile (Welsh et al., 2015), sometimes thought to be an indicator of selenium (Se) and/or uranium (U), is a perennial that occurs in several Jurassic and Triassic sedimentary rock formations of southern Utah and northern Arizona. *Phacelia submutica* commonly known as Debeque phacelia and thought to tolerate high shrink-swell capacity in soil, is a tiny, low-growing spring annual that occurs only in western Colorado in the "clay barrens" of the Atwell Gulch and Shire members of the Tertiary Wasatch Formation (Langton, 2015). *Schoenocrambe suffrutescens*, commonly known as shrubby reed-mustard and also classified in the literature as *Hesperidanthus suffrutescens* and *Glaucocarpum suffrutescens* (Lewis and Schupp, 2014), is a perennial that occurs only in northeastern Utah in the Green River Formation.

We investigated the soil and landscape characteristics at five populations for *Penstemon debilis*, four populations for *Cycladenia humilis* var. *jonesii* in southern Utah, five populations of *Phacelia submutica*, and three populations of *Schoenocrambe suffrutescens*. We manually excavated soil pits to 1m depth or to a hard rock contact, whichever was shallower. We described soil morphology and sampled soils following standard methods (Schoeneberger et al., 2012). We sampled soil at least 50 cm away from the rare plant in its habitat. In the case of *Schoenocrambe suffrutescens* we also sampled at least 50 cm away from a similar plant in a similar habitat. We determined selected soil physical and chemical properties in the laboratory, including particle-size distribution, pH, calcium carbonate equivalent, gypsum content (if present), and total elemental composition (Soil Survey Staff, 2014). In the case of *Schoenocrambe suffrutescens* we also modeled topographic and remotely sensed spectral characteristics (Baker et al. 2016).

Results

Penstemon debilis occurs in soils formed in shale of the Parachute Creek member of the Tertiary Green River Formation. Plants occurred at elevations ranging from 2425 to 2740 m on steep slopes of 45 to 67% gradient. The soils surface was bare, with very high rock fragment content between very few plants. Soils were shallow, ranging from 17 to 55 cm in depth, and roots were observed in between rock fragments in the fractured shale. In contrast to these similar physical properties, different populations had dissimilar soil chemical properties, with pH ranging from 6.8 to 8.3 and the total elemental content of Se, As, and Hg highly variable. Plants were observed to survive on steep, unstable, shale slopes, with stems appearing to elongate as leaves were buried by shifting talus (McMullen, 1998).

Cycladenia humilis var. *jonesii* soils all had similar site and soil physical properties (Boettinger and Sipes, 1997). The plants occurred on stable slopes of 5 to 50% gradient. Soils were mostly bare, with few plants. Soil parent materials ranged from mudstone to shale to siltstone, all fractured in situ. Soil depth to bedrock ranged from 25 to 50 cm in depth with extremely high rock fragment content in subsoil (90 to nearly 100%

by volume) in the lower part. Roots were observed in between rock fragments in the fractured rock. We were unable to sample sufficient fine-earth fraction material (<2 mm) to characterize texture in the laboratory for most horizons. As with *P. debilis*, the soils at each population had dissimilar soil chemical properties. The soil pH ranged from 6.8 to 8.3. Trace element content of the whole soil (<2-mm and rock fragments) was highly variable. Gypsum was present in soils of only half of the populations – soils in the Castle Valley and Onion Creek populations in southeastern Utah contained gypsum, whereas soils in the San Rafael Swell and Deer Creek populations in southcentral Utah lacked gypsum, which is evidence that *Cycladenia humilis* var. *jonesii* is not an obligate gypsophile.

Phacelia submutica soils all had similar site and soil physical properties (Langton, 2015). Plants occurred on stable slopes of 5 to 85% gradient. Elevation ranged from 1,532 to 1,958 m. Soil were bare with very few plants, and all were less than 30 cm depth to hard bedrock. Soil textures were clay with high clay content ranging from 40 to 85% with a mean of 70%. Soils all had strongly alkaline pH, ranging from 7.7 to 9.7 with a mean of 9.0. The electrical conductivity of some soils was relatively high (3 to 5 dS m^{-1}) in the horizon directly overlying bedrock. The roots of these short-lived annuals did not extend to the bedrock.

Schoenocrambe suffrutescens soils were generally bare with very few plants. The depth to hard bedrock in all soils was less than 59 cm, with most ranging from 9 to 39 cm, and all had high rock fragments (greater than 50% by volume). Soil textures were silt loam to loam. All soils were strongly alkaline, with pH ranging from 8.0 to 9.0, with a mean pH of 8.7. Calcium carbonate equivalent was greater than 50% by mass in the fine earth fraction. Available phosphorus (P) was low (less than <2 mg kg^{-1} soil). The edaphic habitat for *Schoenocrambe suffrutescens* was topographically and spectrally distinct, which facilitated modelling of potential habitat and subsequent identification of new occurrences (Baker et al., 2016).

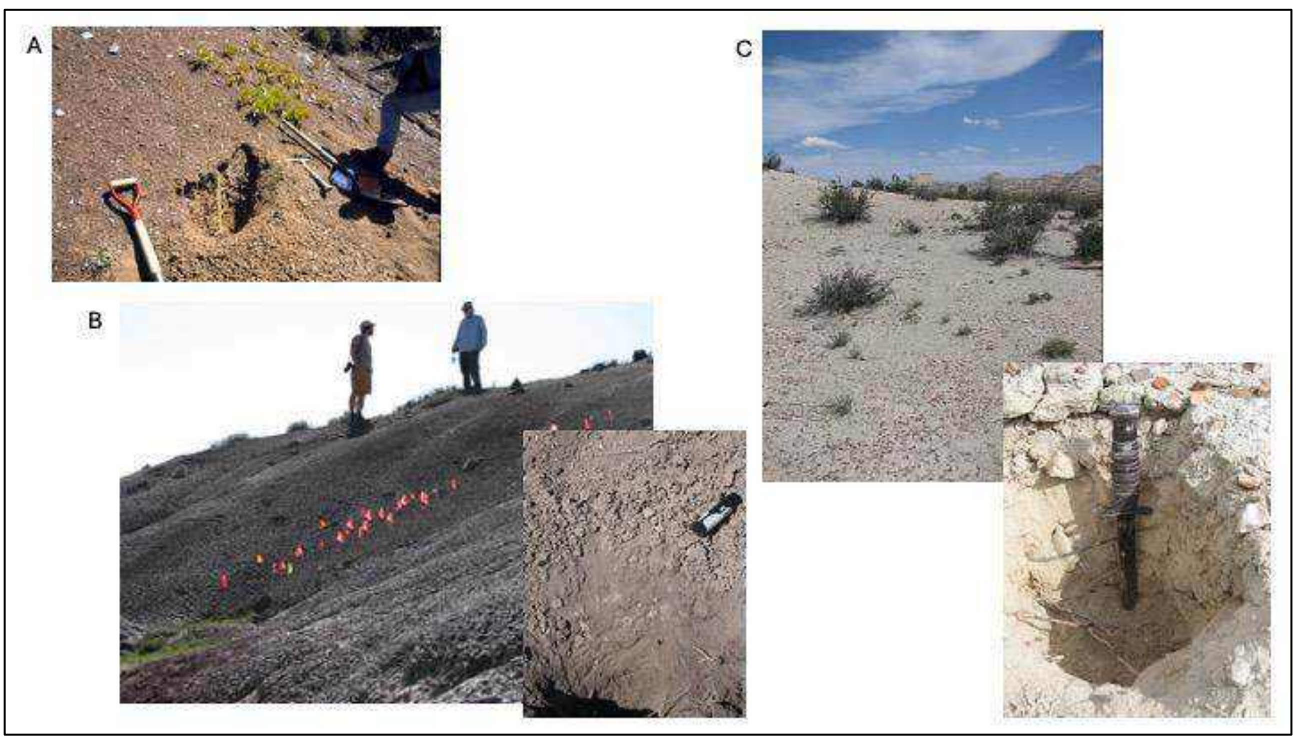

Fig. 1. Typical landscapes and soils of rare endemic plants of the Colorado Plateau. A) *Cycladenia humilis* var. *jonesii* plants (top) and high rock fragment soil on a steep slope in southeastern Utah; depth of soil is 35 cm. B) Red flags mark locations of *Phacelia submutica* on a steep slope in western Colorado; depth of

soil is 30 cm (inset photo). C) *Schoenocrambe suffrutescens* landscape on slope in northeastern Utah; depth of soil is 29 cm (inset photo). All photos by senior author.

Discussion

The key commonality is that all four endemic plant species of the Colorado Plateau can clearly tolerate harsh physical soil conditions. All soils were shallow and the rock fragment content for three of the four species (*Phacelia debilis*, *Cycladenia humilis* var. *jonesii*, *Schoenocrambe suffrutescens*) was very high (50 to 100% by volume). All species were able to tolerate steep slopes and *Phacelia debilis* appeared to have adapted to survive by stem elongation as rock fragments creep downslope due to gravity. The high clay and low rock fragment contents of the *P. submutica* soils were unusual, but still physically challenging for perennials. However, this very shallow-rooted annual is not adversely affected by shallow soils and completes its life cycle in spring when soils are moist, thus avoiding the damaging effects of shrink-swell.

Some endemic plant species of the Colorado Plateau can tolerate gypsum, high concentrations of calcium carbonate, and relatively high concentrations of potentially toxic trace elements such as Se, As, and Hg. However there appears to be no “silver bullet” in terms of a soil chemical property or set of properties that “restricts” these plants to a particular habitat; these species appear to tolerate these chemical conditions rather than require them. In addition, strongly alkaline soils with high pH and/or high concentrations of calcium carbonate have low nutrient availability (e.g., P), adding stress to the harsh soil and landscape physical environment.

These rare, endemic plant species are clearly stress tolerators able to survive in soil and landscape conditions where competitively dominant plant species cannot. We suggest that conservation of rare plant species that occur on otherwise bare areas, on steep slopes, and in shallow soils depends on habitat conservation of these small geographic areas. The occurrence of these plants on bare soil surfaces on distinct geologic formations and often steep slopes can facilitate spectral and topographic modeling of potential plant habitat, which can help locate additional plants and delineate specific geographic areas for conservation.

Conventional grazing decreases soil organic carbon by destroying physical and mineral protections

Abstract

Conventional grazing, with high grazing pressure imposed during the plant growing season, destroys soil structure and carbon (C) protection mechanisms. Soil C is protected from decomposition by encapsulation in soil aggregates or adsorption with metal oxide mineral fractions. However, the processes by which conventional grazing affects soil C protection and the level of soil organic carbon (SOC) remain unclear. We sampled 15 pairs of sites (180 plots) contrasting grazing exclusion inside the fence and conventional grazing outside the fence, in the temperate steppe of Inner Mongolia, China, to elucidate processes affecting soil C protection and to assess the relative contribution of physical versus mineral protection to SOC. We characterized the physical and mineral protection of C by soil aggregate stability (mean weight diameter, MWD) and soil Fe/Al associated organic C, respectively. Our results showed that conventional grazing decreased SOC content (-14.83%) and weakened SOC physical (-4.88%) and mineral (-10.88%) protection, mainly due to increased soil bulk density and pH, and decreased microbial biomass C, compared with grazing exclusion. In addition, conventional grazing-induced reductions in plant inputs (root biomass) could indirectly weaken the physical and mineral protection of C. Declined root-derived C inputs will limit microbial biomass C, thus hindering microbial contribution to soil aggregation and the formation of mineral C fractions. More importantly, we found that destroying physical (57.90%) and mineral (36.76%) protection combined governed the loss of SOC in conventionally grazed grassland. These results imply a need to manage rangelands in a way that retains more litter or root-rich plant species to ensure more plant inputs, promoting physical and mineral protection of soil C.

Introduction

Grassland ecosystems, account for 20% of the world's land area (Yang et al. 2021) and store 10-30% of the global soil organic carbon (SOC) (Ward et al. 2016). As the most widespread land use, livestock grazing profoundly affects SOC by altering plant inputs and soil environment, resulting in a solid potential to regulate SOC dynamics (Lai & Kumar 2020). Conventional grazing is a high-intensity grazing pattern at the peak of the plant growing season. However, previous research has not clarified the mechanism of conventional grazing affecting soil carbon (C) sequestration.

Physical and mineral protection are two fundamental mechanisms for stabilizing SOC (Bai et al. 2020; Chen et al. 2021). Soil aggregates, as the physical protection, are formed by aggregating mineral particles and organic matter (Blanco-Canqui & Lal 2004). While soil metal mineral ions and their oxides (mainly iron, aluminum, and calcium) can interact with organic material through covalent bonds and chelation, limiting SOC mobilization and degradation to act as mineral protection (Ye et al. 2018). Little attention is paid to their relative contribution to SOC in previous research.

Biotic factors ("litter effect" and "root effect") and soil abiotic factors may alter SOC protection in grazing grassland ecosystems (Witzgall et al. 2021; Ye et al. 2018). Increasing litter mass enhanced the input of litter-derived C to soil organic matter by promoting microbial metabolism (Wang et al. 2021), facilitating the bonding and formation of soil aggregation and mineral-associated C. Researchers have generally considered that plant roots might play a dominant role in the protection compared to aboveground plants (or litter) (Sokol & Bradford 2018). Importantly, as a potential soil C pool to maintain SOC stability, root biomass seems to suffer less under grazing disturbance than the changes in litter mass (Yang et al. 2021). Soil abiotic factors could also directly or indirectly influence SOC protection. Grazing might induce extreme trampling to increase soil compaction, directly destroying soil aggregates (Wiesmeier et al. 2012); simultaneously, soil compaction may inhibit root growth and soil microbial activity, especially mycelial extension, thus restricting polymerization of soil aggregates and organo-mineral complexes (Poirier et al. 2018). However, few studies have elucidated the relative contribution of biotic and abiotic factors to the physical and mineral protection in grazed grasslands.

Here, we investigated SOC under conventional grazing and grazing exclusion at 15 sites in a semiarid grassland of northeast China. We tried to elucidate the drivers of physical and mineral protection and the relative contributions of physical and mineral protection to SOC in conventional grazing systems.

Methods

The study site is located in the Hulunbuir Grassland, Inner Mongolia (48.38-50.17°N, 116.73-120.19°E, and 524-780 m altitude). The dominant plant species were *Leymus chinensis* Tzvel. and *Stipa capillata* L. A regional (including 15 sites) field survey was conducted in August 2021. The grassland was fenced into two natural treatments: inside the fence for grazing exclusion and outside the fence for conventional grazing. Grazing was excluded for 2 ~ 35 years in theses 15 sampling grassland.The conventional grazing sites in our study were judged to be heavy grazing based on grazing intensities response ratios for the different intensities of aboveground biomass, SOC content, and soil bulk density in a Chinese grassland meta-analysis (Jiang et al. 2020). Each site was sampled in pairs inside and outside the fence (six pairs of 1m × 1m plots), with a distance of 30m between each pair of sample plots (Song et al. 2018). The soil types were consistent between each pair of sampling plots.

Plant litter was collected in each sample plot and then dried at 65 °C for 48 h. Root biomass was obtained by taking three cores mixed with a root drill in each sample plot, removing stones and soil to retain roots, washing plant roots and then drying them at 65°C for 48h and weighing them. Soil bulk density (BD) was determined using the cutting ring method. After three soil cores were taken by soil drill within each sample plot, they were mixed and passed through a 2 mm sieve to remove stones and roots, and the resulting soil samples were divided into two parts (air-dried and frozen). Frozen soil was used for the determination of soil microbial biomass carbon (MBC), which was fumigated with chloroform and extracted with 0.25 M K_2SO_4 and determined on a TOC analyzer (Multi N/C 3100) (Ding et al. 2016). Air-dried soil was used to determine other soil properties. Soil pH (soil: water of 1: 2.5) was determined using a pH meter. Soil total nitrogen (TN) content was determined using an elemental analyzer (Vario Macro, Germany), and SOC content was determined using an elemental analyzer for soil samples after hydrochloric acid fumigation. The physical protection of soil C was represented by the soil aggregates stability (mean weight diameter, MWD), which was determined by the wet sieving method using a soil aggregates wet apparatus (081301, Eijkekamp, Netherlands) to sieve the soil into macroaggregates (0.25 mm), microaggregates (0.053-0.25 mm), and silt and clay (<0.053 mm) (Kemper & Rosenau 1986). MWD is the sum of the product of the particle size of each aggregate and the weight percent of each fraction (Xu et al. 2021). Mineral protection of soil C was represented as soil Fe/Al associated organic C (Fe/Al-OC), which was extracted from the soil using the CBD method and determined by a TOC analyzer (Fang et al. 2019).

The grazing response ratio of each index was $Ln\ (Index_{conventional\ grazing} / Index_{grazing\ exclusion})$. A mixed linear model was used to test the effect of grazing on each variable, with the site as a random factor. Structural equation modeling (SEM) was used to analyze the pathways by which conventional grazing reduces physical and mineral protection of soil C, and multiple regression analysis was used to analyze the relative contribution of physical and mineral protection to SOC.

Results

SOC content in conventional grazing grassland was 14.84% lower than in grazing exclusion ($p < 0.01$, Fig 1a). For physical protection, the MWD was significantly lower in grazed than grazing exclusion grassland ($p < 0.01$, -4.88%, Fig 1a), resulting from the decrease in weight percentage of macroaggregates and increase in microaggregates ($p < 0.05$, Fig 1a). For mineral protection, soil Fe/Al-OC content was significantly lower in the grazed area than in the grazing exclusion area, reduced by 10.88% ($p < 0.05$, Fig 1a). In addition, Grazing reduced litter mass, root biomass, and MBC ($p <0.01$, Fig 1b). Regarding soil abiotic factors, grazed grasslands had lower soil BD and pH than the grazing exclusion grasslands ($p <0.05$, Fig 1b).

Concerning physical protection, grazing affected soil properties by decreasing root biomass (Fig 1c). Grazing-induced changes in MBC were determined by soil properties (Fig 1c). The changes in MWD were indirectly affected by grazing and jointly determined by MBC, root biomass, and soil properties (Fig 1c). For mineral protection, grazing-induced change in litter mass reduced soil Fe/Al-OC (Fig 1c). Additionally, changes in soil Fe/Al-OC resulted from reduced MBC and increased soil BD and pH by grazing (Fig 1c). Multiple regression analysis indicated that soil physical protection and mineral protection governed SOC content ($p< 0.001$, Fig 1d).

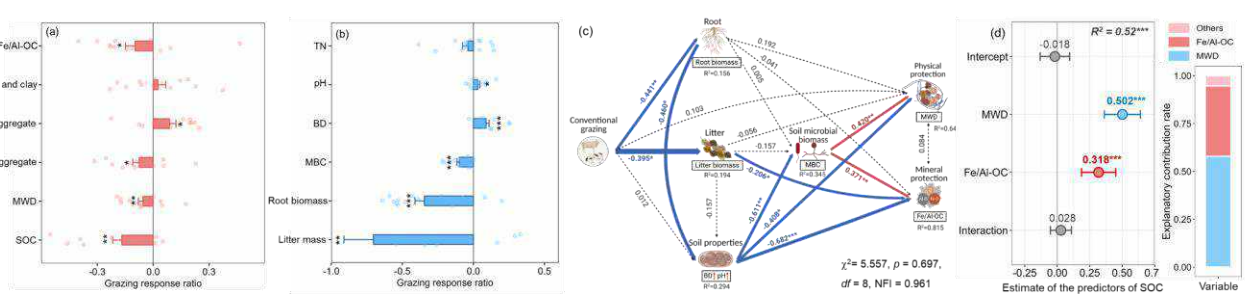

Figure 1 Grazing response ratios for each variable (a, b) with mechanisms by which grazing reduces soil organic carbon and its physical and mineral protection (c, d). The thickness of the arrows in the structural equation model represents the magnitude of the path coefficients, with red arrows representing positive relationships and blue arrows representing negative relationships. “*”, “**”, and “***” indicate that the result was significant at p <0.1, <0.05, <0.01, and <0.001, respectively. SOC: soil organic carbon; MWD:

mean weight diameter of soil aggregate; Fe/Al-OC: Fe/Al associated organic carbon; MBC: microbial biomass carbon; BD: soil bulk density; TN: soil total nitrogen.

Discussion

Plant roots and soil conditions are the main factors influencing SOC physical protection in grazing grasslands. In our study, grazing-induced decreases in root biomass may affect the formation of soil aggregates and alter root-derived C, driving SOC destabilization (Dijkstra et al. 2021). Previous studies found that continuous livestock grazing might inhibit root growth, and lower the input amount of root-derived C into the soil. That might aggravate the negative effects of physical entanglement in the aggregate and root exudates production (Poirier et al. 2018). We found that soil abiotic factors can mediate microbial pathways under grazing, indirectly affecting SOC physical protection. Soil microbial activity and biomass could be inhibited by soil abiotic factors such as soil pH and BD by filtering out some acidophilic microorganisms and reducing oxygen in grazed grasslands. Meanwhile, soil microorganisms decomposed the small molecular organic matter, mycelium, and other binding substances released as a result of the crushing soil aggregates (Fig 1a), thus destroying the physical protection of the SOC (See et al. 2022; Witzgall et al. 2021). All these processes may contribute to SOC destabilization, and the role of soil microorganisms should be considered more in the future.

In particular, grazing-induced reduction in litter mass and root biomass might decrease the potential input amount of plant-derived C, resulting in less production of soil mineral-associated organic C (Yang et al. 2021). Nevertheless, some organic acids (e.g., oxalic acid) in root deposits disrupt covalent metal bonds and mineral adsorption with mineral-associated organic C and increase soil hydrogen ions (Keiluweit et al. 2015). Previous research illustrated that soil microbial biomass and activity were significantly affected by below-ground input (Sokol & Bradford 2018). Then, the lack of microbial-derived C was associated with the decline in vivo turnover of soil microorganisms and the ability of microbial residues to interact with minerals (Lavallee et al. 2020). Our results also suggested that MBC was essential in regulating SOC chemical protection in grazing grasslands.

The multiple regression analysis suggested that SOC physical and chemical protection interact with each other and jointly benefit the retention of SOC. The involvement of soil metallic minerals in forming soil aggregation was like forming stable metal bonds and metal bridges (Bronick & Lal 2005). The adsorption of metal oxides to small molecules of organic matter enhanced the stability of the physical aggregation structure, especially iron and aluminum oxides (Regelink et al. 2015). Grazing negatively affects SOC physicochemical protection and thus promotes SOC loss.

Conventional grazing decreased physical and mineral protection of soil C and SOC compared with grazing exclusion in semiarid temperate grasslands. We highlighted that plant roots were key to maintaining SOC protection and SOC. However, litter mass and soil abiotic factors had a crucial effect on mineral protection. Targeting to improve the physicochemical protection of SOC in grasslands is essential to mitigate the decline in soil C sequestration induced by livestock grazing.

Moderate grazing helps reduce greenhouse gas emissions from typical steppe

Wang, H[1]; Li, FY[1]

[1] Key Laboratory of Ecology & Resource Use of the Monoglian Plateau, School of Ecology & Environment, Inner Mongolia University, Hohhot, 010021, China

Key words: Ecosystem respiration; Methane; Nitrous oxide; Grazing; Mowing

Abstract
Grasslands represent a significant ecosystem that exerts a profound influence on atmospheric greenhouse gas levels in the context of global change. Appropriate grassland management represents an effective means of reducing greenhouse gas (GHG) emissions from grasslands. However, the information on the management effects on GHG emissions from natural grasslands is still insufficient for developing the best practice in grasslands for both production and carbon. The effects of three major management measures, fencing, grazing, and mowing, on ecosystem respiration (CO_2), methane (CH_4) uptake, and nitrous oxide (N_2O) emissions were investigated in a typical grassland area of Xilingol, Inner Mongolia. The results demonstrated that moderate grazing reduced aboveground biomass, decreased CO_2 emissions, promoted belowground nutrient cycling, and increased CH_4 uptake. While mowing increased pasture production and soil carbon and nitrogen content, it was accompanied by higher CO_2 emissions. Reducing grazing frequency slowed biomass loss to some extent, while reducing N_2O emissions. Climatic conditions largely control grassland GHG emissions or uptake, and different management practices control GHGs mainly by affecting the soil micro-environment and soil nutrient content. The results of the study provide data support for carbon sequestration and emission reduction in grasslands. It can be concluded that moderate grazing intensity and frequency are the optimal management practices to mitigate GHG emissions from grasslands. Furthermore, the advantages and disadvantages of increased pasture production and increased GHG emissions from mowing should be weighed to further optimize grassland management.

Introduction
Grassland degradation can induce biodiversity loss and productivity decline, reduce carbon (C) and nitrogen (N) cycling and other ecosystem services, and increases greenhouse gases (GHGs) emissions contributing to global warming (Bai *et al.* 2018). It is imperative to implement sustainable management measures to enhance grassland production while concomitantly minimizing the adverse environmental impact (Taube *et al.* 2014). The main management methods for the Inner Mongolian steppe grasslands are grazing, mowing for hay, and enclosure (Dong *et al.* 2020). Grazing regulates grassland GHG emissions by altering of vegetation and soil physicochemical properties through livestock foraging, trampling and excreta deposition (Tang *et al.* 2019). Mowing or hay harvesting removes a large part of plant aboveground biomass and nutrients, thus alters C and N cycling processes that occur within the ecosystem and thereby altering

greenhouse gases flux (Niu *et al.* 2013). However, the effects of these management measures on grassland GHG emissions are unclear. The function of grassland ecosystems in C sequestration and emission reductions under various grassland management remains a matter of contention, largely due to the high spatial heterogeneity and discrepancies in research methodologies (Piao *et al.* 2022). Further investigation is required to ascertain the implications of differing management practices on GHG emissions in grassland ecosystems.

Here, at a typical steppe located in central of Inner Mongolia, China, we determined the GHGs fluxes in grasslands subjected to experimental mowing, grazing and enclosing (no grazing nor mowing), and analyzed the mechanisms underlying the GHGs variation across management practices. We hypothesized that: (i) grazing at moderate intensity increases ecosystem respiration rate (ER, i.e., CO_2 emission) and N_2O emission, but decreases CH_4 uptake; (ii) In contrast to grazing, mowing decreases ER and N_2O emission, but increases CH_4 uptake; (iii) Management regulates GHG fluxes mainly by altering plant production and soil moisture.

Methods

GHG fluxes measurement in this research was carried out at the designated experimental grassland located at the Observation and Research Station for the Typical Steppe Ecosystem of the Ministry of Education of China (44°10' N, 116°28' E, 1101 m a.s.) with a mean annual temperature of -0.5 °C and a mean annual precipitation of 315 mm. The natural vegetation is typical steppe in this region with *Leymus chinensis* (Trin.) Tzvel., *Stipa krylovii* Roshev and *Cleistogenes squarrosa* (Trin.) Keng. as the dominant species.

A randomized block design was used to arrange four treatments of management practices, with three replications in 12 grassland plots, and the plot size is 33 m × 33 m. The four management practices were (i) whole plant growing season grazing (WG): from May to September; (ii) Spring and summer grazing (SG): only in May and July; (iii) Autumn mowing (AM): mowing around August 20th, leaving a stubble at 6 cm and removing the hay; and (iv) enclosed grassland (EN): no grazing nor mowing. Six sheep were introduced to the grassland for grazing on the 20th day and removed when the stubble height of the dominant grassland species reached approximately 6 cm.

GHG fluxes assessment were conducted via the static chamber technique coupled with gas chromatography test, from June to September. Three gas chamber bottom frames with grooves were set up in each plot for natural sampling. The surface air temperature (AT), soil temperature (ST) and soil volumetric moisture content (SM) was recorded during the collection of gas samples. Gas collection was made once a week during the growing season. At the same time, we monitored plant species richness (SR), aboveground biomass (AGB) and belowground biomass (BGB) and measured soil ammonium nitrogen (NH_4^+-N), nitrate nitrogen (NO_3^--N), soil inorganic nitrogen (SIN), pH, soil total organic carbon (TOC), total carbon (TC), total nitrogen (TN) and bulk density (BD),

2.4. Statistical analyses

One-way analysis of variance (ANOVA) was used in IBM SPSS Statistics.27.0 to assess changes in GHG fluxes, and the environmental factors, including climatic (precipitation, temperature), soil physical (AT, ST, SM, pH, BD, texture) and chemical (TOC, TC, TN, NH_4^+-N, NO_3^--N, C/N, SIN), as well as plant (AGB, BGB, SR) factors, across management practices. An analysis using boosted regression trees model (BRTs) was performed to explore the relative importance of various environmental variables on GHG emissions and uptake by *gbm* package in R v.4.2.1.

Results

Management implications on vegetation and soil

Grassland vegetation and soil were significantly affected by management practices. Compared to EN, grazing (both WG and SG) reduced AGB by 44.03%. Mowing (AM) increased plant AGB by 17.39%, while it did not affect BGB. Compared to EN, WG and AM significantly increased AT and ST, while SG had no such an overall significant effect. Compared to EN, both WG and SG increased soil BD but decreased soil inorganic nitrogen; WG, SG and AM significantly increased TC, SG significantly increased TN, WG significantly increased the C/N ratio, and AM significantly enhanced TOC (Table 1).

Management implications on GHG emissions

Grassland ecosystem respiration (CO_2 release) showed a nearly unimodal curve throughout the plant growing period with peaks observed in late July. CO_2 release was significantly lower under the two grazing management and EN than under AM and EN. The studied steppe functioned as a CH_4 sink throughout the plant growing period with peak uptake occurring in Jun. The soil CH_4 absorption under WG was significantly higher than that under EN and AM. The N_2O emissions during the growing season were more volatile and variable and showed two peaks. The average N_2O emission rates were the lowest under SG, which was significantly lower than the highest rate under AM, EN and WG. (Fig. 1)

Factors driving the emission of the three GHGs under different managements

BRTs model demonstrated the relative contribution of all factors to GHGs fluxes, which explained 86.69 %, 59.28 %, and 59.92 % of the variation in CO_2, CH_4, and N_2O fluxes, respectively. Climatic, soil physical and chemical factors were the major explanatory factors for GHG emissions in grasslands, but their contribution differed to each of the three GHGs. Climatic factors (46 %) had the biggest contribution to CO_2 release followed by soil physical factors (25 %); climate (35 %) and soil chemical (32 %) and physical factors (26 %) are major factors affecting for N_2O emission; while CH_4 uptake was more regulated by soil physical (40 %) and chemical factors (25 %) than by climate factors (21 %). In addition, plant factors also had a certain contribution to variation in GHGs emissions. (Fig. 2)

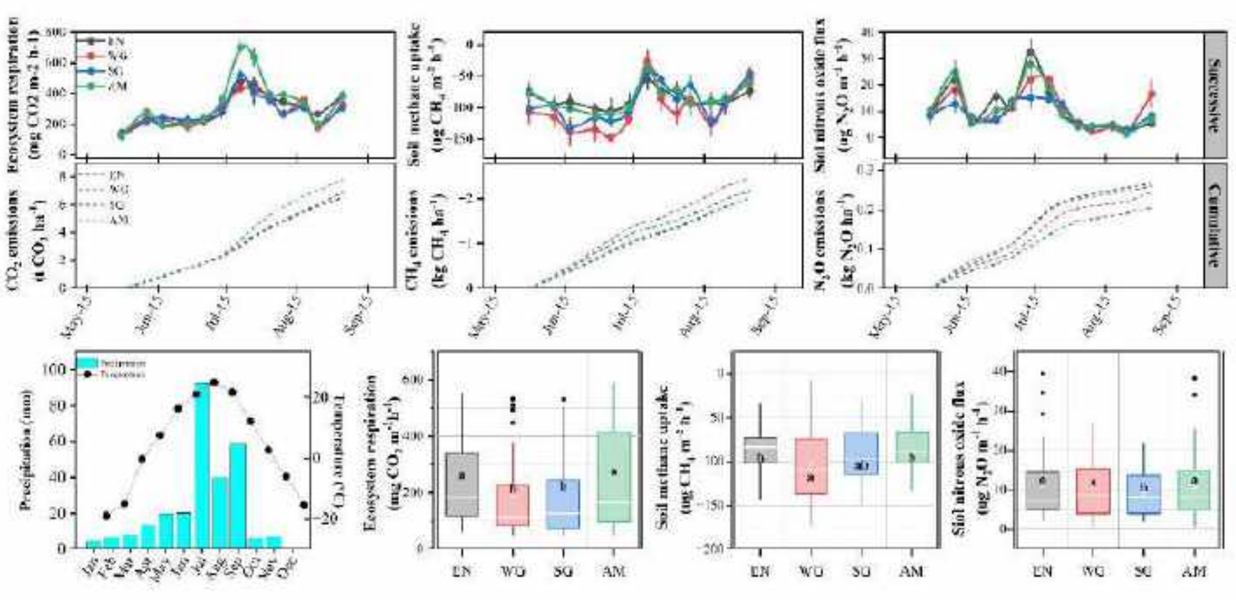

Fig. 1 GHG flux to different managements in growing period and monthly mean temperature and precipitation in the experimental period

Discussion [Conclusions/Implications]

The emission of GHGs from grassland ecosystems is a complex biological and ecological process, and is affected by numerous factors (Dangal *et al.* 2020). Light grazing may induce plant over-compensatory growth thus increase ER (Zhou *et al.* 2017), while mowing has no effect or reduces ER (Jia *et al.* 2012). Grazing reduces plant AGB and plant respiration thus decreases ER, while mowing increases ST that stimulates soil microbial activity and respiration thus enhances ER (Benot *et al.* 2014). Grazing reduces AGB and increases ST, which, in turn, stimulates methanotrophic activities and thus CH_4 uptake (Zhou *et al.* 2007). The increased ST was accompanied by decreased SM and increased soil aeration, which enhances the CH_4 diffusion from atmospheric to the soil (Liu *et al.* 2007). CH_4 uptake is typically inversely correlated with SIN content because NH_4^+-N can be oxidized by methanotrophic instead of CH_4, whereas NO_3^--N enhances soil oxidation potential, influences the activity of methanotrophic, and might reduce the CH_4 uptake (Zheng *et al.* 2024). N_2O is mainly generated through the processes of nitrification and denitrification, which can easily be altered by the variations in soil temperature, moisture, and nutrients induced by grazing and mowing (Xia *et al.* 2022). Soil inorganic nitrogen content may be the reason for a reduction in N_2O emissions under SG, as studies have shown that SIN is a substrate for nitrification and denitrification, and has a significant controlling effect on soil N_2O emissions (Müller *et al.* 2002).

Our BRTs mode indicates that temperature or precipitation are the major controlling factor for GHG emission and uptake in typical steppes, followed by soil physical and chemical properties. The effects of climate and grassland management on grasslands are inextricably linked (Reichstein *et al.* 2013). Some studies have indicated that climate (precipitation) exerts a more pronounced influence on CO_2 release than grassland management (grazing and mowing) (Zhang et al., 2023). However, global-scale studies have demonstrated that grassland management (grazing) exerts a more pronounced effect on grassland carbon stocks than climate change (Zhou *et al.* 2019).

While the climatic factors are dominant in controlling GHGs emissions form ecosystems, different management practices equally affect the GHGs fluxes by altering plant standing biomass and thereby influences soil physical and chemical properties and soil microbial activities. Further investigation into the mechanisms underlying these interactions is essential, especially under the implication from both natural and anthropogenic factors. The implementation of effective emission reduction strategies demands a comprehensive understanding of these complex interactions.

Key words: Grazing; dissolved organic carbon; microbial biomass carbon; soil organic carbon; ^{13}C

Abstract

Grazing represents a multifaceted interaction between livestock and grasslands, encompassing three main mechanisms: defoliation, dung and urine return, and trampling, each of which profoundly affects soil carbon (C) storage processes. To better understand the impact of grazing on soil C dynamics, we conducted an in-situ ^{13}C pulse labeling experiment on a field-simulated grazing platform, incorporating separate or combined treatments of defoliation, excreta return, and trampling. We tracked ^{13}C allocation in dissolved organic carbon (DOC), microbial biomass carbon (MBC) and soil organic carbon (SOC). We found that mowing significantly promoted the accumulation of root-derived DOC and MBC. Trampling also increased root-derived DOC. A positive correlation was observed between root-derived DOC and MBC, whereas no significant correlation was found between root-derived SOC and either root-derived DOC or MBC. Overall, we disentangled the complex grazing behaviors, quantified and tracked the pathways of C among different C pools under different grazing disturbance. Our study also highlights the distinct impact of mowing, trampling, and dung and urine return by ungulates on SOC, and future research should thoroughly consider these mechanisms to improve grassland management practices.

Introduction

Grasslands occupy approximately one-fifth of the Earth's land surface and store an estimated 200–300 Pg of carbon. As a result, carbon allocation dynamics within grasslands play a critical role in shaping the global carbon balance (Bai & Cotrufo, 2022). In these ecosystems, minor shifts in plant and soil carbon pools can affect atmospheric CO_2 concentrations. Investigating the turnover and sequestration of grassland carbon is therefore essential for understanding its impact on global climate change. As active components of the soil carbon pool, dissolved organic carbon (DOC) and microbial biomass carbon (MBC) are critical indicators for predicting soil carbon release and stability.

Grazing represents a complex interaction between livestock and grasslands, encompassing three key mechanisms: mowing, dung and urine return, and trampling. Each of these mechanisms can significantly impact soil carbon storage processes. Although DOC accounts for only a small fraction of soil organic carbon (SOC) (approximately 0.25%), it represents the most dynamic and mobile component of SOC (Angst et al., 2023). DOC plays a pivotal role in SOC formation and the processes of soil carbon transport and transformation. Labile compounds within DOC contribute directly to SOC through the *in vivo* turnover process of the soil microbial carbon pump, while some recalcitrant components can also form SOC directly through mineral adsorption (Liang et al., 2017). Grazing by livestock can significantly alter the composition and diversity of plant communities, which may, in turn, affect the quantity and composition of root exudates DOC and the leached DOC from surface litter, ultimately influencing the formation of SOC (Wei et al., 2023). Plant-derived DOC plays a crucial role in the process of being converted into stable SOC, with the involvement of soil microorganisms. MBC is an important driving force for the decomposition and transformation of SOC. Microorganisms fix or release carbon into the soil or atmosphere through the decomposition of organic matter. Dung and urine return can increase available nutrients, which is more conducive to the formation of MBC. Overall, grazing promotes SOC formation through living root inputs. However, further evidence is still needed to determine whether the changes in DOC or MBC under grazing conditions will ultimately affect SOC.

Methods

Study site and experimental design

The study was conducted in a semiarid steppe at the Duolun Restoration Ecology Station of the Institute of Botany, Chinese Academy of Sciences (42° 02′ N, 116° 17′ E), located in Inner Mongolia, China. The site experiences a mean annual temperature of 2.1°C and an average annual precipitation of 378 mm.

In May 2015, a simulated grazing experiment was initiated using a randomized block design with factorial treatments. The treatments included mowing to simulate defoliation by livestock (with and without mowing), the addition of a liquid mixture of dung and urine (with and without addition), and simulated trampling (with and without trampling). Trampling was performed by a man who wore hoof-shaped shoes and carried a counterweight walking in the plots. These factors were combined to create eight distinct treatment combinations (Liu et al., 2015). The experiment was replicated across eight blocks, resulting in a total of 64 plots. Detailed information on the experimental design is available in Wei et al. (2023) and Liu et al. (2015).

$^{13}CO_2$ pulse labeling

The labeling experiment began on July 29, 2022, during the 8th year of the ongoing experimental treatments. In each of the eight treatments, five replicate subplots were selected for labelling (40 total). Labeling was conducted on consecutive sunny days, with one plot labeled per day, requiring a total of 5 days to label all 5 replicate plots. We constructed a labeling chamber using steel pipe supports and transparent polyethylene film (with a light transmittance of over 92%), measuring 0.5 m × 0.5 m × 0.6 m. The bottom of the chamber was inserted into the soil to a depth of 5 cm.

The $^{13}CO_2$ pulse was generated by slowly injecting a sodium bicarbonate solution, made by dissolving 1.0 g of sodium bicarbonate ($NaH^{13}CO_3$, 99 atom% ^{13}C) in 40 mL of water, and then adding 100 mL of 1.0 M H_2SO_4. To prevent excessive $^{13}CO_2$ concentrations, the sodium bicarbonate solution was added to the sulfuric acid solution in two stages. Twenty-four hours after labeling, we collected soil samples and measured for DOC, MBC and SOC.

MBC and DOC were measured using the chloroform fumigation-extraction method. Two soil subsamples, each equivalent to 7.5 g dry weight and stored at −20°C, were prepared for analysis. One subsample underwent chloroform fumigation in the dark for 24 hours, while the other remained unfumigated as a control. Following treatment, both subsamples were extracted by shaking them with 30 mL of 0.25 M K_2SO_4 for 1 hour, and the resulting solutions were filtered. Total organic carbon in the extracts was quantified using a TOC/TN analyzer (Multi N/C 3100, Analytik Jena, Jena, Germany). DOC was determined from the unfumigated samples, while MBC was calculated as the difference in organic carbon content between the fumigated and unfumigated samples.

Data analysis was conducted using R version 4.3.0. Initially, we employed linear mixed models (LMMs) with 'treatments' as a fixed effect and 'block' as a random effect to examine the impacts of mowing, trampling, and dung and urine return on ^{13}C-DOC and ^{13}C-MBC. These models were implemented using the lmer function from the lme4 package. Linear regression analysis was performed using R software to explore the relationships between ^{13}C-SOC and ^{13}C-DOC or ^{13}C-MBC.

Results

Defoliation significantly increased root-derived DOC (+33.03%) and MBC (+33.85%) ($p < 0.05$, Fig. 1 a, b). Trampling also increased DOC (+34.43%, $p < 0.05$, Fig. a). MBC was positively correlated with root-derived DOC (p < 0.05, Fig. c). While SOC showed no correlation with MBC or DOC (Fig. d, e).

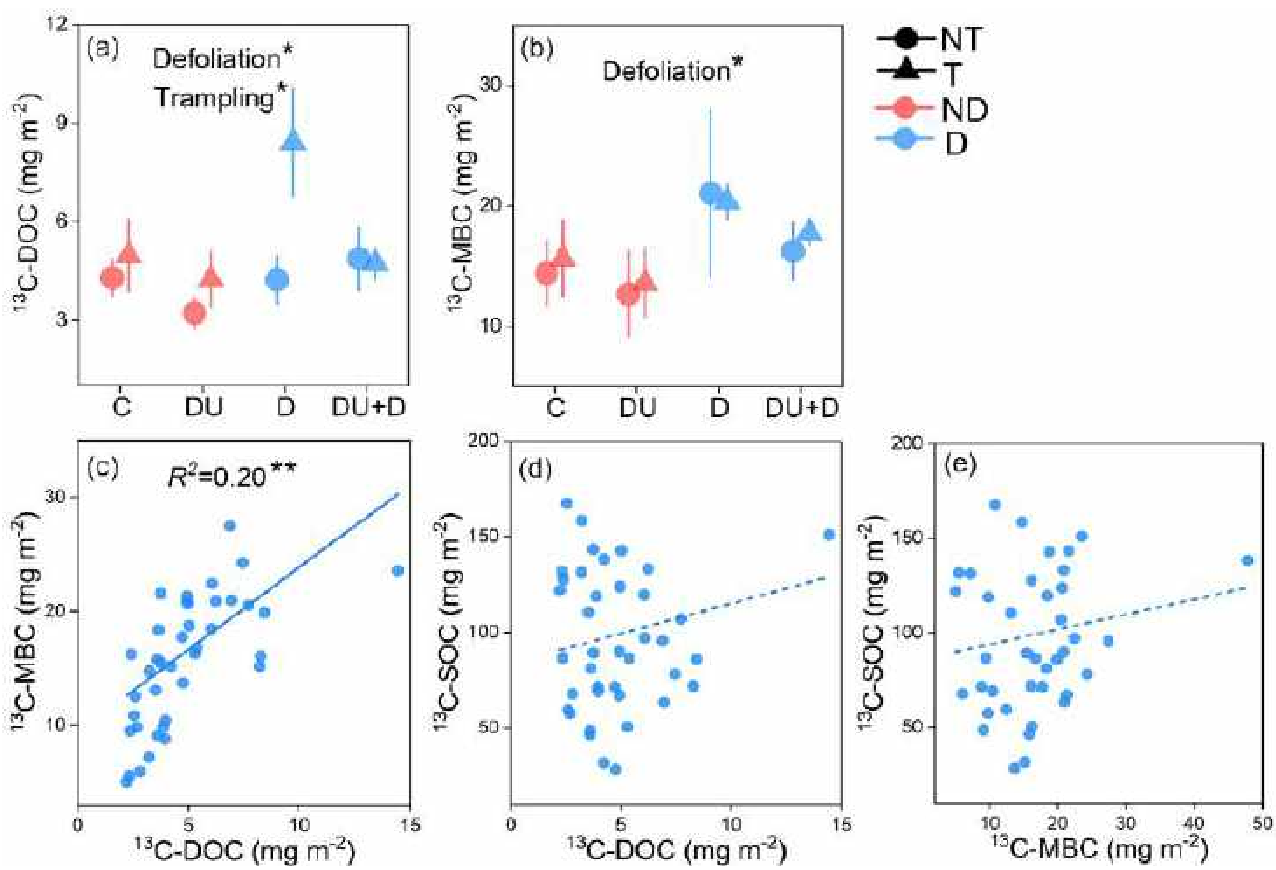

Fig. 1 The effects of grazing treatments on root-derived DOC (a), MBC (b). The relationship between ^{13}C-MBC and ^{13}C-DOC (b), ^{13}C-SOC and ^{13}C-DOC (d), ^{13}C-MBC (e). Note: C: control, D: defoliation, DU: Dung and urine addition, T: trampling.

Discussion

This study employed a ^{13}C isotope pulse labeling to quantitatively analyze the impact of living root-derived carbon inputs under grazing conditions on DOC and MBC. It also explored the relationship between root-derived DOC, MBC, and root-derived SOC under grazing.

Defoliation leads to increased root biomass (or specific root area). The positive correlation between root exudation and SRL suggests that changes in root functional traits enhance plant tolerance to defoliation, promoting the formation of root-derived DOC (Huang et al., 2021). DOC, as an unstable carbon source, is more readily utilized by microorganisms, serving as a carbon source for microbial activity. The positive correlation we found between ^{13}C-DOC and ^{13}C-MBC supports this hypothesis. However, the lack of a relationship between ^{13}C-SOC and either DOC or MBC indicate that other pathways may be ultimately dominating SOC formation under grazing, such as soil microbial necromass carbon. Liang et al. (2019) reported that microbial necromass carbon contributes more than 50% to SOC in grasslands. Therefore, future research could focus more on the changes in soil microbial necromass carbon to better understand SOC formation.

Livestock trampling compacts soil and promotes the contact between soil and roots, which may destroy soil aggregates to a certain extent, promote root growth and produce more root-derived DOC (Wei et al., 2021). Trampling has been shown to break plant material into fragments, facilitating the incorporation of litter into the soil (Mancilla-Leyton et al., 2013). This process, in turn, may enhance litter decomposition by stimulating microbial activity.

Abstract

Grasslands store 10–30% of the world's soil organic carbon (SOC) and have the potential to partially mitigate rising atmospheric CO_2 concentrations. Large ungulate grazing plays a crucial role in regulating SOC storage in grassland ecosystems. However, a more detailed mechanistic understanding of how grazing influences SOC dynamics is still needed. We investigated soil C formation among different C pools, including particulate organic carbon (POC) and mineral-associated soil organic carbon (MAOC)in a multiyear field experiment by quantifying litter-derived C inputs, in response to mowing, trampling, and dung and urine return (and combinations), treatments. We found that mowing significantly enhanced litter-derived SOC and POC formation. Trampling increased SOC, POC and MAOC pool, possibly by enhancing mixing of litter and soil, and increasing C accessibility for soil microorganisms. Our results elucidated the specific mechanisms of large ungulate grazing by quantifying the C inputs and formation processes. Accurately quantifying the contribution of plant C input to SOC pool under various management practices in grasslands is the next critical step toward improving predictions of SOC dynamics.

Introduction

Ninety percent of the terrestrial carbon stocks are stored underground in the form of root biomass and soil organic carbon (SOC) (Bai & Cotrufo, 2022), is highly sensitive to small fluctuations. The C balance of grassland soils is affected by carbon inputs that affect long-term carbon sequestration, especially litter C inputs. For analysis, soil carbon was divided into two distinct carbon pools: mineral-associated soil organic carbon (MAOC, <53 μm) and particulate organic carbon (POC, >53 μm). The MAOC pool is stable over long timescales and is considered to cycle more slowly than the POC pool. Because of the large extent of grasslands globally, it is important to have a quantitative understanding of the dynamics of soil C to make a credible estimate of the possible impacts of grazing management on the global C cycle.

Grazing is a complex interaction of livestock and grasslands, involving three potentially important mechanisms: defoliation, dung and urine deposition, and trampling, each of which may strongly influence processes of soil C storage. Defoliation reduces plant biomass, height, and coverage (Zhu et al., 2012), which in turn increases UV exposure and affects soil parameters such as moisture (Li et al., 2022). Soil moisture is crucial for litter decomposition in semi-arid grasslands, and grazing limits litter decomposition by reducing soil moisture (Wang et al., 2020). Besides, trampling alters soil physical properties. For instance, it increases bulk density (Liu et al., 2015) but decreases aeration and moisture (Wang et al., 2018), thus limiting microbial activity and litter decomposition. Trampling also breaks up litter and incorporates it into the soil, making it more accessible to microbes, which promotes the formation of SOC or POC (Wei et al., 2021). Furthermore, dung and urine return increasing nitrogen availability (Liu et al., 2015), which accelerates litter decomposition by enhancing soil microbial biomass, and increasing MAOC formation. Overall, grazing can promotechang soil organic carbon formation through litter decomposition. However, evidence for this mechanism remains limited. This study investigated the effects of grazing on organic carbon formation from litter carbon, ^{13}C-labeled litter was used to trace the fate of carbon in the different C pools.

Methods

Study site and experimental design

We conducted the study in a semiarid steppe at the Duolun Restoration Ecology Station of the Institute of Botany, the Chinese Academy of Sciences (42° 02′ N,116° 17′ E, mean annual temperature is 2.1 ◦C, mean annual precipitation is 378 mm), Inner Mongolia, China.

In May 2015, we applied a factorial combination of mowing (M+ or M-, adding a liquid mixture of dung and urine (D+ or D-), and trampling (T+ or T-), which resulted in eight different treatment combinations (Liu et al., 2015). Eight replicant blocks were established, resulting in 64 plots total. Please refer to Wei et al. (2023) for specific experimental design.

In early June 2018, decomposition collars were placed in each plot (Wei et al., 2023). Soil samples from the 0-5 cm depth were extracted using a homemade auger (diameter = 11 cm, height = 5 cm), sieved (5 mm), and roots and residual plant material were removed. PVC collars (diameter = 10 cm, height = 6 cm) were inserted into the core holes, and the sieved root-free soil was refilled. PVC rings (diameter = 10 cm, height = 1 cm) with a 1 mm mesh were placed over the collars to prevent fresh litter from entering. The 1 mm nylon mesh provided limited protection against solar radiation. Two decomposition PVC collars were set up in each subplot, with the PVC collars matching the treatment of the subplot. At the end of September, one PVC collar received marked litter (2.5 g per collar, spread on the soil surface), while the other collar served as a control (bare soil). The litter was collected from 3-month-old *Stipa kilovii* plants, labeled with ^{13}C-CO_2, with a carbon content of 461.5 g kg^{-1}, nitrogen content of 16.2 g kg^{-1}, and a C:N ratio of 28.5. Prior to application, the litter was cut into 1-2 cm pieces and applied evenly. Each year (i.e., 2019 and 2020), soil and remaining litter samples were collected from the four collars in each plot. Soil samples from the corresponding bare soil controls were also taken.

Soil carbon was fractionated into POC and MAOC pools. A physical fractionation method was used to separate organic carbon into these two pools. Soil samples (10 g air-dried soil) were shaken with 30 mL of a chemical dispersant (sodium hexametaphosphate: NaHMP, 50 g L^{-1}) at 200 rpm for 18 hours. After shaking, the sample was passed through a 53 µm sieve under water using a vibrating sieve (AS 200 Control, Retsch, Germany) to ensure that all MAOC was thoroughly washed. The two fractions were dried at 65°C and weighed.

All analyses were performed using R 4.1.2. We firstly performed linear mixed models (LMMs) that included 'treatments' as a fixed effect and 'block' as a random effect to test the effects of mowing, trampling, and dung and urine on litter-derived SOC, POC and MAOC using the lmer function in the package lme4.

Results

Mowing significantly enhanced litter-derived SOC formation after two years of decomposition ($p < 0.05$), with increases of 15% and 34% in newly formed SOC, respectively (Fig. 1 a, d). Both mowing and trampling promoted POC formation after two years of decomposition, but only trampling enhanced MAOC formation (Fig. e, f). However, no effect of grazing treatments on litter-derived POC was observed during the first year of decomposition (Fig. 1b). The return of dung and urine had a limited impact on SOC formation in both years, but promoted the formation of MAOC after one year decomposition (Fig. 1c).

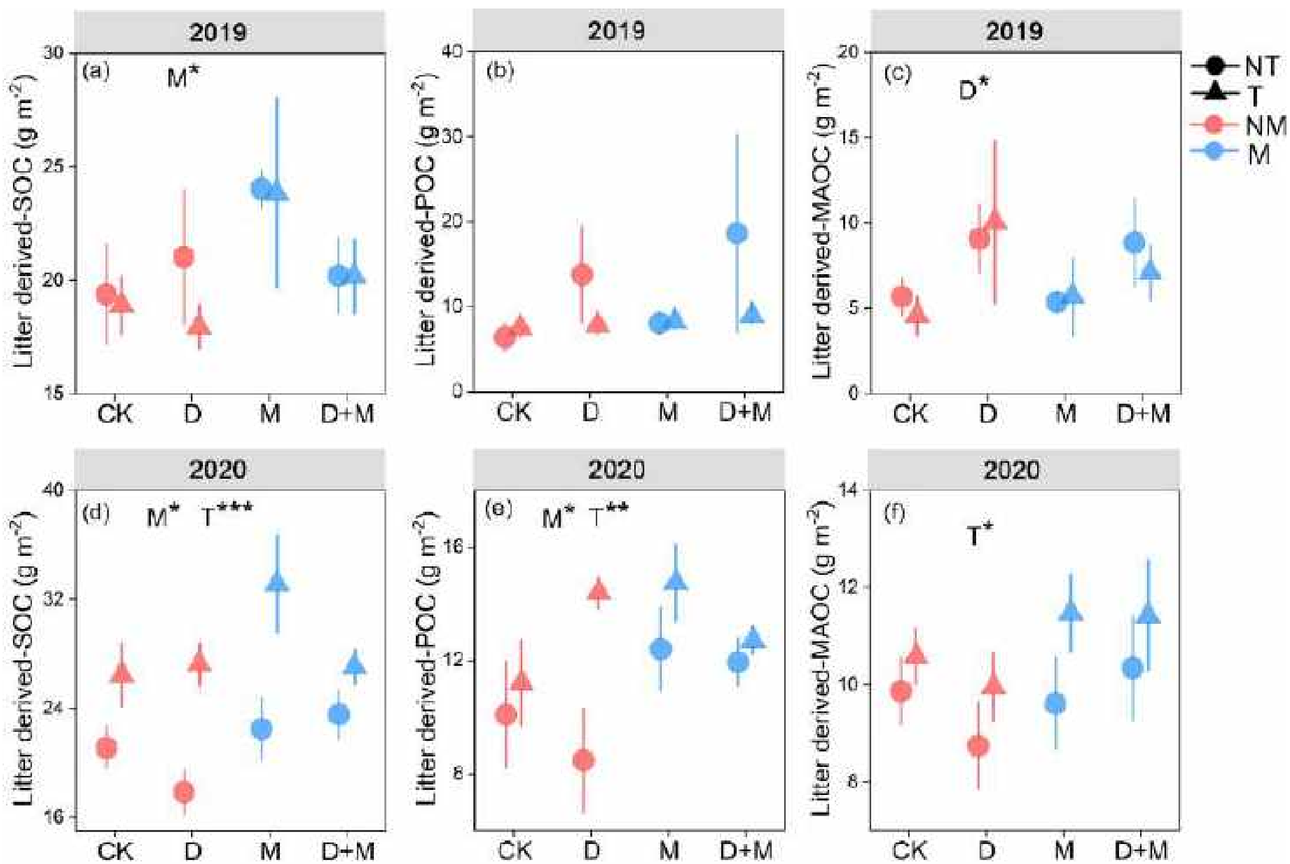

Fig. 1 The effects of simulated livestock grazing treatments on litter-derived SOC, POC, MAOC in 2019 (a, b, c) and 2020 (d, e, f). Note: CK: control, M: mowing, D: dung and urine return, T: trampling.

Discussion

Previous studies have demonstrated the impact of livestock grazing on changes in plant carbon inputs to the soil and the decomposition of litter inputs (Zhou et al., 2017). In this study, we used a ^{13}C isotope tracing method to quantify the effects of plant carbon inputs on SOC and the contribution of decomposed litter carbon to the SOC pool under grazing.

Mowing reduced aboveground biomass, plant height, and plant coverage, thereby increasing canopy light transmittance and UV exposure at the soil surface. In arid and semi-arid ecosystems, UV-induced litter decomposition plays a critical role in the decomposition of aboveground litter (Wang et al., 2017). Studies have shown that UV-induced increases in litter biodegradation, such as the decomposition of complex compounds, are more important than direct UV-driven abiotic degradation (Jiang et al., 2022). Changes in the physicochemical properties of litter compounds can accelerate subsequent microbial decomposition, a process known as the photodegradation effect (Wang et al., 2017). Therefore, the increased UV intensity in mowed areas promotes microbial involvement in organic carbon formation. However, it is undeniable that the increase in UV radiation, which leads to reduced soil moisture, may also somewhat limit the transfer of litter decomposition to the soil carbon pool.

Trampling causes soil compaction, increasing the proximity of soil microbes to litter, making it easier for microbes to decompose the litter and promoting the formation of POC (Helgason et al., 2014). Furthermore, trampling mixes litter with soil, increasing the proximity of litter to microbial communities and enhancing litter decomposition (Liu et al., 2018). Previous laboratory incubation experiments have found that trampling facilitates the incorporation of litter into the soil, promoting microbial utilization of litter carbon and the physicochemical stabilization of decomposed litter carbon (Wei et al., 2021).

Key words: fire modelling; juniper woodland; sagebrush steppe treatment evaluation project; treatment durability

Abstract

Increased wildfire size and frequency pose major challenges to rangeland conservation. A common strategy for mitigating fire risk in sagebrush-dominated rangelands is to use fuel treatments that alter the amount and structure of burnable material, resulting in lower fire intensity, and creating access points for fire suppression resources. For fuel treatments to be practical in management, durability (lasting effectiveness) is critical. We present 15 years of data on fuel accumulation and resultant modeled fire behavior through time in prescribed fire, mechanical, herbicide, and control plots using data from the Sagebrush Steppe Treatment Evaluation Project (SageSTEP). In shrub-dominated plots ('shrubland network'), fire and mechanical treatments reduced fuel beds by up to 49%, resulting in modeled flame lengths that were significantly lower than untreated control plots. In sagebrush systems experiencing conifer expansion ('woodland network'), however, treatments increased surface fire spread rate by 15-21 times that of untreated areas due to increased herbaceous fuels. However, treatments also completely removed the risk of canopy fire spread. By 15 years post-treatment, durability was limited in shrubland systems, though prescribed fire and mechanical treatments continued to perform better than herbicide or untreated control treatments through year 10. In woodland plots, the infilling and growth of trees began to limit durability by post-treatment year 15. An improved understanding of fuel treatment effectiveness and durability will allow natural resource managers to evaluate tradeoffs and synergies in conserving rangeland ecosystems and reducing the potential for fast spreading and high intensity wildfire.

Introduction

Fire regimes in sagebrush-dominated ecosystems historically were typified by long periods without fire, facilitating a patchwork of late successional sagebrush canopy with intermittent native bunchgrass prairies in recently burned areas. In the last century, much of the sagebrush steppe has become degraded by invasive annual grasses, conifer encroachment, human land use and ignitions, climate change, and altered fire regimes (Balch et al., 2013). Cheatgrass (*Bromus tectorum*) is an invasive annual that is particularly problematic, as it recruits well after disturbance (Peterson, 2005; West and Hassan, 1985) and creates continuous, highly flammable fuels that aid fire spread (Brooks and Pyke, 2000), which further promotes invasive recruitment and increases fire risk (Bradley et al., 2018; Link et al., 2006). Similarly, higher elevation sagebrush ecosystems are at risk from increases in pinyon and juniper trees, which outcompete the shrub and grass understory, often reducing surface fuels but increasing the risk of high severity crown fires. Land managers implement fuel treatments to reduce or redistribute burnable material in hopes of decreasing fire intensity and burn severity (Reinhardt et al., 2008). In annual grass-invaded sagebrush, herbicide, mowing, and prescribed fire treatments can reduce fuel loads and reduce subsequent wildfire risk (Ellsworth et al., 2022). For areas with increased shrub and tree fuel, treatments such as prescribed fire (Davies and Dean, 2019) and conifer reduction (Dittel et al., 2018) may break up continuous woody cover, decreasing the spread of invasive species, reducing flammable fuel loads, and providing access points for fire suppression (Davies and Dean, 2019; McIver et al., 2010).

Long-term experimental data provide information on the effects of fuel treatments on vegetation change and fuel accumulation; however, modelling allows us to leverage that data to estimate potential fire behaviour. Here we used the long-term treatment plots in the SageSTEP network (McIver et al., 2010) to 1) understand how fuel treatment type affects fuel accumulation in shrublands and woodlands 2) understand the durability of treatments over long time periods; and 3) develop management recommendations for retreatment intervals that maximize restoration and conservation of sagebrush ecosystems while mitigating fire risk.

Methods

The SageSTEP network spans an elevation range of 262-2500 m and a precipitation range of 164-458 mm providing an opportunity to examine responses to fuel treatments across climatic and productivity gradients (McIver and Brunson, 2014). At each of 19 sites, woody fuel treatments were applied across the entire area of each treatment plot (prescribed fire, mechanical, herbicide, or untreated control). Prescribed fires were intended to remove all woody vegetation. Mechanical treatments in shrubland network plots consisted of mowing shrubs to remove approximately half of the canopy. Mechanical treatments in woodland network plots consisted of cutting and dropping all trees. Herbicide treatments were done in the shrubland network plots only; Tebuthiuron, an herbicide that targets broadleaf plants, was applied to remove approximately half of the shrub canopy. Pre-treatment data were collected, and treatments were applied in year 0 and post-treatment data were collected in years 1, 2, 3, 6, 10, and 15 following treatments. Tree height and woody and herbaceous plant biomass and cover data were collected by species at each sampling event and were used to create custom fuel models for each site at each sample year.

To estimate the impact that fuel treatments had on fire behaviour over the 15 year study period, we parameterized the fire behaviour modelling system Fuel Characteristic Classification System (FCCS) in the Fuel and Fire Tool (FFT) (Prichard et al., 2013) with these custom fuel models. Slope assumptions for each model run were based on the average % slope (range 0-10%) (McIver and Brunson, 2014) and wind speed assumptions were based on the 80th percentile wind speed over the summer (June-September) from the nearest remote automated weather station for the study years.

Environmental scenarios were chosen to represent the range of fuel moisture expected as vegetation phenology progresses from the active growing season (fully green scenario; D2L4 scenario in FFT), through partially curing stages (1/3 cured and 2/3 cured scenarios; D2L3 and D2L2, respectively), to late in the summer, when fuels are completely dry and risk of high intensity fire is greatest (fully-cured scenario;

D2L1). Model outputs chosen to characterize fire behavior included rate of spread (ROS; m min^{-1}), flame length (FL; m), and reaction intensity (RI; the rate of heat release per unit area of the flaming front; kW m^{-2} min^{-1}) (Byram, 1959). Linear mixed models were also used to test for differences in the rate of spread, flame length, and reaction intensity (response variables) as a function of environmental scenario (*i.e.* fuel moisture conditions), treatment, and time since treatment.

Results

In the shrubland network, reduction of woody fuels and subsequent release of the herbaceous understory from shrub competition resulted in changes in modelled fire behaviour metrics (rate of spread, flame length, reaction intensity) that differed by shrub fuel treatment. Prescribed fire plots had the greatest reductions (49%) in modelled fire behaviour metrics, as this treatment was the only one to remove a large portion of the total fuel load from the sites. Shrub and downed woody fuel remained present but was sparse throughout the fifteen years after prescribed fire, while herbaceous fuel increased. The increases in herbaceous fuel in this study were primarily driven by perennial deep-rooted grasses through year six. In years 10- 15, perennial cover returned to levels seen in the control and there was a concomitant increase in annual grasses. The increase in herbaceous fuel likely increased fuel continuity assuring rapid fire spread, while the reduction of woody and shrub fuels decreased flame length. The reduction in reaction intensity with prescribed fire was short-lived. We anticipated a reduction in modelled flame length due to the mow treatment, but we found that mowing was nearly as effective as prescribed fire at reducing reaction intensity and fire rate of spread. However, the reduction in modelled fire spread and reaction intensity lessened in year 3 onward, whereas reduced modelled flame lengths were maintained for at least 10 years, with variability in sites. Herbicide treatments did not alter fuel loads or modelled fire behaviour.

In the woodland network, prescribed fire reduced shrub fuel but substantially increased herbaceous fuel, while mechanical tree reduction resulted in both increased live shrub fuel and downed wood. These changes in vegetation structure and fuel loads modified predicted fire behaviour such that fuel treatments increased surface fire behaviour for the first fifteen years post-treatment. By year fifteen, however, all treatments prevented crown fire spread, which was possible in control plots in later years of the study due to increased density of small pinyon and juniper trees. These findings demonstrate a significant management trade-off between short-term increases in surface fire behaviour for restoration of shrubland plant communities and long-term reductions in the potential for crown fire spread.

Discussion and Conclusion

Fuel treatments are commonly applied in sagebrush ecosystems to reduce fire risk associated with annual grass invasion and conifer encroachment. These fuel treatments can have significant effects on vegetation communities and fuel loads, thus affecting future fire behaviour. While these treatments may provide useful tools for managers, we need to better understand the durability and long-term effects of fuel treatments on vegetation and fuels, particularly along productivity and climatic gradients. As there are proposed fuel breaks for 11,000 miles in the Intermountain West, USA, it is imperative we understand the short- and long-term implications of these fuel treatments in current and future climate conditions. While there are important site-specific results to consider, we commonly saw woody fuel treatments in the shrubland network that remained durable through years 10 to 15 post-treatment. In the woodland network, in contrast, regeneration of young trees limits the efficacy of treatments in the long term. We recommend that site-specific regeneration dynamics be closely monitored, and manual removal of small trees be done at 5 year intervals to preserve treatment integrity.

The efficacy and spatial arrangement of fuel treatments, as well as initial site conditions are highly influential on potential for access and fire suppression, as well as for protecting valuable natural resources. Treatment effectiveness may depend on weather conditions for prescribed burning, appropriate use of machinery, and adequate herbicide application. Additionally, practitioners should consider the broader landscape to strategically place treatments where they are readily accessible by fire personnel and take advantage of existing roads, prevailing wind direction, and local topography to best protect valued resources. Repeated treatments will need to be considered when initial treatment begins to lose effectiveness, as we begin to see in the later years of this study. Finally, understanding pretreatment condition and inherent site characteristics, such as resilience to disturbance and ability to resist invasion, can help guide placement of treatments and estimate the likelihood that the fuel treatments will be ultimately beneficial rather than contribute to further degradation (Chambers et al., 2019, 2014; Shinneman et al., 2019).

Abstract

Fire is a fundamental process in the rangelands of the Great Plains, and dynamic mosaics of areas burned at different times are essential for maintaining and supporting biodiversity, livestock production, and wildlife habitats, among other ecosystem services. The semi-arid rangelands of the Southern Great Plains typically have strong spatial heterogeneity in vegetation structure, which can affect the pattern of fire and its impact on plant diversity and spatial pattern but have received little attention in research. In this study, we investigated the effect of prescribed fires on plant α- and β-diversity and their spatial pattern in a mesquite-oak savanna landscape in the Edwards Plateau. In an 182.2 ha (450-acre) burn unit in a research ranch managed with a pyric herbivory regime, we sampled 288 randomly located 1-m^2 plots in both the pre-fire and post-fire seasons and collected data on plant species composition and abundance. We also mapped the areas burned within the burn unit using high-resolution (21 cm) multispectral data and machine-learning classification. Plant α-diversity was measured using species richness, evenness, and Shannon's H index, and β-diversity using the Sørensen index of dissimilarity and its turnover and nestedness components. Our results show that the prescribed fire appeared to promote α-diversity in soils with sufficient moisture but weakened the overall spatial structure of α-diversity. The prescribed fire negatively affected β-diversity, likely through both direct effects of fire on plants and indirect effects of intensified selective grazing after fire. Differential changes in species composition of forbs and grasses had an important influence on β-diversity. Burn pattern significantly influenced spatial patterns of post-fire β-diversity. These complex effects of prescribed fire on plant α- and β-diversities and their spatial pattern likely have implications for these heterogeneous savanna landscapes' ecosystem functions and services.

Introduction

Previous research on the interaction of fire and grazing (Fuhlendorf et al. 2006, 2009, 2017) has primarily focused on areas burned uniformly in the Southern Great Plains. However, processes in patchy burns across heterogeneous wooded savanna rangelands with variable herbaceous fuel continuity and seasonal precipitation remain underexplored, particularly regarding their influence on α- and β-diversity, including turnover and nestedness components (Anderson et al. 2011; Baselga 2012; Heydari et al. 2017). Plant diversity, often measured through α-diversity (e.g., species richness within a specific area) and β-diversity (variation in species composition between areas), plays a crucial role in ecosystem dynamics. Fire is a key ecological driver that shapes species composition, ecosystem stability, and resilience, yet its spatial effects on plant diversity across different soil types (Winter et al. 2011) remain unclear. Studies have shown that fire influences ecosystem stability and species composition spatial variability (McGranahan et al. 2018), affecting turnover and nestedness components of β-diversity (Anderson et al. 2011; Baselga 2012; Heydari et al. 2017). By analyzing pre- and post-fire spatial patterns, we can better understand fire's role in diversity changes and its broader implications for ecosystem, function, structure, and services, particularly in maintaining habitat heterogeneity and species diversity in fire-adapted semi-arid rangelands. This study addresses these gaps by examining patchy prescribed fires in mesquite-oak savannas. Specifically, it aims to 1) quantify burn patterns and changes in diversity, 2) assess the magnitude and spatial variability of these changes, and 3) determine how burn status spatially influences diversity. These findings will advance the understanding of fire's role in shaping plant diversity and ecosystem dynamics in semi-arid rangelands.

Methods

This study was conducted on a Texas A&M AgriLife Research ranch (Fig. 1a) in the eastern Edwards Plateau of Texas (30.809670 N; -99.865701 W). The study area includes two nearby pastures, where prescribed burns were conducted in February 2019 (Fig. 1b). The monthly rainfall pattern around the study period (2018-2019) is shown in Figure 1c.

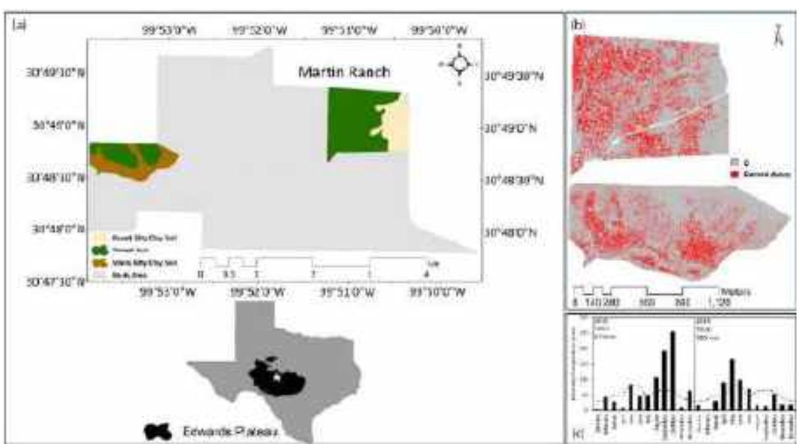

Figure 1. The (a) study area in the ranch with the map of soil types in the study area (TA = Tarrant, VaB = Valera, KaB = Kavett), (b) the maps of burn patterns from the burn units, and (c) the monthly precipitation (bars) from 2018 to 2019 compared to PRISM 30-yr standard (dash line) at the study site in the eastern Edwards Plateau of Texas.

Field data was collected in September-December 2018 (prefire) and September-December 2019 (postfire). Quadrat placement was randomly stratified by soil type, with 120 quadrats in each dominant (TA and VaB) and 48 in the secondary (KaB) soil series, consistently for both periods. Maps of burn status (burned, unburned) were developed by classifying high-resolution (21-cm) aerial imagery using the random forests

(RF) classification method. The α-diversity at each sampling point was calculated based on the percent cover data of plant species for prefire and postfire seasons. The incidence-based β-diversity (β.SOR, β.SIM, and β.SNE) was calculated for all pairs of sampling points (Baselga 2012; Baselga & Orme 2012). The prefire to postfire change in each diversity measure ($x\Delta$ = post - pre) was the dependent variable, and soil type and burned status were the fixed factors of the two-way ANOVA models with Bonferroni corrections on the adjusted p-value. To test normality and homogeneity of variance before ANOVA, Shapiro-Wilk and Levene's tests were run on the data without transformations. For both α-diversity and β-diversity, simple Mantel (xD), cross-Mantel tests (xB, $X_{pre}X_{post}$), and partial Mantel tests (X_{post}D.B) were performed to assess the spatial structure and cross-correlation in terms of spatial continuity; where D is a spatial distance matrix (Euclidean distance between sampling points and B is a variable distance matrix (absolute value of the difference in burn status between sampling points).

Results and Discussion

Prefire and postfire measures of α-diversity and their spatial patterns

Fire likely promoted α-diversity in soils with sufficient moisture as changes were 3 times more negative in unburned areas, especially in KaB soil with higher water-holding capacity (Fig. 2ab). There were significant differences in prefire to postfire changes α-diversity (Shannon index, p = 0.014) of all species between burned and unburned areas in the KaB soils alone or the study area (Fig. 2a). As shown in Figure 2b, the changes in α-diversity were primarily driven by annual and perennial forbs. The most notable differences between the burned and unburned areas were in the cool and warm season annuals and the warm season perennial forbs (Fig. 2c).

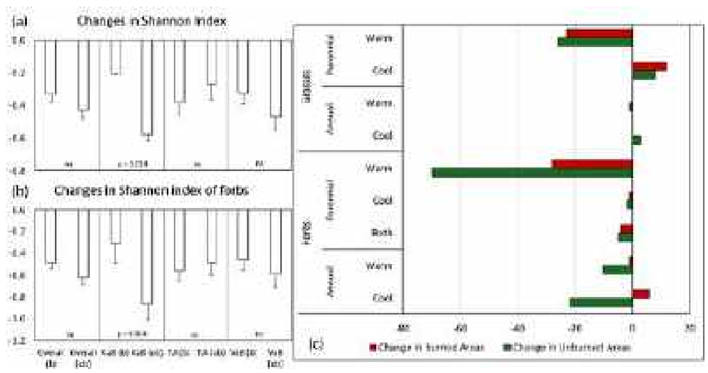

Figure 2. Prefire to postfire change in α-diversity in burned [B] and unburned [UB] areas overall and within each of the soils for (a) all species and (b) forbs. (c) Average changes in species frequency by functional groups in burned and unburned areas in KaB soil.

The spatial pattern of the changes in α-diversity from α_{pre} to α_{post} season in the study area is complex. Moreover, the spatial continuity of α-diversity weakened after the fire (Mantel's r = -0.028, p = 0.038). Still, the spatial pattern remained consistent as both $\alpha_{pre}\alpha_{post}$ spatially correlated (Mantel's r = 0.117, p = 0.017) and α_{post} correlated with burn pattern (Mantel's r = 0.038, p = 0.002). The spatial pattern of the burned areas within the study area was complex, influenced by the strong spatial heterogeneity of the vegetation and fuel characteristics of these semi-arid savannah landscapes (Bradstock, 2010; Singh et al., 2018). As these burned patches were interspersed with unburned areas, the varying changes in α-diversity between burned and unburned areas logically weaken the spatial structure in terms of spatial continuity (the correlation between the differences in variable values and the distance separation between sampling points). These results suggest that prescribed fires likely diminish the spatial structure of α-diversity, at least in the short term, given the typically heterogeneous burn patterns in these diverse savannah landscapes. The spatial pattern of α-diversity can likely be sustained in areas with low soil moisture, where the effects of fire and the changing weather patterns on α-diversity align similarly.

Prefire and postfire measures of β-diversity

Overall, fire negatively impacted β-diversity as the average values of β-diversity (β.SOR and β.SIM) decreased significantly ($p < 0.001$), while that of species nestedness (β.SNE) increased significantly (Fig. 3a). β-diversity measures between sampling points within the burned areas decreased more than those between points within the unburned areas (Fig. 3b). We observed a decline in overall differences in species composition within burned areas. Meanwhile, unburned areas exhibited slightly higher β-diversity, primarily affected by dry-down conditions (Fig. 3b).

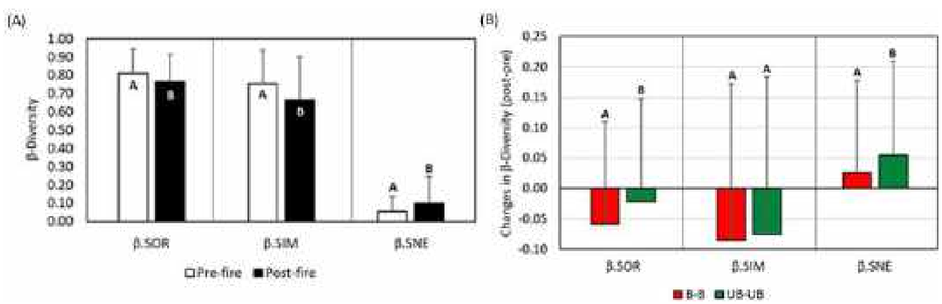

Figure 3. (A) The prefire and postfire β-diversity measures (mean±std), and (B) the change (mean±std) for pairs of sampling points within burned (B-B) and unburned (UB-UB) areas.

Beta diversity decreases after a fire, likely due to reduced herbaceous species frequency, increasing common perennial bunchgrass species (e.g., *Nassella leucotricha*), and stimulating post-fire grazing, which altered its spatial structure. Mantel test showed significant alterations in the spatial structure from β_{pre} (Mantel's $r = 0.019$, $p = 0.05$) to β_{post} (Mantel's $r = -0.021$, $p = 0.03$) β.SOR, but not in either of its components (β.SIM and β.SNE). There was no spatial correspondence between $\beta_{pre}\beta_{post}$ spatial patterns, but β_{post} (Mantel's $r = 0.038$, $p = 0.002$) and its components had a significant spatial correlation with the burn pattern. In terms of β_{post}D.B, spatial structure in β-diversity (β.SOR) remains. These results suggest that the combined effect of burn pattern and dry-down conditions from lack of precipitation influenced the spatial structure of β-diversity.

Conclusions and Implications

Our study highlights the important dynamics of patchy fires on plant diversity during dry-down periods in Mesquite-Oak savanna landscapes. Fire modifies plant diversity within burned areas by influencing α-diversity through soil moisture availability, reshaping species composition based on burn pattern, and altering spatial patterns in response to weather conditions and grazing intensity. Postfire, α-diversity increased based on soil moisture characteristics, while β-diversity declined, disrupting the prefire spatial structure. These findings underscore the ecological ramifications of postfire conditions on plant community dynamics, indicating that heterogeneous fires promote species replacements. These shifts, influenced by interactions among fire, soil, grazing, and weather, reveal the dynamic role of patchy fire in reshaping herbaceous biodiversity. This study provides a foundation for refining prescribed fire practices that promote biodiversity and ecosystem resilience. Also, it provides insights for adaptive fire management strategies considering soil and vegetation dynamics and conservation of fire-dependent semi-arid rangelands.

Historic fuel treatment effects on plant community dynamics following wildfire

Newingham, BA[1]; Donoso, MU[2]; Williams, CL[2]; Howard, BK[1]; Ellsworth, LM[3]

Key words: fuel treatment, wildfire, sagebrush, invasive species

Abstract

Wildfire has substantially increased in sagebrush ecosystems resulting in degraded wildlife habitat, reduced forage, and altered fire regimes. Mechanical mowing, prescribed burning, and herbicide are fuel treatments aimed to reduce woody or herbaceous fuels; however, their long-term effect on plant community composition, as well as the response after wildfire, is unknown. We utilized data from three SageSTEP sites (https://www.sagestep.org) to examine plant community composition before and after fuel treatments, as well as after three sites had burned in a wildfire. After fuel treatments, reductions in sagebrush coincided with increased native perennial bunchgrass cover but also annual, invasive grass cover. Perennial forb increases were ephemeral after treatments. Immediately prior to wildfire, sites differed in species composition with control plots having the most shrubs and the prescribed fire plots having the most perennial grasses. After wildfire, shrubs were substantially reduced. Perennial grass cover generally increased, particularly in prescribed fire plots, although perennial grass responses were site dependent. Annual grass invasion varied by site and treatment after wildfire, and invasive forbs were dynamic post-wildfire. These results illustrate the need for long-term data to understand plant community dynamics after both fuel treatments and subsequent wildfire. Long-term monitoring of post-wildfire community trajectories will help deduce how strongly historical fuel treatments affect pre-wildfire composition and consequent post-wildfire recovery.

Introduction

Fuel reduction treatments are intended to reduce fuel loading of herbaceous and/or woody fuels. In sagebrush ecosystems in the western United States, woody fuels have increased due to increasing shrub density; herbaceous fuels have increased due to invasive annual grasses, primarily *Bromus tectorum* (cheatgrass). Cheatgrass recruits well after disturbance (West and Hasan 1985, Peterson 2005) and creates continuous, highly flammable fuels that aid fire spread (Brooks et al. 2004), which promotes further recruitment and increases fire risk (Link et al. 2006, Bradley et al. 2018). As a result, annual grass invasion has increased the size, frequency, and duration of wildfires in sagebrush ecosystems (Balch et al. 2013).

In addition to increasing fuel loads, annual grass invasion displaces native plants, which can in turn reduce biodiversity, forage quality, and wildlife habitat (DiTomaso 2000). Fuel treatments are intended to reduce fuel loads and fire risk in efforts to restore native plant communities. However, some fuel treatments may increase invasive species from physical disturbance and the reduction in native species (Potts and Stevens 2009, Freund et al. 2021, Pyke et al. 2022), which may inadvertently increase non-native dominance and further degrade an area. Additionally, fuel treatments may provide open niches for invasive species initially that are exacerbated when a wildfire occurs. We have little information about how fuel reduction treatments and subsequent wildfire interact to alter the post-fire trajectory of ecosystem succession. Considering that fire return intervals have decreased substantially in sagebrush ecosystems (Baker 2006), it is imperative we understand how prior fuel treatments affect post-wildfire plant community responses. While we assume that fuel treatments reduce risk to ecosystems that burn in wildfire, it is possible that the dual disturbances of fuel treatments and subsequent wildfire have negative impacts.

Using data from long-term fuel treatment experiments that burned in wildfires, we examined plant successional trajectories following fuel treatments and wildfire. Three sagebrush shrubland sites in the Sagebrush Steppe Treatment Evaluation Project (SageSTEP) burned in wildfires approximately ten years after fuel treatments were implemented. We present ten years of post-fuel treatment data along with 3-4 years of post-wildfire data on plant functional group responses in control, tebuthiuron, prescribed fire, and mowing plots.

Methods

Experimental Design

The Sagebrush Steppe Treatment Evaluation Project (SageSTEP) is a long-term plot network with 19 sites across six states and a range of environmental conditions in the Intermountain West, USA. Fuel treatments in shrublands were implemented from 2006-2009. Prescribed fire treatments were applied in late summer and early fall with the intention of consuming most woody vegetation. Herbicide treatments included tebuthiuron (Spike 20P; 1.68 kg/ha) and imazapic (Plateau; 22.2% acid equivalent), which were applied to reduce woody and herbaceous fuels, respectively. Mowing treatments were applied to reduce shrub cover by 50%. Annual vegetation, fuels, soil, and climate data have been collected for all treatments at all SageSTEP sites (McIver and Brunson 2014, Pyke et al. 2014, Freund et al. 2020). Three of the original shrubland sites, characterized by Wyoming big sagebrush and invasive annual grasses have burned in recent wildfires: Owyhee, Nevada (2018); Moses Coulee, Washington (2019); and Rock Creek, Oregon (2020).

Field data were collected from April to June each year during the peak growing season in the year prior to treatment, annually post-treatment, and for 3-4 years post-wildfire. Treatment plots contained between 12 and 22 sampling subplots; all subplots were 30 x 33 m in size. Plant cover was measured on five-30 meter transects using the line-point intercept method with 300 points per subplot. We looked at foliar cover across four functional groups (perennial grass, annual grass, annual forb, and shrub) to assess the effect of fuel treatments on the post-wildfire plant community. Full field sampling protocols are available in Stebleton and Bunting 2009, Bourne and Bunting 2011, and Wozniak and Strand 2019.

Statistics

All statistical analysis was performed using R (R Core Team 2024). Total foliar cover data was used across all sites for all functional groups to assess temporal and treatment effects before and after wildfire. Using the glmmTMB (Mollie et al. 2017) package in R, Beta Generalized Linear Mixed Models (Beta GLMMs) were used to model plant community resilience. To meet the distribution requirements of Beta GLMMs, total foliar cover values were scaled for each functional group at each site to range between 0 and 1 by normalizing each functional group's cover value relative to the total cover within each plot. To ensure reliable model performance, the data was filtered to include only those plots where the scaled foliar cover values were greater than 0 and less than 1. In the model, total foliar cover was considered the response variable; treatment, year, and their interaction were considered fixed factors; and plot number was used to account for variability and manage repeated measures within the same plot. A beta distribution with a 'logit' link function was used to appropriately model the proportional response variable. To ensure model fit and reliability, the DHARMa (Hartig 2024) package in R was used to visually inspect residual versus predictor plots and quantile (Q-Q plot) residuals. The model was run for each functional group for each site using the same predictors and response variable. Percent changes were calculated by comparing estimated marginal means of treatments relative to control values, and statistical significance (p-values) was determined through pairwise contrasts (using emmeans), with significance at $\alpha = 0.05$.

Results

At Owyhee post-wildfire (2019-2023), perennial grass cover was not significantly affected by any fuel treatment compared to control (all $p > 0.05$). Annual grass often substantially increased, such as by 260% in tebuthiuron (2019), but these increases lacked statistical significance. In prescribed fire, annual forb cover decreased by 46% in 2022 (p=0.021) and increased by 24% in 2023 (p=0.035) relative to control; annual forb responses were otherwise varied with no significant trends. Shrub cover in mowing and prescribed fire was generally lower than in control, but not significant, except in 2021 when shrub cover in mowing plots was 80% lower than in control (p=0.014).

At Moses Coulee post-wildfire, perennial grass consistently exhibited large and statistically significant increases in all three treatments relative to control. In 2021, perennial grass cover increased by 124–455% ($p \leq 0.001$) depending on the treatment, remained elevated in 2022 (90–209%, $p \leq 0.001$), and continued to be high in 2023 (85–303%, $p \leq 0.002$). Annual grass notably increased in the first-year post-wildfire (2021) in tebuthiuron (93%, p=0.016) and prescribed fire (97%, p=0.011) plots, though subsequent years yielded smaller or non-significant changes. Annual forb responses were not significant aside from a large decrease in prescribed fire plots in 2022 (73%, p=0.001). Shrub cover effects were more limited, with significant reductions observed in 2023 under tebuthiuron (79%, p=0.004) and prescribed fire (69%, p=0.049).

At Rock Creek post-wildfire, perennial grass cover rose by 91–95% across treatments relative to control ($p \leq 0.004$) in 2020, with similar increases (75–113%, $p \leq 0.018$) in 2021. In 2022, prescribed fire produced a significant increase in perennial grass cover (47%, p=0.026). However, by 2023, all treatments again yielded significant perennial grass increases relative to control (60–68%, $p \leq 0.004$). In 2022, annual grass cover in prescribed fire plots was 413% greater than in control (p=0.012). However, in 2023, annual grass cover did not significantly differ between treatments and control. Annual forb changes were variable, highlighted by a notable 170% increase in prescribed fire relative to control in 2022 (p=0.001), with few differences between treatments and control in 2023. Changes in shrub cover relative to control were minimal and lacked statistical significance across all treatments and years.

Discussion

The variability in plant functional group responses to different fuel treatments across the three sites underscores the importance of tailoring post-wildfire management strategies to specific ecological contexts. While previous studies (Chambers et al. 2021, Ellsworth et al. 2022) found that prescribed fire can facilitate herbaceous recovery in sagebrush ecosystems, our findings further demonstrate increases in perennial grasses under prescribed fire. This consistency, especially compared to more variable outcomes under mowing and tebuthiuron, suggests that prescribed fire's broad-spectrum effectiveness is robust across environmental settings and temporal scales. In contrast, the modest or non-significant changes in perennial grass at Owyhee and the inconsistent responses of annual grasses and forbs to mowing and tebuthiuron highlight that these other treatments may only be beneficial under certain pre-fire conditions or site-specific biotic and abiotic factors.

This work enhances our understanding of how fuel treatments interact with local conditions to shape vegetation trajectories. Although shrubs are predictably reduced post-fire due to their fire intolerance, our results indicate that whether gaps left by shrubs are filled by perennial grasses, annual forbs, or annual grasses depends heavily on the chosen treatment and the site's inherent resiliencies or vulnerabilities. This aligns with ecological principles suggesting that community recovery is contingent on environmental gradients, seed sources, and disturbance histories. While managers may find prescribed fire a consistently reliable tool to promote perennial grasses, the more context-dependent results from mowing and tebuthiuron caution against a one-size-fits-all approach. Thus, it is important to integrate local site assessments—soils, climate, seedbank composition, and pre-fire vegetation—before deploying fuel treatments.

Frequent prescribed fire contributes to soil organic carbon sequestration and pyrogenic carbon stability in South African mesic grasslands

Nicolay, R[1]; Tedder, M[1]; Mkhize, N[2]; Kirkman, K[1]

[1] School of Life Sciences, University of KwaZulu-Natal, Pietermaritzburg 3209, South Africa; [2] School of Agricultural, Earth and Environmental Sciences, University of KwaZulu-Natal, Pietermaritzburg 3209, South Africa.

Key words: Prescribed burning; Soil organic carbon (SOC); Mesic grasslands; Carbon sequestration; Fire management

Abstract

Grasslands serve as crucial terrestrial carbon sinks, storing substantial amounts of organic carbon (OC) in aboveground vegetation, roots, and soils. However, effective carbon sequestration in grasslands depends on management practices. South African subtropical mesic grasslands are fire-adapted ecosystems, dependent on fire as a key ecological force shaping and sustaining them. Fire influences carbon sequestration by removing above-ground biomass, redistributing nutrients, and contributing inputs through thermal mineralisation.

This study assessed the impact of varying fire frequencies and season of prescribed burns on soil organic carbon (SOC) stocks, total nitrogen (TotN), and carbon-to-nitrogen (C:N) ratios, as well as the stability of refractory organic matter (refractory OM) and black carbon (BC) fractions across soil depths up to 30 cm. Results showed that fire frequency and season of prescribed burns significantly influence SOC and TotN stocks, with annual winter and spring burns resulting in the highest SOC stocks and wider C:N ratios in the top 5 cm of soil. Conversely, biennial and triennial burns showed reduced SOC stocks, with triennial burns displaying the lowest levels and even SOC loss below 5 cm. Over 20 years, SOC stocks increased under all fire regimes except for triennial burns, where stabilization or reduction was noted.

Additionally, our findings indicate that increased fire frequency leads to the maintenance of BC within the soil, though BC remains stable across soil horizons. Refractory OM and BC levels were greater in areas that were unburnt or experienced longer burn intervals, likely driven by a decline in soil pH and increased acid saturation associated with less frequent fires. These patterns suggest that while regular fires can contribute to surface SOC stocks, the management of fire intervals is crucial for maintaining deeper, more recalcitrant carbon fractions. This emphasizes the beneficial role of regular grassland fires in carbon sequestration and suggests practical management strategies for fire-adapted mesic grasslands.

Introduction

Grasslands serve as crucial terrestrial carbon sinks, storing significant amounts of carbon in aboveground vegetation, roots, and soils (Bikila et al., 2016; Ward et al., 2016). The management practices applied to these ecosystems play a central role in determining their carbon storage potential (Ward et al., 2016). Prescribed fire management is a common practice in South African grasslands, but its long-term sustainability remains a concern due to carbon and nitrogen losses from biomass during burns (Materechera et al., 1998; Snyman, 2002). Understanding the timing and frequency of prescribed fires is essential for ensuring the long-term sustainability of grasslands and maximising their carbon sequestration potential.

While grasslands managed with prescribed fire have demonstrated substantial carbon sequestration (Teixeira et al., 2022), the specific impact of fire frequency and season of prescribed burns on soil organic carbon (SOC) stocks, total nitrogen (TotN), and carbon stability remain poorly understood. In this context, carbon stability refers to the presence of stable, recalcitrant carbon (RC), a fraction of soil organic matter (SOM) that is resistant to decomposition and is a key to long-term carbon storage. This study examines the maintenance of stable carbon fractions as concentrations through soil depth and evaluates total carbon sequestration over time by comparing current SOC stocks to those measured in 2001 by Fynn et al. (2003), allowing for an assessment of carbon accumulation over a 20-year period. The Ukulinga Grassland Fire Experiment (UGFE), established in 1950 in the subtropics where rainfall is summer-dominant, provides a unique opportunity to examine carbon stocks and turnover following prescribed fire treatments (Fynn et al., 2003). Studies from the UGFE suggest that seasonal burns, particularly in spring, mitigate carbon losses by facilitating rapid litter decomposition and incorporation into soils before burning, while autumn and winter burns reduce surface carbon pools through wind erosion and leaf litter removal (Fynn et al., 2003).

Fire has been noted to influence the turnover of stable carbon fractions such as black carbon (BC) and refractory organic matter (refractory OM), critical for long-term carbon storage (Gao et al., 2017; Glaser & Amelung, 2003). These RC forms resist decomposition, yet their distribution and stability across soil depths may be shaped by fire frequency and soil acidification (Findlay et al., 2022; Masiello, 2020). Suppressed fire regimes can maintain soil acidity in already acidic soils, limiting microbial activity and SOC turnover or availability. In contrast, low-intensity fires, through the deposition of alkaline mineral ash containing inorganic carbonates (e.g., calcium, magnesium, sodium, potassium, silicon, and phosphorus), may contribute towards increasing soil pH and aiding nutrient availability (Agbeshie et al., 2022; Bodí et al., 2014). This study investigates the effects of prescribed fire on SOC stocks and sequestration (20 years), TotN, and stable carbon fractions (refractory OM & BC) in South African mesic grasslands. We hypothesise that fire frequency drives shifts in soil carbon sequestration, stability and pH, with increased fire frequency enhancing surface SOC retention but reducing refractory OM and BC stabilisation in deeper soil layers.

Methods

The Ukulinga Grassland Fire Experiment (UGFE), at the University of KwaZulu-Natal Research Farm in Pietermaritzburg South Africa (-29.667° S, 30.399° E; altitude 843 m), examines the effects of prescribed burning on subtropical mesic grasslands under summer-dominant rainfall. Soils at the site are sandy clay loam, with an orthic A over a soft plinthic B horizon (Soil Classification Working group, 1991), and the mean annual rainfall is 790 mm, ~95% occurring in summer (November to February). Mean temperatures range from 26.4°C in February to 8.8°C in July (Fynn et al., 2003). Vegetation is classified as KwaZulu-Natal Hinterland Thornveld, dominated by native C4 grasses (Mucina & Rutherford, 2006).

The UGFE, initiated by J.D. Scott in 1950 to study historically prescribed burning regimes, was established with a randomized split-plot design, incorporating three replications for each treatment on plots measuring

18.3 × 13.7 m. The UGFE has been entirely excluded from domestic livestock and large wild ungulate grazing regimes. For this study, 9 burn treatments within this experiment, namely annual, biennial, and triennial burning in winter, spring, or autumn, as well as fire exclusion, were utilised. Burns were conducted according to seasonal protocols: spring burns followed the first 12.5 mm of rainfall (usually within September), while winter burns were conducted in early August. The experimental plots in this study were consistently burned in accordance with the established UGFE protocol throughout the duration of the experiment, with no deviations in application and no impact from wildfires. Soil organic carbon (SOC) stocks were assessed at a second time point (2021) and compared to those measured 20 years earlier in a study by Fynn et al. (2003). The rate of carbon sequestration over this 20-year period was then estimated.

To assess prescribed fire history on grassland SOC accumulation, soils were collected in May 2021 using a 2.8 cm soil corer. Four random cores per plot were sampled to a depth of 30 cm, segmented into 5 cm increments and composited. Samples were dried (65°C, 48 hours), homogenised, sieved to 0.5 mm, and analysed for total SOC and nitrogen using a Leco TruMac CNS analyser. Organic carbon and nitrogen concentrations were calculated and converted to SOC and TotN stocks (Mg ha^{-1}) per treatment (FAO, 2020). Recalcitrant carbon fractions (ROC and BC) were quantified using a thermogravimetric analyser (TGA) under a nitrogen atmosphere, with ROC recorded between 475–550°C and BC between 550–650°C.

Hierarchical linear mixed models assessed the effects of fire frequency, season of prescribed burns, and soil depth on SOC stocks (2021), SOC sequestration (20yrs), TotN, C:N ratios, and carbon fractions. Plots were treated as random effects to account for variability between them, and fixed effects included nested interactions between fire treatments and soil depth. Diagnostic checks confirmed model assumptions (normality, equal variance, linearity, independence, & overall fit of the model) were met, and post hoc Tukey HSD tests evaluated significant differences between treatments. Pearson's correlation assessed the relationship between soil pH and BC levels, while one-way ANOVAs examined acid saturation and fire treatment effects. Statistical analyses were conducted in R (R Core Team, 2023), using standard packages for data processing and visualisation.

Results

Total Carbon, Nitrogen, and Refractory Organic Carbon Status

Soil organic carbon (SOC) and total nitrogen (TotN) stocks declined significantly with increasing soil depth (SOC: $\beta = -0.396$, $p = 0.02$; TotN: $\beta = -0.046$, $p < 0.001$, Figure 1). SOC stocks were highest in annual winter burns ($\beta = 0.995$, $p < 0.001$) and fire exclusion treatments relative to SOC stocks in the biennial and triennial burn treatments in autumn and winter ($p < 0.01$). Depth had a marginally positive effect on C:N ratios ($\beta = 0.003$, $p = 0.05$), with fire exclusion significantly reducing C:N ratios ($\beta = -4.310$, $p < 0.001$).

Refractory organic carbon (ROC) concentrations were highest in the top 5 cm of soil (19.62 ± 0.929 g/kg) and declined significantly with depth ($p < 0.001$). Burning treatments did not affect ROC levels, while black carbon (BC) remained stable across soil depths (1.87 ± 0.180 g/kg). Grasslands excluded from fire exhibited the greatest BC concentration (10.27 ± 2.141 g/kg), relative to annual and biennial burns BC quantities. A significant negative correlation between BC and soil pH ($r = -0.384$, $p < 0.001$) revealed that acidified soils retained more BC.

Carbon Sequestration and Fire Frequency

SOC sequestration over 20 years varied by fire treatment and depth, with triennial burns showing negative sequestration in the 5–10 cm soil layer (winter: -0.16 ± 2.0 Mg C/ha; spring: -0.46 ± 3.42 Mg C/ha; autumn: -1.03 ± 2.23 Mg C/ha). In contrast, annual winter burns exhibited the highest SOC sequestration (1.1 ± 1.0

Mg C/ha) in the top 5 cm. Depth was the strongest predictor of changes in SOC sequestration with SOC decreasing with increasing depth ($p = 0.001$).

Soil Acidification and Fire Exclusion

Plots with fire exclusion and triennial treatments had significantly lower pH than more regularly burned plots ($p < 0.001$, $F_{9,80} = 4.67$). Soils excluded from burning had the lowest pH, with a mean of 4.2 ± 0.3, while annual winter burns had near-neutral pH levels (pH 6.1 ± 0.4). Acid saturation was notably greater in unburnt soils and those with extended burn intervals, indicating maintained acidification with reduced fire frequency.

Black carbon (BC) accumulation was highest in fire-excluded plots (10.27 ± 2.141 g/kg), followed by triennial winter burns (6.13 ± 0.474 g/kg). BC content was negatively correlated with pH ($r = -0.384$, $p < 0.001$), with higher BC concentrations observed in plots with lower pH values.

Discussion [Conclusions/Implications]

The significant declines in SOC and TotN stocks with increasing soil depth highlight that the greatest concentrations of SOC and TotN are found in the topsoil, emphasizing the importance of protecting this layer to prevent losses. The greatest SOC in the top 5 cm of soil under annual and biennial burns, particularly in spring, suggests this layer has the greatest capacity for SOC sequestration, supporting findings from similar studies that link moderate fire temperatures with enhanced microbial activity and nutrient cycling (Fynn et al., 2003; Ohrtman et al., 2012).

Low levels of SOC sequestration (measured within a 20-year timeframe) below 5 cm under Triennial burns suggest losses, likely driven by biomass accumulation and shifts in lignin composition, resulting in incomplete combustion. These results challenge the assumption that SOC stocks stabilise within 20 years.

While Fire exclusion appeared to promote BC accumulation, it also appeared in acid conditions, possibly inhibiting nutrient cycling. This is consistent with studies linking fire suppression to the buildup of lignified biomass and coarse BC particles, which stabilise in acidic conditions but limit overall carbon turnover (Agbeshie et al., 2022; Docherty et al., 2012), akin to the 'use it or lose it' principle. The negative correlation between BC and soil pH suggests that acidic soils favour BC retention but hinder the decomposition of organic material, emphasizing the dual role of fire in stabilising and mobilising carbon fractions. The persistence of SOC and recalcitrant carbon forms such as ROC and BC in deeper soil horizons remains an area for further study. These stable fractions, influenced by ash deposition and fire-induced changes in soil, play a vital role in long-term carbon storage and climate mitigation (Lorenz & Lal, 2005).

These results suggest that the interval of prescribed burns must balance carbon sequestration objectives with the maintenance of soil fertility and grassland functionality. Prescribed fire in subtropical grasslands with summer-dominated rainfall, particularly in spring, appears to sustain mesic grasslands as carbon sinks. Annual and biennial burns, particularly in spring, optimise carbon sequestration and nutrient cycling while mitigating soil acidification.

Woody species composition, diversity and vegetation structure of two rangelands areas along a climatic gradient in Burkina Faso (West Africa)

Sawadogo I[1, 2, 3]; Worou N[2]; Bayen P[3]; Kouassi F[1]

[1]University Félix Houphouët Boigny, B.P. 165, Abidjan 31, Cote d'Ivoire; idrissaw2017@gmail.com; [2]International Livestock Research Institute (ILRI), BP 24265 Ouakam, Dakar, Senegal; [3]University of Dédougou. BP 176 Dedougou, Burkina Faso

Key words: Burkina Faso; Sidéradougou rangeland; Mankarga rangeland; woody species; conservation

Abstract
Climate variability added to anthropogenic pressures leads to habitat fragmentation, degradation and loss of rangelands resources in Burkina Faso. Studying vegetation structure and woody species composition is important in monitoring vegetation dynamics for efficient rangeland management. This study was carried out to characterize woody vegetation along a climatic gradient. Sixty-four quadrats of varying size were laid in each of the rangeland (Sidéradougou and Mankarga). Thus, the inventory unit was 1000 m² (50 m x 20 m) in savannas and 500 m² (50 m x 10 m) in gallery forests. In each plot, all woody species with a diameter at breast height (DBH) ≥ 5 cm were systematically identified and measured. The data were analyzed by using Shannon-Wiener diversity and equitability indices, and the structural analysis was carried out based on frequency, density, DBH, height and basal area/ha-1. A total of 89 forage plant species belonging to 64 genera and 25 families from Sidéradougou and 80 plant species belonging to 57 genera and 23 families from Mankarga was identified. Fabaceae and Combretacea was the dominant family in the two rangelands with diverse population structures. The small trees and shrubs dominated the rangeland suggesting its status under a secondary stage of development. Some woody species require urgent conservation measures. Therefore, local and regional stakeholders should integrate and work together to develop and implement sound conservation and management strategies that encourage the sustainable utilization of rangeland resources.

Introduction
Pastoral ecosystems play a major role in the global climate balance and provide numerous ecosystem goods and services (FAO 2020). They also contribute to socio-economic well-being through the woody and non-woody forest products that they provide. The use of these woody and non-woody forest products makes an invaluable contribution to food production in rural areas (Nacoulma et al. 2011). Woody plants forages provide proteins essential to the dietary balance in livestock feeding strategy on natural pasture during the dry season (Du et al. 2023). Moreover, in Sahelian rangelands, fodder supply from annual fodder species during the dry season or in years of low rainfall remain problematic. In this circumstance woody species

become an important source of forage in the livestock feeding strategy (FAO 2020). Anthropogenic activities are exerting high pressures on natural resources inducing a rapid biodiversity erosion that affects the capacity of ecosystems to provide the goods and services for human uses (Cardinale et al. 2012).

Thus, the current study in the Sidéradougou and Mankarga rangelands in Burkina Faso is critical due to a lack of documentation on the diversity and structure of the woody forage plants. Specifically, it seeks to answer the following research questions: (i) What is the species richness and diversity of woody vegetation in the Sidéradougou and Mankarga rangelands? (ii) How are rangelands structured in terms of tree density, basal area, and diameter class distribution?

Materials and methods

Study area

The research was carried out in the Mankarga and Sidéradougou sylvopastoral zones, located respectively in the Sudanian and Soudano-Sahelian zones of Burkina Faso. Mankarga's rangelands cover an area of 6,270 hectares and lie between latitudes 11°59' and 12°06' North, and longitudes 00°53' and 00° 59' West. The Sidéradougou area covers 51,500 ha and lies between latitudes 10°30' and 11°104' North and meridians 3°55' West and 4°50' East (Fig.1).

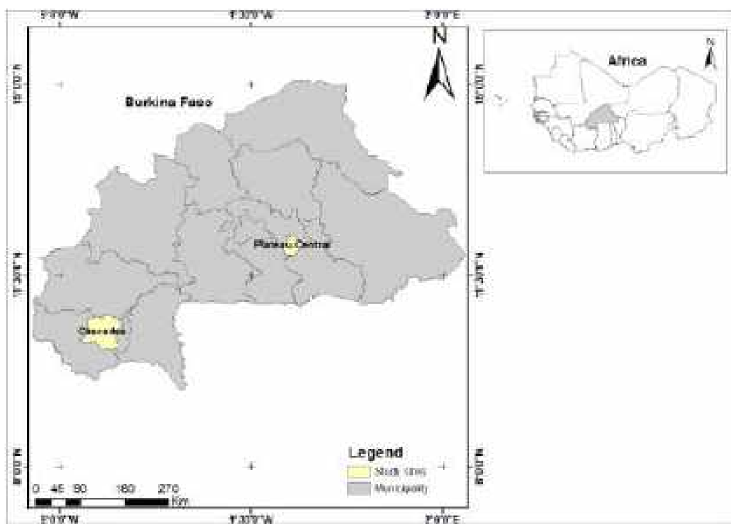

Figure 1: Map showing the study sites.

Data collection

Floristic inventories were conducted at two study sites at the onset of the dry season (November to December 2023) when the plots were readily accessible. A total of 128 plots were established, comprising 64 plots per site within homogeneous stands of plant formations. The inventory unit was 1000 m² (50 m × 20 m) in Savannas and 500 m² plots (50 m × 10 m) in gallery forests. Within (Thiombiano et al. 2016) each sampling plot, phytosociological methods were employed to assess woody plant.

Vegetation data analysis

Diversity indices

The Shannon diversity (H') and evenness (J) indices are used to measure both species richness and species evenness (Kent, 2012). The Shannon Wiener diversity index (H') was computed for each plant community types using the equation:

$$H' = -\sum_{i=1}^{s} pilnpi \quad (1)$$

where S = total number of species in the community (richness) and pi is relative abundance of the i^{th} species in a sample plot. The Shannon evenness (J) was calculated from the ratio of observed diversity to maximum diversity using the equation:

$$J=H'/Hmax=H'/lns \quad (2)$$

Where Hmax is the maximum level of diversity possible within a given population, which equals ln (number of species). J (species evenness) is normally ranges between 0 and 1, and with 1 representing a situation in which all species are equally abundant (Magurran, 2003).

Structural data analysis

To analyze the population structure of woody plant species, tree diameters were categorized into 5 cm intervals. The diameter class distribution of each vegetation type was fitted to a theoretical value of the Weibull distribution, whose probability density function is defined as follows (Johnson and Kotz, 1970) :

$$f\ (x) = \frac{c}{b}\left(\frac{x-a}{b}\right)^{c-1} exp\left\{\left(\frac{x-a}{b}\right)^{c}\right\} \quad (3)$$

In this equation, x represents the tree diameter; a (threshold parameter) equals 5 cm; b is the scale parameter linked to the central value of diameters; and c is the shape parameter of the structure, also known as the Weibull slope.

Results

Floristic composition and species diversity

A total of 169 woody species, spanning 121 genera and 48 families, were identified across the two rangelands. In the Mankarga rangelands specifically, 80 species from 57 genera and 23 families were recorded, while the Sidéradougou rangelands harbored 89 species across 64 genera and 25 families. In Sidéradougou, Fabaceae emerged as the most represented family (7.86% of species), followed by Combretaceae and Malvaceae (both at 5.61%). In contrast, Combretaceae was the dominant family in Mankarga (10% of species), followed by Fabaceae (7.5%) and Rubiaceae (5%).

The species richness of inventoried individuals varied across pastoral zones, averaging 10.28 ± 2.51 in the Sidéradougou rangelands and 9.61 ± 2.70 in the Mankarga rangelands (Table 1). Considering the species richness, statistical analyses revealed that there was no significant difference between gallery forest and wooded savannas within the same rangeland or between the two rangelands. The diversity indices (Shannon's index, Shannon evenness) exhibited significant variations along the two rangelands ($P < 0.001$) and among different vegetation types (Table 1). The Shannon evenness (J) values for the rangelands of Sidéradougou and Mankarga were 0.87 ± 0.13 and 0.83 ± 0.18, respectively, indicating a relatively equal distribution of species within the communities of both rangelands.

Table 1: Diversity indices by plant formation type in each Rangeland

Rangelands	Index	Gallery forest	Woodland savanna	Overall	Chi-square	p
Sidéradougou	J	0.95±0.02[a]	0.93±0.02[b]	0.87±0.13	70.67	<0.001

	H	2.32±0.18[a]	2.26±0.21[a]	1.95±0.57	83.33	<0.001
	S	11.47±1.76[a]	11.40±2.03[a]	10.28±2.51	78.01	<0.001
Mankarga	J	0.84±0.17[a]	0.85±0.19[a]	0.83±0.18	21.46	<0.001
	H	2.18±1.41[a]	2.01±0.56[a]	1.91±1.04	45.45	<0.001
	S	10.73±2.13[a]	10.46±2.38[a]	9.61±2.70	70.32	<0.001

Values along columns with different letter differ significantly.

Woody forage plant population structure

The diameter class distribution of woody forage species in the two rangelands exhibited reversed J-shape (L-shape) pattern (Fig. 2). The majority of individuals fell within the 5-20 cm diameter class. This indicates that the species frequency distribution peaked in the lower diameter classes and gradually decreased towards the higher classes. The 'c' parameter of the Weibull distribution ranged between 0.72 and 0.82, confirming this trend.

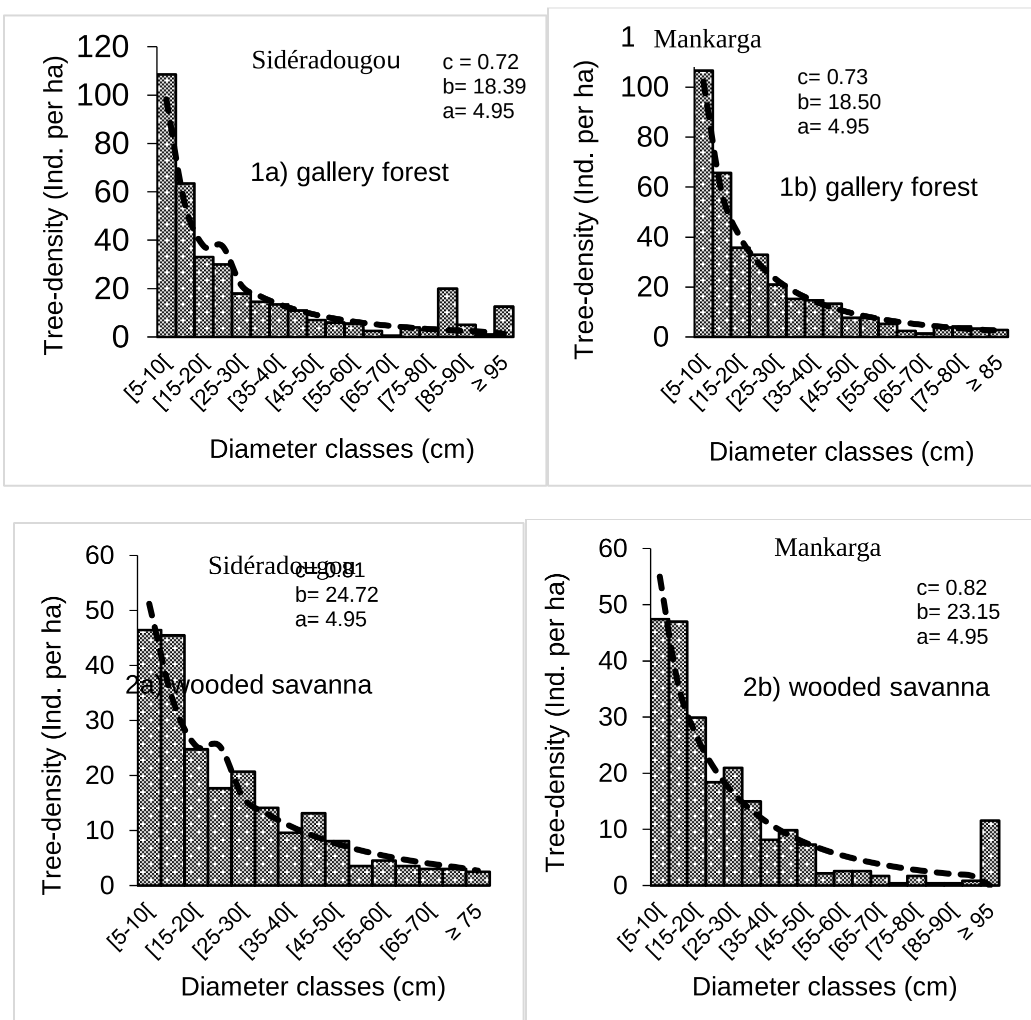

Figure 2: Diameter class size distribution of the two vegetation types in the two rangelands: gallery forest 1a and 1b; wooded savanna 2a and 2b

Discussion

Floristic composition and species diversity

Across the studied rangelands, the Sidéradougou rangeland recorded an average Shannon-Weiner diversity index (H) of 1.95 and an evenness (J) value of 0.87. Similarly, the Mankarga rangeland showed an average Shannon-Weiner diversity index (H) of 1.91, accompanied by an identical evenness (J) value of 0.87. These values are lower than those reported for forest corridor from Burkina Faso (H'= 2.85) (Sanou et al., 2021), but higher than Sahelian woodland formations from Burkina Faso (H'= 1.76; J= 0.55) (Savadogo et al., 2016). Cavalcanti et al. (2004) classify forest diversity into four categories based on the Shannon-Weiner diversity index: high diversity is indicated by a value above 3.0, medium diversity falls between 2.0 and 3.0, low diversity ranges from 1.0 to 2.0, and very low diversity is below 1.0. Therefore, the woody species diversity of the two rangelands falls within the low category, as the estimated value is between 1 and 2. The low value of the Shannon diversity index suggests that there are various factors contributing to these results, including illegal harvesting, agricultural expansion, overpopulation, and livestock intervention (Atsbha et al., 2019). Fekadu et al. (2019) have highlighted that human intervention, overgrazing, and illegal activities pose threats to the diversity and distribution of woody species in rangelands.

The species richness observed in this study is lower than that reported by Sambaré et al. (2011) in similar gallery forests in Burkina Faso. This discrepancy may be attributed to the intensity of disturbance factors and climatic variations that hinder the establishment of certain species in both study sites.

Population structure of fodder trees

The inverse J-shape of the diameter class distribution characterizes tree populations dominated by small diameter individuals. This size class distribution pattern serves as evidence that woody species have young populations with genuine capacities for rejuvenation in these rangelands. However, the absence of trees with large stem diameter in the stands could lead to the regression of the individuals stands because large trees are the best seed producers and thus support the natural regeneration (Tesfaye et al., 2004). The density of plant species decreased with increasing diameter at breast height (DBH) classes, and the lower DBH classes exhibited a greater diversity of species compared to the medium and higher DBH classes. Similar studies have shown that species with a diameter at breast height greater than 30 cm were exploited by local populations for construction and charcoal production (Badji et al., 2014). According to Atsbha et al. (2019), this bell-shaped pattern indicates a low reproductive rate and poor species recruitment.

Conclusions and implications

Assessment of diversity and regeneration status of tree species is crucial for their sustainable utilization, management, and conservation. This study examined the overall population structures of tree species in the Sidéradougou and Mankarga rangelands, revealing significant insights into their contribution to ecosystem health. This study makes a significant contribution to our understanding of tree species diversity and regeneration patterns in African savannas, providing valuable insights for policymakers and conservation practitioners working in similar ecosystems.

Active restoration improved self-restoring ability in extremely degraded alpine meadow

Zhanhuan Shang[1]

[1]State Key Laboratory of Herbage Improvement and Grassland Agro-Ecosystems, College of ecology, Lanzhou University, Lanzhou 730000, China.

Key words: Grassland restoration; Long-term restoration; Native plant seeds; Reseeding; Self-recovery ability

Abstract

About 60% of alpine meadow has been degraded, with around 8% considered extremely degraded on the Qinghai-Tibetan Plateau. The natural restoration of extremely degraded land will take more than 200 years and is the biggest challenge for ecological restoration worldwide. To improve the effectiveness of restoration, reseeding native plant seeds has become the main active restoration approach for extremely degraded meadow. However, it is still unclear whether this active restoration approach of native plant reseeding can promote the self-recovery ability and natural regeneration of extremely degraded alpine meadow. To address this knowledge gap, we have conducted long-term active restoration research of extremely degraded meadow on the Qinghai-Tibetan Plateau. Our findings indicate that the meadow vegetation was in an unstable state after active restoration within 10 years. After 10 years of active restoration without meadow management, the plant community degraded again. Soil nutrients also declined significantly after 10 years of active restoration without meadow management, with notable geographical variations. Long-term active restoration did not significantly improve the soil carbon storage. During the long-term recovery process, the vegetation carbon pool was regulated by nitrogen, while the soil carbon pool was primarily regulated by living plant roots. However, long-term active restoration had positive effects on soil seed bank density and species number. Reseeding native perennial grass seeds can improve the soil seed bank and the vegetation-soil system's resilience of alpine meadow. Therefore, for the active restoration targeting the extremely degraded alpine meadow, it is necessary to implement good post-restoration management practice to enhance the meadow's self-recovery ability. Additionally, introducing moderate livestock grazing could promote the ecological restoration's effect and ensure sustainable recovery of alpine meadow.

Introduction

The extensive and severe land degradation worldwide poses a significant challenge to the restoration of Earth's ecosystems, particularly affecting grassland ecosystems. Since the 21st century, approximately 50% of the global grassland area has experienced degradation, with about 5% suffering from severe degradation that makes ecological restoration extremely challenging (Bardgett et al., 2021). On the Qinghai-Tibetan Plateau, the alpine grassland covers an area of 125,000 km², of which 70% has been degraded, and 8% has been severely degraded, referred to as 'Heitutan' degraded grassland by local herders, or 'bare land' degraded grassland (Dong et al., 2020). This severe degradation of alpine grassland results in the disappearance of the topsoil layer (approximately 0-30 cm), the loss of the soil seed bank, the spread of weeds and toxic plants, leading to a loss of biodiversity, the reduction of permafrost, and increased water and soil erosion. This condition is likened to scalp stripping and has been termed the 'ecological cancer' of the Qinghai-Tibetan Plateau. The ecological restoration of severely degraded alpine grasslands on the Qinghai-Tibetan Plateau has been designated as a key mission in China's 'Master Plan for Major Projects for the Protection and Restoration of Important National Ecosystems (2021-2035)'. However, the natural restoration of severely degraded land can take over 200 years or even longer, and in high-altitude areas with cold temperatures and low oxygen levels, the restoration of severely degraded grasslands becomes even more complex and challenging.

We understand that successful ecological restoration requires not only the recovery of a more integrated ecosystem structure but also the restoration of multiple functions, which is a process that takes a long time. Generally, on the Qinghai-Tibetan Plateau, the initial step in restoring severely degraded grasslands is to establish high-coverage vegetation to prevent water and soil loss by reseeding local plant seeds. Subsequently, this approach aims to gradually foster biodiversity and soil fertility, and enhance the ecosystem's self-recovery ability, which is known as active restoration (Dong et al., 2020). However, current studies on active restoration are limited to short-term cases, which do not adequately explain the approach's impact on the recovery process of vegetation, soil fertility, and soil seed banks, nor do they clearly answer questions about the outcomes of long-term restoration (Dong et al. 2020). To address this gap, we conducted field investigations and soil measurements in the laboratory for long-term active restoration projects (over 10 years) in three independent highland counties (elevations is 3900-4200 m a.s.l.). This paper presents the findings of this investigation regarding vegetation, soil nutrients, and soil seed banks, which could provide valuable references for the long-term active restoration of severely degraded alpine grasslands on the Qinghai-Tibetan Plateau.

Methods

The geographical coordinates of the field investigation site are 32°31'-35°40' N and 97°54'-121°50' E, located in the eastern part of Qinghai-Tibetan Plateau. The region experiences an annual average temperature range of -3.5°C to 4°C, with an accumulated temperature of 775 to 2104°C, and receives an annual precipitation of 448.6 to 569 mm, predominantly from May to September. The altitude ranges from 3900 to 4200 m a.s.l., characterized by low oxygen levels, cold conditions, and frequent strong winds and snowfall. The predominant vegetation in the grassland is alpine meadow, with the soil type being alpine meadow soil. The dominant plant species in these meadows include *Kobresia pygmaea, K. humilis, Stipa przewalskyi, Festuca ovina, Poa pratensis, and Elymus nutans*. The severe degraded alpine grasslands originated from overgrazing in alpine meadows, its vegetation coverage of approximately 40-60%, which is now dominated by weeds and toxic plants, with large areas of bare land. All of the long-term active restored grasslands have a history of over ten years and have been managed under traditional grazing practices. The active restoration methods employed were consistent with those used in local government restoration projects conducted more than ten years ago. The reseeding of native plant seeds involved grasses, specifically *Poa pratensis, Elymus nutans*, and *Festuca ovina*, following the same technical standards.

Our field site encompassed three distinct counties (Maqin, Dari, and Gande) with each site being more than 100 km apart from the others, ensuring true replication across similar field types. Within each site (county), we selected three types of grasslands: long-term active restored grassland, undegraded grassland, and severely degraded grassland. This resulted in a total of nine grasslands that were investigated and sampled. In each grassland, we established 20 plots measuring 50cm×50cm to assess plant species, coverage, and species frequency, yielding a total of 180 plots. Additionally, within each grassland, we selected 3 plots to collect soil and root samples from two distinct soil layers (0-10 cm, 10-20 cm). These soil samples were taken to the laboratory for analysis of soil and root carbon and nitrogen content. To assess the soil seed bank, we extracted soil cores (diameter 5 cm) from 20 plots in each grassland, targeting two soil layers (0-5 cm and 5-10 cm). The germination method was conducted in a greenhouse over a period of 7 months, which allowed us to accurately identify the germinable seeds from the soil seed bank.

Results

The three α-diversity indices (Shannon-Wiener index, Simpson index, species Richness) exhibited a consistent trend across the three types of grasslands, generally indicating that undegraded grasslands (UG) have greater diversity than severely degraded grasslands (DG), which in turn have higher diversity than long-term restored grasslands (LR; Table 1). However, at the WSX site, some indices for LR were found to be higher than those for DG (Table 1). Although the DG sites showed higher plant species diversity compared to the LR sites, the majority of species in the DG sites were weeds and toxic plants (Table 1). Community composition analysis revealed that long-term restoration efforts have not resulted in an improvement in the vegetation status of the restored grasslands when compared to both the degraded and undegraded grasslands.

Table 1. Community α-diversity of three grassland types in three sites

Grassland types	Shannon-Wiener index			Simpson index			Richness
	JMC	WSX	QZX	JMC	WSX	QZX

JM: The study site of Junmuchang in Maqin county; WSX: The study site of Wosai in Dari county; QZX:The study site of Qingzhenxiang in Gande county; LR-Long term active restoration grassland; DG-extremely degraded grassland; UG- undegenerated grassland.

The undegraded grasslands have the highest levels of soil organic carbon (SOC) and total nitrogen (TN), while the severely degraded grasslands (DG) have the lowest levels of SOC and TN (Table 2). There is a significant variation in SOC and TN values among the three sites (Table 2). The changes in SOC and TN across the three types of grasslands are more consistent in the 0-10 cm soil layer compared to the 10-20 cm layer (Table 2). Overall, the long-term active restoration of grasslands has led to an improvement in soil organic carbon and nitrogen content (Table 2).

LR-Long term active restoration grassland; DG-extremely degraded grassland; UG- undegenerated grassland. Little letter means the significant among grassland types ($p<0.05$).

There is no significant difference in the organic carbon content of both living and dead roots among the three types (Table 3). The total nitrogen content in the living roots is highest in the degraded grassland and lowest in the undegraded grassland (Table 3). The total nitrogen content in the dead roots of the degraded grassland is higher than that in the long-term restored grassland and the undegraded grassland, but the difference is not statistically significant (Table 3). Overall, long-term restored grassland has improved the organic carbon content in living roots.

Table 3. Organic carbon and total nitrogen of grassland root (Mean±SE)

Based on the species composition of the soil seed bank, the degraded grassland exhibits the highest species richness, whereas the long-term restored grassland shows the lowest (Table 4). The soil seed bank of the degraded grassland is predominantly composed of forb species. The long-term restored grassland has a comparable species richness to the undegraded grassland, with gramineous plants being the dominant species in both types of grasslands (Table 4).

Table 4. Species diversity of soil seed bank in three grasslands in three seasons (Mean±SE)

Season	Grassland types	Shannon-Wiener index	Simpson index	Richness
April	UG	2.13±0.21	0.73±0.10	12.56±3.09
	DG	2.30±0.33	0.76±0.18	15.33±2.87

	LR	1.65±0.22	0.75±0.05	8.11±2.26
December	UG	1.85±0.51	0.78±0.13	10.00±4.47
	DG	2.12±0.26	0.83±0.07	13.44±1.67
	LR	2.01±0.17	0.84 ±0.03	9.44±1.24

The seed density in the soil seed bank across the three types of grasslands follows a similar pattern, with the highest density observed in the undegraded grassland and the lowest in the severely degraded grassland (Table 5). Additionally, the seed density is highest in April and lowest in December (Table 5). The degraded grassland contains several species that produce a large number of seeds, such as the forb *Pedicularis kansuensis* Maxim. The long-term restored grassland has increased the seed density of the soil seed bank, and the plant species composition is now dominated by perennial grasses (Table 5). The soil seed bank is an indicator of vegetation recovery potential, especially in grassland ecosystems. Thus, these findings suggest that long-term restoration efforts can enhance the vegetation recovery ability of this type of grassland.

Table 5. Seed density of soil seed bank of three grassland in three seasons (Mean±SE)

Grassland types	April	August	December

Discussion [Conclusions/Implications]

Our independent experimental results from the three counties demonstrated that long-term active restoration has a certain positive effect on the recovery of extremely degraded grasslands. However, the lack of post-restoration management may have led to a significant decline, or even the disappearance, of the restoration approach's effectiveness. The typical characteristic of degraded alpine meadows is a marked increase in weed and toxic plant species, which, of course, serves as an effective self-protection mechanism against the grazing pressure on grassland ecosystems (Shang et al., 2016). The increase in weeds and toxic plants also enhances vegetation coverage, soil seed bank density, and soil nutrition, features that have been improved by long-term restoration efforts (Guo et al., 2019).

It is noteworthy that long-term active restoration did not change the degraded status of the grasslands, and there has been a decline in vegetation coverage and biomass. Consequently, the return of plant biomass to the soil system has decreased, leading to more severe soil degradation. As available soil nutrients diminish and the soil becomes more barren, it becomes increasingly difficult to further enhance the grassland's restoration ability. A key reason is that during long-term restoration, the grasslands continue to experience grazing disturbance, a common issue in global ecological restoration efforts (Xu et al., 2023). Our previous studies have shown that active restoration can enhance soil nutrient accumulation, but the restored grasslands should reduce grazing or implement rest-grazing through fencing (Feng et al., 2010; Gao et al., 2019). In this study, all long-term restoration grasslands were not well managed after the restoration measures were implemented. Throughout the long-term restoration process, the grasslands were grazed by local herders, with over-grazing occurring, which reduced the effectiveness of the restoration efforts.

Active restoration with native plant seed reseeding and reduced disturbance, coupled with improved management practices, could enhance the recovery effects for severe degraded grasslands. Furthermore, we advocate against implementing restoration projects without proper subsequent management, as this could lead to more severe degradation, particularly in ecologically fragile areas such as dry and cold regions. Although there is a significant need to restore degraded grasslands on the Qinghai-Tibetan Plateau, the pressure from livestock breeding on these grasslands necessitates a primary reduction in livestock numbers and an increase in protection or conservation efforts (Shang et al., 2014). If the large number of livestock cannot be reduced, the effectiveness of ecological restoration efforts will be greatly limited. Drawing on ecological theory and practice, active restoration with native plant reseeding has a positive effect and can significantly improve grassland recovery, which underscores the importance of post-restoration management (Xu et al., 2019). Local herders should adopt planned-grazing practices on restoring grasslands, which could greatly enhance their recovery. This is because the economic interests of ecological restoration in severe degraded grasslands are ultimately closely linked to the local herders.

Abstract

Legumes, acting as important fixers of nitrogen (N), are characterized by high forage quality. However, these key species are suffering from substantial declines in rangeland worldwide, especially in degraded ecosystems, with subsequent constraints on livestock performance. There is an urgent need to restore legumes to improve forage quality and quantity. We developed a cutting-edge reseeding technology, and a new re-seeding machine, to introduce legumes into degraded rangeland. Compared with traditional no-tillage reseeding, the new reseeding technology can dramatically improve germination rates of reseeded legumes by creating suitable micro-habitat for seed germination and seedling establishment, e.g., higher soil temperature and moisture. Legume-reseeded rangeland was more productive than non-reseeded rangeland, primarily due to enhanced ecological niche complementarity and compensatory growth through interspecific facilitation. Four years after legume reseeding, soil nitrogen and organic matter content were increased by more than 10%. Beneficial soil microbes, e.g., the abundance of arbuscular mycorrhizal fungi, was significantly increased by 31% after legume reseeding. In general, introducing legumes into degraded rangeland can improve forage production and quality, and simultaneously enhance rangeland sustainability by promoting soil health.

Introduction

Legumes are integral components of rangeland ecosystems, contributing significantly to soil fertility and enhancing the overall nutritional value of forages (Ganjurjav et al., 2024). However, rangeland degradation, driven by climatic change and anthropogenic disturbances, has led to a rapid decrease in diversity and abundance of legumes (Xu et al., 2020; Tognetti et al., 2021). This loss of legumes has profound ecological and economic consequences, for instance, reducing soil carbon sequestration and nitrogen fixation, and decreasing forage quality and quantity (Stagnari et al., 2017). Reintroducing legumes into degraded rangelands has been recognized as a critical strategy for restoration and renewal (Waddington, 1992; Mi et al., 2024). Nevertheless, the successful establishment and persistence of legumes are often hindered by abiotic factors (e.g., drought; light competition) and biotic factors such as competition from native vegetation in rangeland. To facilitate seedling establishment and achieve long-term maintenance of legume proportion in rangeland, there is an urgent need to develop effective agronomic practices. Here we focus on the approach of reintroducing legumes into degraded steppes and then investigate the effect of legume reintroduction on forage production and soil nutrient content. This study aims to provide practical implications for rangeland restoration and ecosystem sustainability.

Methods

Study area and experimental design

The study site is located at a temperate steppe in Hulunbuir, northeastern Inner Mongolia, China (49 ° 20 ′ ~ 49 ° 26 ′ N, 119 ° 55 ′ ~ 120 ° 9 ′ E, altitude 628 ~ 649 m), with an annual average temperature of -3 ~ 0 ℃, and an annual average precipitation of 350 ~ 410 mm. The precipitation is seasonal and mainly occurs from June to September. The study area is moderately degraded steppe. In June 2020, we reseeded yellow-flower alfalfa (*Medicago falcata*) into degraded rangeland using no tillage machine with inverted T-shaped or V-shaped slots, and the un-reseeded area was treated as non-reseeding (NR) treatment. We randomly selected ten 1 × 1 m sample plots for paired sampling, applying both non-reseeding (NR) and reseeding (R) treatments.

Sampling and measurements

After reseeding, we buried button-type temperature and humidity monitors in each slot, which can automatically record data every hour. These monitors recorded soil relative humidity data from July 19th to September 6th, 2020, and soil temperature data from June 17th to September 23rd, 2020. We randomly selected three 1-meter-long slots in each plot, and counted the number of alfalfa seedlings in each slot 7 days after reseeding to calculate germination rate. Aboveground living plants in each plot were harvested and sorted by species in middle August 2024 (peak growth period). All plant species were classified into three functional groups: legume, forb, and grass. We collected soil samples at the depths of 0-15 cm and measured total nitrogen and organic carbon content using an elemental analyser (Vario Macro, elementar, Germany) and a CN analyser (Elementar, Germany), and measured the abundance of arbuscular mycorrhizal fungi (AMF) using phospholipid fatty acid (PLFA) analysis.

Statistical analysis

When investigating the impact of inverted T- or V-shaped slot reseeding on soil temperature and humidity, we performed one-way ANOVA using the *aov* function in the *stats* package. If significant effects were found, we used the *agricolae* package for a Duncan test. We used the *t.test* function in the base *stats* package to detect the difference between non-reseeding (NR) and reseeding (R) treatments. The *ggplot2* package was used for data visualization. All statistics and data visualization were performed in R 4.3.3 (R Core Team, 2024).

Results

The inverted T-shaped slot increased soil temperature and humidity.

We developed a new re-seeding machine using inverted T-shaped slot to introduce legumes into degraded rangeland (Fig. 1). The inverted T-shaped slot significantly increased soil temperature and relative humidity in the ditch by 1.2℃ and 60%, respectively. The increase in soil temperature and relative humidity provided a suitable microenvironment for seed germination (Fig. 2, Table 1), and therefore the inverted T-shaped slot increased seed germination rate by 120%.

Fig. 1 The ditch created by the V-shaped slot or the inverted T-shaped slot.

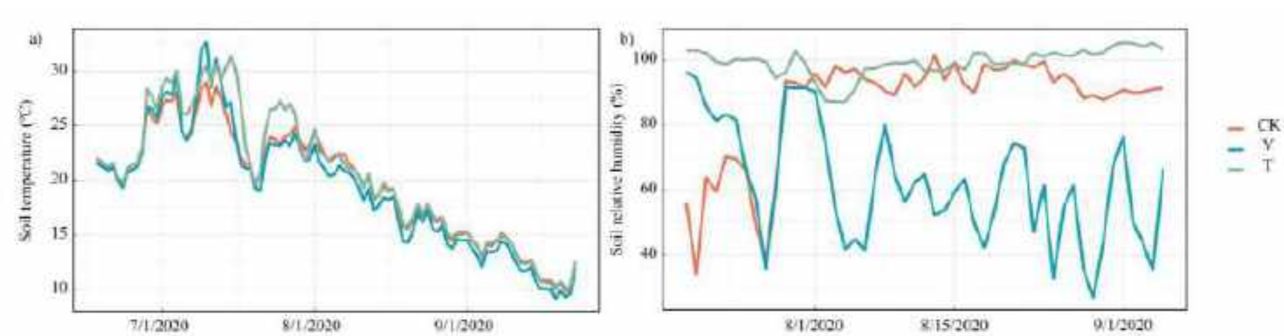

Fig. 2 Effects of the inverted T-shaped slot on soil temperature (a) and humidity (b). CK, control; V, V-shaped slot; T, inverted T-shaped slot.

Table 1 Effects of reseeding method on soil temperature and humidity and gemination rate

Reseeding method	Soil relative humidity (%)	Soil temperature (°C)	Gemination rate (%)
Control (CK)	86.31 ± 2.34 b	19.69 ± 0.51 b	-
V-shaped slot (V)	62.20 ± 2.59 c	19.32 ± 0.57 b	25.41 ± 7.93 b
Inverted T-shaped slot (T)	99.24 ± 0.62 a	20.42 ± 0.60 a	55.96 ± 11.53 a

Note: different lowercase letters following values (mean ± SE) represent significant ($P < 0.05$) differences, while identical lowercase letters indicate no significant differences among or between treatments.

Reseeding legumes increased soil nutrient content and AMF biomass.

Legume introduction increased soil total nitrogen content 14% and increased soil organic carbon content by 7.5% after four years of reseeding legumes (Fig. 3a, b). Reseeding legumes increased the abundance of AM fungi by 31% (Fig. 3c).

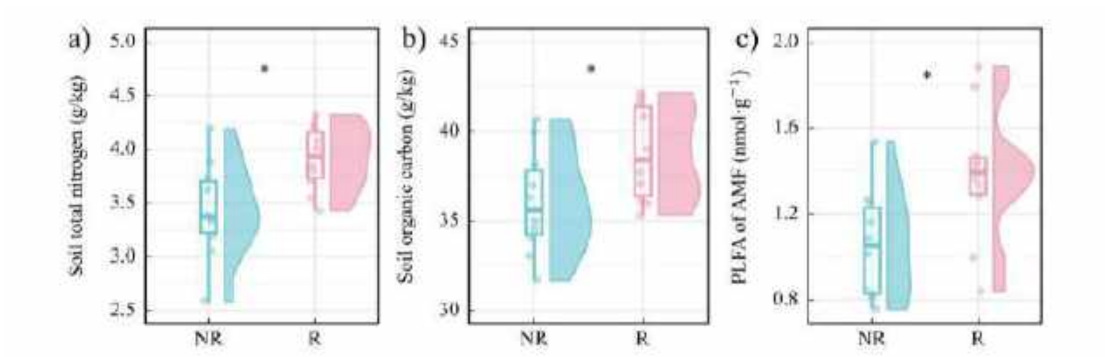

Fig. 3 Effects of reseeding legumes on soil nutrient content and AMF abundance. The difference between the reseeding (R) and non-reseeding (NR) treatments is indicated by asterisks (P < 0.05).

Reseeding legumes increased plant biomass and changed community composition.
Reseeding legumes significantly improved the productivity of degraded rangeland. For instance, total biomass production was increased by 148%, which mainly came from the increase in the biomass of legume functional group (Fig. 4a). After reseeding, the proportion of legume functional group significantly increased, while the proportion of grass and forb has significantly decreased (Fig. 3b).

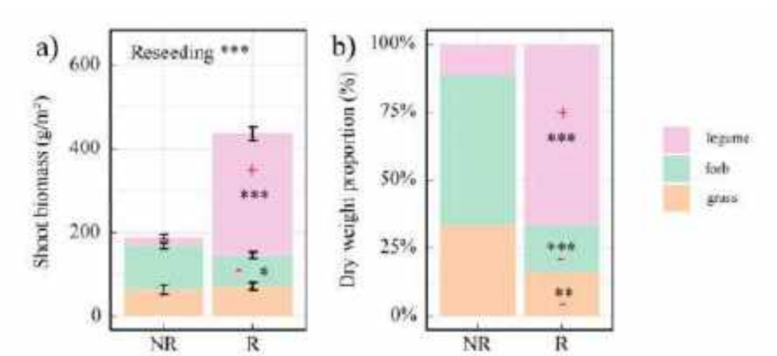

Fig. 4 Effects of reseeding legume on plant biomass and community composition. The difference between the reseeding (R) and non-reseeding (NR) treatments is indicated by asterisks (*, P < 0.05; **, P <0.01; ***, P <0.001). The symbols '+' and '-' indicate a significant increase and decrease by reseeding, respectively.

Discussion
In summary, we have developed an effective solution for restoring temperate degraded steppes through reseeding legumes. The inverted T-shaped slot significantly improved the germination rates of legume seedlings by promoting soil temperature and humidity. The successful establishment of legumes can dramatically improve forage production and simultaneously enhance soil health indicated by an increase in soil fertility and the abundance of AMF. Our study shows that reseeding legumes in temperate steppe can promote forage production and enhance rangeland sustainability.

Reseeding via the inverted T-shaped slot serves as an effective practice for creating favourable microhabitats. Compared to the tradictional V-shaped slot, the inverted T-shaped slot can create a ditch with smaller surface soil cracks and larger underground voids. These attributes not only help reduce soil water loss and maintain soil temperature, but also mitigate the underground competition of native species against the reseeded ones. The improvement of microhabitat could benefit seedling establishment, according to a previous study (Lett and Dorrepaal, 2018). The successful introduction of legumes led to substantial increases in plant productivity, driven primarily by a high proportion of legumes in plant communities. One of our recent studies found that reseeding legumes can further improve the performance of neighbouring species (Guo et al., 2024). This is because the presence of legumes can enhance ecological niche complementarity and promote compensatory growth through interspecific facilitation (Guo et al., 2024). It is well known that legumes can gradually enrich soil nitrogen availability through biological nitrogen fixation. This will stimulate microbial processes that enhance soil organic carbon sequestration (Abalos et al., 2020; Gou et al., 2023; Hu et al., 2024). Our findings align with previous studies, showing significant increases in soil total nitrogen and carbon storage following legume introduction. Additionally, microbial restoration is a critical objective for degraded ecosystems. In our study, the abundance of AMF was increased dramatically by reseeding legumes. The increase in AMF abundance can improve multiple ecosystem functions, e.g., the formation of soil aggregates and plant growth, leading to positive feedback for restoration.

Our study has revealed the multifaceted benefits of legume restoration in improving ecosystem function within degraded rangelands. In the future, efforts should be directed towards harnessing the ecological advantages of legumes to restore degraded rangelands. Furthermore, it is essential to develop appropriate management strategies to maintain the proportion of legumes in plant communities, thereby ensuring ecosystem sustainability.

Enhancing the resilience of Saharan rangelands by reseeding drought tolerant native shrubs: the case of *Lygos raetam* in southern Tunisia

Ouled Belgacem, A[1]; Ben Abdellatif, M.[2]; Louhaichi, M[1]

[1]International Center for Agricultural Research in the Dry Areas (ICARDA), Tunis Office, Tunisia; [2]Groupement de Dhahar Al-Moustakbel, Douz, Tunisia

Key words: Restoration, Saharan rangelands, *Lygos raetam,* Tunisia.

Abstract

Lygos raetam is a desert and drought-tolerant shrub native to North Africa and West Asia. Goats and camels readily graze its fruits and flowers, and it is well known for its capacity to stabilise mobile sands.

This study was carried out in the communal rangelands of Dhahar, Saharan area of Southern Tunisia, to assess the impact of reseeding *L. raetam* on natural vegetation cover and sand mobility. A sandy rangeland site located at the border of the African Eastern Sand Sea was subjected to three management treatments: two years of rest, reseeding *L. raetam*, and free grazing (control). In all plots, total plant and perennial species percentage covers were determined and monitored for 5 years. Results showed that despite the improvement in the percentage of total vegetation cover recorded, the rest technique seems insufficient and inefficient in cases where vegetation degradation has reached an advanced stage. On the other hand, despite the negative effect of drought, there were considerable positive impacts of reseeding *L. raetam* on vegetation cover and active dune stabilization. The good establishment and survival of *L. raetam* seedlings may encourage rangeland managers and pastoral communities to undertake rehabilitation by reintroducing promising native Saharan species when ecosystems lose their natural resilience.

Introduction

In arid and Saharan areas of North Africa and more specifically in Southern Tunisia, several studies showed that they are subject to human and climate drivers that can result in reduced production and ecosystem functions and services (Jama and Zeila 2005; Ouled Belgacem and Louhaichi 2013). Overgrazing remains the primary anthropogenic factor impacting arid and semi-arid vegetation (Smet and Ward, 2005). Overgrazing is associated with overstocking and drought, further contributing to degradation, and reducing biodiversity and rangeland productivity (Ouled Belgacem et al. 2019).

Several attempts have been made to restore degraded rangelands in dry areas with exotic herbaceous species and shrubs (Zaafouri et al. 1994). Most of these attempts have largely failed due to the inability of the introduced species to adapt to the ecological constraints of the region. As a result, reseeding with native species has become a more attractive option (Aronson et al. 1993).

The irregular annual precipitation and frequent droughts that characterize desert zones affect native plant regeneration and growth, causing land degradation and amplifying desertification. Zaafouri et al. (1994) showed that the success of rangeland restoration depends on the choice of plant species adapted to soil and climatic conditions, adequate sowing techniques, and plant development control. For these reasons, restoration activities in arid zones require the investigation of local germplasms that present good flexibility and adaptation to unfavourable climatic conditions. However, restoration and rehabilitation with endemic germplasm require research into culture conditions and water deficit responses (Zaafouri 1993).

Lygos raetam (Forssk) Heywood is a xerophilic and psammophilic species in the Fabaceae family, common in arid desert ecosystems and widely distributed in North Africa and West Asia where it grows under unfavourable dry conditions. This shrub is well known for its significant role in combating wind erosion and stabilizing dunes and provides an important dietary source for camels. Flowers are well appreciated by small ruminants mainly goats. Additionally, this species represents a viable fuel source for humans (Cheriti et al. 2009) and different therapeutic virtues (Said et al. 2002).

This study is carried out in the El Mahmouda area, in the collective rangelands of Dhahar of Douz in Southern Tunisia, aiming at assessing the impact of rangeland rest and reseeding of *L. raetam*, on plant cover dynamics.

Methods

The experiment was conducted in the El Mahmouda zone, communal rangelands of Dhahar, desert area of southern Tunisia (mean annual rainfall is <80 mm). The zone covers 40000 ha with many micro-reliefs (small depressions, large dunes, etc.). The natural vegetation cover is very sparse and mainly dominated by perennial species such as *Rhanterium suaveolens*, *Haloxylon schmittianum, Stipagrostis pungens*, and *Anthyllis henoniana*. Annual species like *Savigna parviflora*, *Asphodelus tenuifolius*, *Schismus barbatus* and *Matthiola longipetala* are observed during wet seasons.

The study was carried out during the spring (March-April) of five years between 2008 and 2012. The experiment is established as a Completely Randomized Design (CRD) with three management treatments tested: i) strict protection, ii) reseeding *Lygos raetam,* and iii) free grazing (control). Each treatment was replicated three times (3 plots of 2500 m^2 area each).

For each management treatment and within each plot, five transects, 50 m long each, were installed. A fine pin was dropped straight down into the ground every 50 cm along the line. Each of the 100 hits per line was recorded according to the plant species. The results are expressed in terms of percentage vegetation cover (R, %) as:

$$R = (n / N) * 100$$

where n is the number of hits of all plant species and N is the total number of hits.

The data were analysed using analysis of variance (ANOVA) based on the CRD statistical model using SPSS (20.0).

Results

Analysis of variance of total plant cover showed highly significant differences ($P = 0.0001$) between applied management treatments (Table 1). The plots reseeded with *L. raetam* recorded significantly higher total plant cover compared to the protected ones. The lowest values were registered at the freely grazed plots. In these plots most of the plant species were annuals. However, there was also a relatively higher percentage cover of other perennial species in the reseeded plots. Additionally, both total plant cover and *L. raetam* species cover showed a slight decrease with decreasing mean annual rainfall. Given the important contribution of the *L. raetam* seedlings to the total vegetation cover in the reseeded plots, its slight decrease confirms the high adaptation of this species to the harsh environment (Table 1).

Discussion

Lygos raetam species is a dominant perennial shrub in active sand dunes and stabilized sand fields in the Saharan zone of Tunisia. The results of the study confirm the reputation of the species for high tolerance of frequent droughts and water deficits. The establishment and survival of the seedlings seem to be attributed to their excellent root growth (Dhief et al., 2011), which enables plants to exploit a larger volume of soil, which may ensure recruitment success and testify thus an adaptive strategy to deal with drying soils and decreasing soil moisture.

Table 1. Total vegetation and *Lygos raetam* covers (%) with management modes according to mean annual rainfall. Values are means ± SD.

Year	Rainfall (mm)	Control		Rest		Reseed	
		Total	*L. raetam*	Total	*L. raetam*	Total	*L. raetam*
1	163.5	15±1.26	1..90±0.86	13..05±1.45	4.20±1.22	15.80±1.37	8.60±2.26
2	63	13.10±0.92	1.80±0.68	12.79±1.26	4.60±1.38	13.90±1.13	7.60±1.88
3	60.2	9.80±.09	1.20±0.28	10.60±1.50	3.60±1.48	11.52±1.99	6.50±1.78
4	62.8	8.40±0.82	1.50±0.38	10.40±0.47	3.40±0.82	11.02±0.69	6.10±1.69
5	130	8.40±0.35	1.50±0.42	11.70±1.32	3.50±1.66	13.80±1.29	6.18±1.44

On the other hand, the significantly higher total vegetation cover recorded in the plots reseeded by *L. raetam* may be attributed to the improvement of the availability of water and nutrients or the protection against direct irradiance and overheating (Moro et al., 1997) resulting from the small ''islands of fertility'' created around the plants of this Fabaceae species (Barakat et al., 2013).

L. raetam can grow and stabilize mobile sand dunes in conditions of extreme water deficit, and it appears to be suitable for revegetating and restoring degraded Saharan ecosystems. Thus, *L. raetam* can be suggested as one of the best species for the early stabilization of dunes and biomass production for livestock, mainly camels.

Key words: Ecosystem services; Climate change; Soil water content; Biodiversity

Abstract

Rangeland degradation is becoming a serious problem in semiarid areas affecting rangeland productivity and hence the livelihood of the pastoralists. Degraded rangelands have low levels of soil carbon stock and diminished potential for biomass production. To overcome this problem, a re-seeding strategy is one option that needs to be considered. Accordingly, a study was conducted to examine the impact on biomass production, carbon stock, soil water content and biodiversity of re-seeding highly degraded rangeland with native grasses. Random sampling techniques using quadrats (0.5m x 0.5m) for biomass and species composition assessment were employed on re-seeded and non-seeded plots. Simpson's index of diversity was used to calculate the biodiversity of the vegetation. The soil organic carbon was calculated from soil samples taken at three depths (0-10 cm, 10-20 cm, and 20-30 cm) from re-seeded and non-reseeded plots. The results showed that vegetation composition recovered from the soil seed bank, forage biomass was higher, and carbon stock better on the re-seeded plot. There were sixteen species recovered in addition to *Chloris Gayana* and *Cenchrus ciliaris* on the seeded plots. The Simpson diversity of vegetation on the seeded plots was 0.78 compared with zero on the non-seeded ones. The dry matter yield for re-seeded plot and non-reseeded plots were 3.6, and 0.2 t/ha, respectively. Carbon stock was 15% higher under the restored rangeland compared to non-restored. The overall soil water content was 16.3 and 10.75% for re-seeded plot and non-re-seeded plots, respectively. Options to improve the productivity of highly degraded rangeland for multiple benefits could involve re-seeding with native grasses with integration of appropriate planning and continuous sourcing of grass seeds.

Introduction

Ethiopia's rangelands, covering 62% of the country's land area, provide essential feed for livestock and support the livelihoods of 12-15 million pastoralists (Gina 2015). However, like many other rangelands of the worldwide, Southern Ethiopia's dry land rangelands are facing degradation due to factors such as vegetation loss, increased abundance of unpalatable plants, bush encroachment, conversion to cropland, and overgrazing, exacerbated by climate change (Abdulahi et al. 2016).

Despite these challenges, protected vegetation can recover rapidly. Restoration methods, including reseeding, natural regeneration, and soil and water conservation practices, can address the underlying causes of degradation (Ouled Belgacem et al. 2019). Improved rangeland management can enhance ecosystem services, such as carbon sequestration (Henry B et al. 2024). By implementing appropriate rangeland management rules and successful restoration/rehabilitation practices, it is possible to slow and reverse land degradation, thereby increasing rangeland carrying capacity. This study aims to:

- Determine the capacity of reseeding native grasses on degraded rangelands to enhance ecosystem services, including carbon sequestration, forage production, and biodiversity.
- Raise awareness among development actors about the multiple environmental benefits of specific rangeland management practices.

Methods

Area description and site selection

The assessment was conducted in the rangelands of southern Ethiopia, specifically in the Dugda-Dawa district. This area, located between 4-6°N and 36-42°E, exhibits gentle slopes ranging from 1600 meters above sea level (masl) in the northeast to approximately 1000 masl in the extreme south, bordering Northern Kenya, and reaching 1780 masl in the central vicinity. Rainfall in this region is bimodal, with long rains occurring between March and May and short rains between September and November. The Dugda-Dawa district is a highly degraded rangeland where rehabilitation efforts, including reseeding with native grasses, have been initiated by the Yabello Pastoral and Dryland Agricultural Research Center. Local pastoralists reported that this specific area had been left degraded for over 33 years before the reseeding initiated began.

Data sampling procedures

Sampling was done for reseeded and non-reseed areas. The biomass was calculated using the 50 quadrats (0.5m X0.5m) that each taken from the reseeded area and non-reseeded area. Dry matter yield of grasses was determined after oven drying at 105 °C for 24 hours at Yabello Pastoral and Dry land Agriculture Research Centre.

Six samples of soil were collected from the depth of 0-10cm, 10-20cm and and 20-30 cm, from both reseeded and non-reseeded and bulked together for analysis of organic soil carbon by methods of Black and Walkely method used as described by Sahlemedhin and Taye (2000). Soil bulk density was analyzed following standard procedures (Bashour and Sayegh, 2007). The soil organic carbon stock was calculated using equation (Guo and Gifford, 2002). For soil water content, soil sampling was done using 5mm can from 10 point at depth of 0-10 cm and 10-25 cm within each area. Soil samples were covered and taken to laboratory for gravimetric moisture analysis (Michael 1978). Gravimetric moisture contents were calculated by expressing the percentage moisture on dry mass basis.

Simpson's diversity index was used to quantify the species composition. The data analysed and presented with descriptive methods, like percentage and average of the two areas.

Results

Dry matter yield

This result indicates a high potential for restoring degraded rangelands to support feed production. The previously barren, vegetation-deprived rangelands have shown promising signs of recovery. Although the initial seeding involved a mixture of two grass species with minimal tillage, the subsequent emergence of diverse vegetation has led to a significant increase in biomass in the reseeded area. It's important to note that the average dry matter yield for reseeded was 3.6 t/ha and for non-reseeded area was 0.2t/ha of a single cutting during the growing season. This suggests that the total annual dry matter yield for the reseeded area could potentially be double the value shown above if two cuts for the two seasons considered.

Soil organic Carbon and vegetation composition
Some differences were observed in soil organic carbon (%) content, particularly at the upper depth (0-10 cm) where 1.06 and 0.85 for reseeded and non-reseeded, respectively. The soil bulk density for reseeded and non-seeded areas were 1.21gm cm^{-3} and 1.3 1gm cm^{-3}, respectively. This may be due to the incorporation of root systems, organic matter and some tillage in the reseeded area. When calculating carbon stock (t/ha) for the upper depth (0-10 cm), the reseeded area exhibited approximately 15% higher carbon stock compared to the non-seeded area. This finding suggests that highly degraded pastoral areas can respond to climate change mitigation efforts through measures like reseeding. Such measures can improve rangeland resource management, minimize current vulnerabilities, and enhance resilience to future changes in rangeland degradation. The increased carbon stock in the reseeded area demonstrates the potential of such measures to improve the capacity to respond to climate change. The reseeded area, comprising two grass species, exhibited an increase in plant species diversity to eighteen, including twelve grasses and six non-grasses. Of the twelve grass species, eleven were perennial and highly desirable for livestock feed. The Simpson's Diversity Index calculated a biodiversity value of 0.78 for the reseeded area. The five dominant plant species in terms of percentage composition were *Digitaria melanjiana (*37.78%), *Chloris gayana (25.9%)*, *Indigophera spinosa (4.75%)*, and *Eragrostis capitulifera (3.77%)*.

Soil water content at reseeded and non-reseeded areas
Soil water content significantly influences plant growth and other soil properties. In this study, the soil water content of the reseeded area was found to be higher than that of the non-reseeded area at similar depths. The overall average of soil water content was 16.3 and 10.75% for re-seeded plot and non-reseeded plots respectively. Compared to the non-reseeded area, the reseeded area exhibited a 51.4% and 51.7% increase in soil water content at the 0-10 cm and 10-25 cm depths, respectively.

Discussion
The reseeded area exhibited increased biomass yield and vegetation composition. This improvement can be attributed may be to the long-term persistence of a soil seed bank, which was activated by minimal tillage on the highly degraded rangeland. In contrast, highly compacted, degraded rangelands have limited potential for aeration and water infiltration, hindering vegetation recovery. Amaha et al. (2009) found that degraded rangelands have the capacity to regenerate from existing soil seed banks, demonstrating their potential for recovery. Similar to our findings, Sahar Ezzat et al. (2013) reported enhanced biomass production through reseeding. While various factors influence soil organic carbon, the reseeded area showed promising results. As noted by Lal (2004), increased soil carbon content can improve soil properties and enhance adaptation capacity. Degraded rangelands, whether affected by overgrazing or fire, are susceptible to significant losses of soil organic carbon due to erosion and accelerated decomposition of soil organic matter. However, the increased vegetation cover in the reseeded area may have contributed to higher soil organic carbon content, biomass, and soil water content.

Suliman and Ahmed (2013) reported that reseeding with tillage can increase soil water content. Additionally, Duma (2000) noted that increased vegetation cover can lead to increased soil water content. The higher soil organic matter content in the reseeded area may also contribute to improved water retention

(Kimble et al., 2007). Several factors may contribute to the higher soil water content in the reseeded area, including reduced evaporation due to vegetation cover and increased infiltration rates, as the absence of plant cover in the non-reseeded area can lead to increased runoff and decreased soil moisture (Sadeghi et al., 2007).

Conclusion

It was concluded that reseeding on highly degraded rangelands have positive impacts on forage biomass productivity and protects the land from further erosion and degradation. The increased soil carbon stock and soil water content resulting from reseeding suggest that this practice may be a suitable option for highly degraded environments. The improved vegetation composition following reseeding indicates that this practice can enhance ecosystem stability and thus leading to increased livestock productivity and improved livelihoods in semi-arid environments.

Acknowledgements

The authors would like to express their gratitude to the Oromia Agriculture Research Institute's Yabello Pastoral and Dryland Agriculture Research Center for their financial support of this research. Additionally, we acknowledge the valuable contributions of the Animal Feed Resources and Rangeland Management Research Team staff in collecting high-quality data. We are also grateful to the pastoralists who generously participated in this study.

Development of an environmental decision support system for predicting the natural distribution of Festuca ovina in land restoration efforts

Saffariha, M[1]; Jahani, A[2]; Roche, LM[1]; Hosseinnejad, Z[3]

[1] Department of Plant Sciences, University of California Davis, Davis, California, USA; [2] Faculty of Assessment and Environment Risks Department, Research Center of Environment and Sustainable Development, Tehran, Iran; [3]Department of Environment, Natural Resources and Environment, Malayer University, Hamedan, Iran

Key words: environmental decision support system; Festuca ovina; machine learning; multilayer perceptron

Abstract

Anthropogenic activities, species invasions, and ecological factors are rapidly altering rangeland ecosystems, challenging the sustainability of plant species habitats. To address this, reliable prediction models are needed to forecast and map species distribution under varying ecological conditions. This study compares three machine learning methods—Multilayer Perceptron (MLP), Radial Basis Function (RBF), and Support Vector Machine (SVM)—in predicting the distribution of Festuca ovina in Eshkevarat Protected Area eastern Guilan province in Iran. This 30,347-ha mountainous protected area is located in the hills of the Alborz Mountains, ranging from 200 to 3600 m in elevation. We analyzed F. ovina distribution in 305 randomly selected plant sample plots, recording 10 ecological variables in each plot. Three machine learning models were developed to predict the likelihood of F. ovina distribution. Results showed that the RBF model had more misclassifications (11 samples) compared to MLP and SVM models (10 samples), suggesting that MLP and SVM were more accurate for distribution modeling. Additionally, MLP demonstrated a higher R2 value (0.87) compared to SVM (0.85), indicating that MLP was the most precise model for predicting F. ovina distribution. Thus, we developed the F. ovina Distribution Model (FODM) using the MLP model. Sensitivity analyses revealed that soil texture, soil depth, electrical conductivity (EC), pH, and vegetation density significantly influenced F. ovina distribution, with sensitivity coefficients of 0.48, 0.47, 0.45, 0.41, and 0.41, respectively. Based on the finalized FODM, we designed an Environmental Decision Support System (EDSS) tool to assist rangeland managers in mapping F. ovina distribution. The practical application of the EDSS tool demonstrated its effectiveness in using the FODM for decision-making and land management. This tool is a valuable resource for rangeland managers, enabling them to make informed decisions regarding F. ovina restoration and effectively utilize the predictive capabilities of the FODM in real-world applications.

Introduction
Festuca ovina is a perennial, cool-season plant that holds both agricultural and ecological significance. This valuable rangeland species is currently being threatened in Iran's rangelands due to livestock and human activities. Known for its palatability and high nutritional value for livestock, F. ovina also plays a crucial role in soil conservation and fertility through nitrogen fixation (Acharya et al., 2006). Besides its nutritional benefits for wildlife and soil protection, F. ovina is ecologically important due to its excellent drought tolerance, robust bunch-type root systems, and adaptability to various soil types, making it ideal for reclamation projects in areas with 30 to 61 cm of annual precipitation. This stress-tolerant grass thrives in a wide range of soils, including poor soils, and provides effective ground cover in areas with limited precipitation. As we explore the impact of ecological variables on the distribution of F. ovina to model its distribution across the study area, Hulvey et al. (2017) suggested that plant distribution modeling can help identify restoration islands that can eventually be expanded to the entire area. In some state of art studies, MLP models were designed for planning environmental enhancement based on natural condition (Aboufazeli et al., 2021, 2022; Jahani et al., 2023). The main objectives of this study are: (1) to model the distribution of F. ovina in a protected rangeland, (2) to compare various machine learning techniques to identify the most accurate model, (3) to prioritize model inputs (plant and ecological variables) through sensitivity analysis, and (4) to design an environmental decision support tool for the distribution of F. ovina.

Methods
To model the impact of ecological variables on the distribution of Festuca ovina, we utilized machine learning techniques including MLP, RBF, and SVM, prioritizing the ecological factors that influence its distribution. Building on previous research regarding the environmental requirements of F. ovina, the majority of the plot data collection was guided by this prior work. We then determined the quantitative impact of each variable on F. ovina distribution. A graphical user interface was subsequently developed as a decision support system for mapping F. ovina habitats under the ecological conditions of degraded rangelands.

To model and predict F. ovina distribution under varying ecological conditions, a grid network was established to randomize sampling across the entire habitat. The grid dimensions were 1000 × 1000 m within the boundaries of the Eshkevarat Protected Area. During the summer of 2021, F. ovina distribution was recorded within 2 × 2 m sample plots at 305 sampling points. Based on available resources, maps, and the region's ecological conditions, including landform, soil, and vegetation, 10 ecological characteristics were recorded at each sample plot. These included landform variables such as elevation, land slope, and geographic aspect; soil variables like soil depth, soil electrical conductivity (EC), soil pH, and soil texture class; and vegetation variables including vegetation density, vegetation type, and land use. The variables of soil depth, soil EC, and soil pH were recorded as continuous data without classifying their variability.

Annual temperature (ºC) and annual precipitation (mm) also affect species distribution; however, these variables were highly correlated with elevation. Due to the insufficient number of climate stations in the region, they were not included as input variables in the model. The selected variables were then used to build a model to predict F. ovina distribution across the study area.

Results
Based on the accuracy analysis of the three models, the most effective model for predicting Festuca ovina distribution (FODM) was developed using the MLP approach. Although MLP and SVM exhibited similar

accuracy rates (0.967), the MLP model demonstrated a higher R^2 (0.87) and a lower MSE (0.02), indicating that it provides a more precise classification of F. ovina distribution (Table 1).

Figure 1 illustrates the results of the sensitivity analysis, which quantifies the impact of FODM input variables on the model's output. The FODM output classifies F. ovina distribution into two categories: 0 and 1. According to the average sensitivity coefficients, soil texture (0.48), soil depth (0.47), electrical conductivity (EC) (0.45), pH (0.41), and vegetation density class (0.41) are identified as the most significant factors influencing F. ovina distribution (Figure 1).

Discussion [Conclusions/Implications]

In this study, we identified the most accurate distribution model for Festuca ovina by analyzing various ecological factors and employing machine learning techniques. An Environmental Decision Support System (EDSS) application was developed to classify degraded lands for F. ovina distribution and to assist in making informed decisions on restoration plans. Ecological evaluation and plant restoration planning often depend heavily on spatial data, making it crucial to link a Decision Support System (DSS) with a Geographic Information System (GIS) containing the necessary thematic layers. This integration of GIS and DSS has become a common approach for addressing decision-making challenges in plant restoration planning and land allocation. Based on the findings of this study and the developed EDSS for F. ovina distribution modeling, we successfully addressed the primary concern of decision-makers in identifying optimal land areas for vegetation restoration through F. ovina planting.

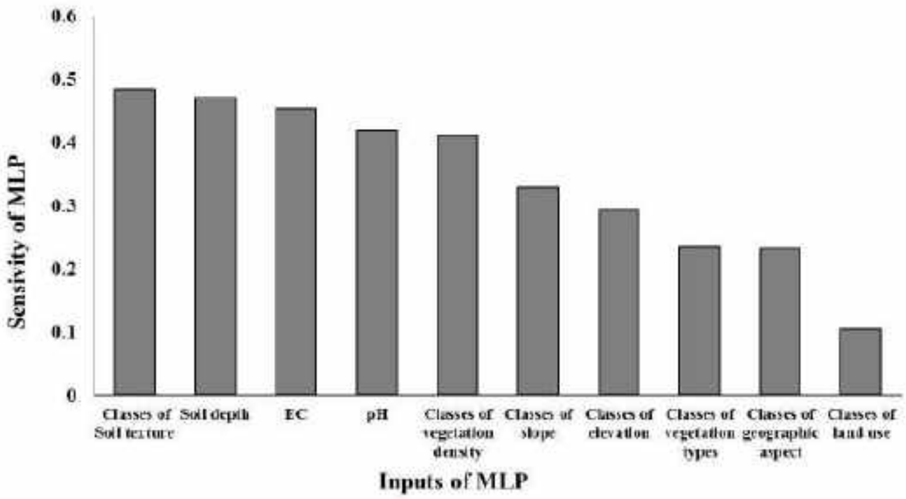

Figure 1. The impact value (0 to 1) of input variables on the FODM outputs in sensitivity analysis of model

One advantage of this research is our use of machine learning models to understand the distribution of F. ovina, whereas previous studies (Hulvey et al., 2017) assessed plant distribution in dryland ecosystems solely by overlaying ecological maps. Initially, we applied three modeling techniques—MLP, RBF, and SVM—to model the distribution of F. ovina in the Eshkevarat protected area, where ecological factors alone influence plant distribution. The results showed that, according to the RBF confusion matrix, there were more misclassifications in the data (11 samples) compared to MLP and SVM (10 samples), making MLP and SVM more accurate in classifying F. ovina distribution. In terms of species distribution prediction models, artificial neural networks (ANN) generally have higher prediction accuracy compared to other methods like regression (Piri Sahragard et al., 2015). While the differences between the studied machine learning models were minimal, these models, particularly MLP, provided satisfactory results in F. ovina distribution classification, making them highly applicable for studying plant communities and rangeland habitats. Overall, it is important to note that machine learning methods offer a more robust approach than spatial statistical methods due to their ability to analyze complex nonlinear relationships between input and output variables.

Four spinifex species of the East Kimberley

Wright, ALJ[1]

[1]Gelganyem Seed Operation, PO Box 5, Kununurra, WA 6743, Amy.Wright@gelganyem.com.au

Key words: Native seed collection, land restoration, spinifex

Abstract
The Kimberley sits in the northwestern corner of Australia, in the state of Western Australia. In the wet season, between December and March, spinifex grass species in the Kimberley flower, set seed and are ready to be harvested for use. Four spinifex species have been selected for discussion; the method of identification, collection and storage will be discussed for *Triodia bitextura, T. bynoei, T. epactia and T. racemigera.* Many spinifex species, such as *Triodia racemigera,* are poorly understood and not enough is known about their habit, habitat and distribution. This impacts revegetation projects as certain plant species protected by legislation cannot be returned through re-seeding. A greater understanding of the spinifex species of the Kimberley will be beneficial for the successful management, conservation and rehabilitation of the northern rangelands.

Introduction
This paper aims to share knowledge and provoke discussion on the collection and use of spinifex seed in the restoration industry in the East Kimberley, focusing on four species: *Triodia bitextura, Triodia bynoei, Triodia epactia* and *Triodia racemigera*. It will outline the species distribution, plant and seed characteristics and habitat. The plant identification, seed harvesting and processing techniques and storage methodology will be discussed. Finally, the future of spinifex seed collection will be discussed as it relates to land restoration in northern Australia.

Spinifex, the common name for approximately 64 species of perennial hummock grasses in the genus *Triodia*, is endemic to Australia and is characteristic of arid and semi-arid rangeland regions (Pitman and Wallis 2012; Jacobs 2004). In the Kimberley region of Western Australia, spinifex is common throughout much of the environment and is well suited to the harsh climate and frequent bushfires that affect country each year (Gamage et al. 2014; Wright and Fensham 2018). Spinifex is important to the local communities of the East Kimberley for several cultural reasons, including hunting, medicinal and food purposes. The book *Kimberley Bush Medicine* states that "decoctions of the leaves or resin (of spinifex) are used as an external medicinal wash to treat the symptoms of colds, influenza and general soreness" (King and Horsfall 2023). According to *Kimberley Bush Food*, the seed of some spinifex species from the Kimberley region were collected to be ground into flour and made into damper (King and Horsfall 2023). The Gelganyem Seed Operation (GSO) works in the East Kimberley region to collect, treat and store native plant seed, including spinifex seed, predominately for use in the rehabilitation of the Argyle Diamond Mine. The cultural significance of spinifex is emphasised in the name of the Gelganyem Seed Operation (GSO); the term Gelganyem refers to a traditional Miriwoong fishing method of crafting fishing nets from rolled spinifex (Gelganyem 2024).

Due to its high cultural and environmental value, the return of spinifex to rehabilitation areas is a critical element of land restoration. Each year the GSO collects the seed of six species of spinifex from a 200km provenance area around the Argyle Diamond Mine (the mine), to be spread on the mine site at the beginning of the wet season. The seed is separated into mixes, based on the suitability of each species for the geographical characteristics of the areas designated and prepared for rehabilitation that year.

The timing of seed collection, as well as the seed cleaning and storage methodology, is critical to maximise viability and subsequent germination of spinifex seeds. Most spinifex species are manually harvested during the wet season using hand sickles. Size, fullness and colour of spinifex seed florets are some of the factors which differ between each species and are indicators of the optimal time for seed collection and of seed viability. Samples of each seed batch collected are sent to Curtin University to test for viability and germination rate, the data of which inform future collections and seeding rates for rehabilitation projects. The spinifex seed collected by the GSO is ‘smoked’ prior to seeding, a process which aims to break the seeds' dormancy mechanisms and increase germination rates (Connolly 2014).

Certain limitations affect the return of some spinifex species to restoration areas, including species protected under the Biodiversity Conservation Act 2016. An example is *T. racemigera*, a Priority One species known to have existed on the mine site before mining began. Due to its protected status, this species will not be reintroduced to rehabilitation areas. The Department of Biodiversity, Conservation and Attractions states that a Priority One species is in urgent need of further survey (Department of Biodiversity, Conservation and Attractions 2016). Further work to understand the distribution and level of threat to priority spinifex species may result in the reclassification of some species and enable restoration practitioners to return those species to areas they inhabited prior to human disturbance.

Methods

Identification

Identification of *Triodia* species is required to collect seed and is undertaken by observing habitat, habit and seed morphology. Online resources, such as Florabase (Western Australian Herbarium, Florabase 1998), Flora of Australia Key (KeyBase 2013) and AusGrass (Lucid Central, Aus Grass 2002) are used to assist with identifying species. The GSO maintains an herbarium of East Kimberley plant specimens, identified by professional botanists with regional expertise to ensure correct plant identification prior to seed collection. Figure 1 shows the East Kimberley distribution of *T. bitextura, T. bynoei, T. epactia* and *T. racemigera*.

T. bitextura is identifiable by its habitat, which can include a variety of soil types, plant habit, and seed morphology. Identifying features include the seeds' light cream colour, long wispy awns, and the plants' curled leaf-blades. *T. bitextura* is widely distributed throughout the East Kimberley and is collected by the GSO in several locations. As this species commonly grows in open fields, there are instances where it can be mechanically harvested, using custom-built native grass harvesters.

T. bynoei is commonly found around Lake Argyle Road and the surrounding regions of Kununurra, often on rocky escarpments and creek beds. Identifying features include the inflorescence structure and awns, which appear similar to those of *T. bitextura* in their feathery appearance.

T. epactia grows in several habitats, including sandy plains and rocky hills. It is hand collected by the GSO in two locations, on rocky outcrops, and is identified by its distinct spikelet and inflorescence morphology, amongst other characteristics.

T. racemigera grows alongside other spinifex species at certain locations and the different species are distinguished in the field by the inflorescences and spikelet morphology. Due to its status as a protected species, *T. racemigera* seed is not collected and subsequently the species will not be returned to rehabilitation areas.

Seed Collection

Spinifex plants which are planned for collection are checked regularly when seed heads develop, to ensure that the seed is collected at an optimal time. This optimal time is when the seeds easily separate from the inflorescence. When ready to collect, gently threshing a seed head into a cupped palm should dislodge a portion of the seed. Issues affecting seed viability and germination rate, such as 'false seeding' events and pest damage, are taken into consideration when collecting seed. Spinifex species can be separated roughly into early, mid and late wet season collections, as the seed of each species matures at a different rate. Factors such as rainfall and temperature affect the development of seed, so seed of the same species will often mature at different rates in different locations. Careful planning goes into seed collection, to ensure that the seed is collected at the optimal time in each location.

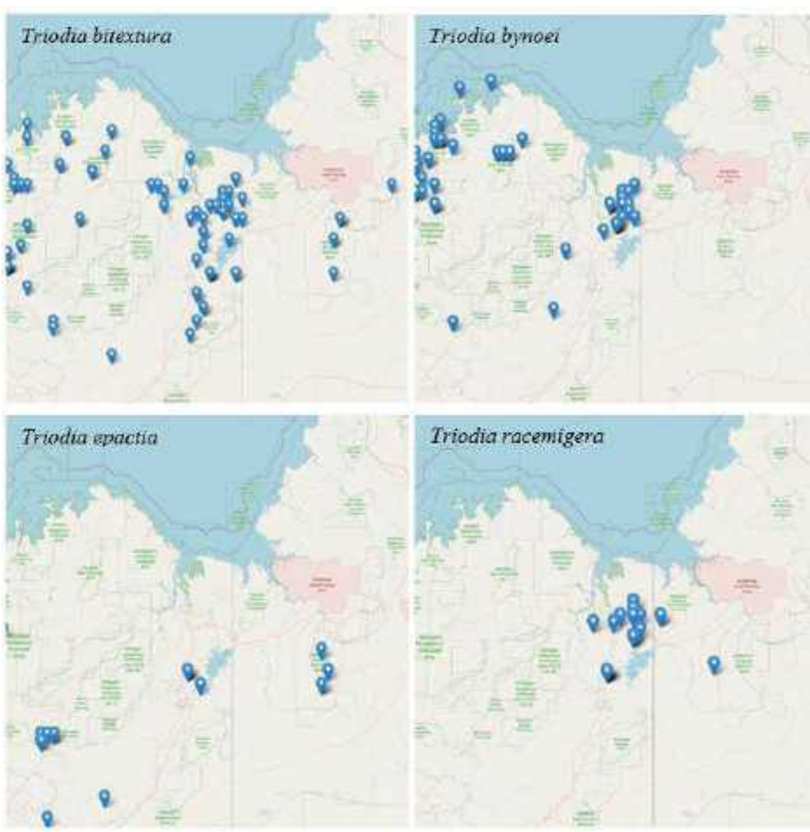

Figure 1: East Kimberley occurrence record maps for four spinifex species (Western Australian Herbarium, Florabase 1998)

Seed Processing
The seed heads collected are laid out in a well-ventilated area, on a flat surface such as a tarpaulin, in a thin layer to dry completely. Once dry, the seed heads are threshed into a container, then 'cleaned' using a sieve, to separate the seed from all other plant material. Correct cleaning allows for efficient storage and reduces the likelihood of pests. Seed which is contaminated with pests is CO_2 treated prior to storage. This is done by placing the clean seed into an airtight bag, which is filled with CO_2, and left for a minimum of 2 weeks. The seed is then re-inspected for pests prior to bagging and placing in storage.

Seed Storage
Anecdotal evidence from seed collectors in northern Australia suggests that allowing spinifex seed a 12 month 'maturing' stage in a non-climate-controlled area increases its germination rate. This is undertaken by the GSO by placing bags of cleaned spinifex seed in a raised, well-ventilated and dry area, prior to cool room storage, where it is kept between 15ºC and 16ºC. This maturing process can be complicated by certain factors such as high humidity and rainfall, especially during the wet season, which increases the risk of seeds absorbing moisture and developing mould. This is managed by ensuring the seed stays in a well-ventilated and dry environment, and by ensuring that the seed is completely dry prior to bagging.

Discussion
Spinifex seed collection is undertaken by the GSO in the East Kimberley region to return species to degraded country. Understanding plant identification, seed collection, cleaning and storage processes are critical for maximising the seeds germination potential and therefore, for the success of rehabilitation efforts involving direct seeding.

Restoring *T. bitextura, T. bynoei* and *T. epactia* to rehabilitation areas in the East Kimberley is a high priority due to their environmental and cultural significance and it is critical to return the country to a level of plant species diversity that closely resembles its pre-mining state.

To progress the native seed industry, it is essential to encourage continuous learning and knowledge sharing across all aspects of seed collection. Enormous rehabilitation efforts will likely be required in the future, and for these to succeed in the Kimberley, the sustainable and accurate collection of seed is of paramount importance. Wild populations of native plants are not capable of sustaining unethical seed harvesting methods, where the quantity of seed collected impacts the survival of plant populations. This fact highlights the need for correctly identified and collected seed, which has the highest possible germination rate, and which therefore reduces the overall volume of seed required to achieve successful rehabilitation outcomes.

There are many difficulties surrounding the collection and use of native seed, including storage, germination and legislative limitations. These challenges often lead to a reduced species diversity in rehabilitation areas compared to baseline levels. Whilst managing potentially at-risk species is crucial, further study of these species could better inform their management and potential reintroduction to former habitats. Improving our understanding of all Kimberley spinifex species will improve restoration, conservation and management outcomes.

Acknowledgements
I would like to thank Gelganyem team members, Riley Shaw, Katrina Nissen, William Rosewood and Robert Hill for the native plant knowledge they have imparted to me over the past 15 months. I'd also like to acknowledge Gelganyem and Rio Tinto for their financial support of the Gelganyem Seed Operation. Finally, I'd like to thank Matt Fletcher and Rose Ridgeway for their amazing editorial support of this paper.

Determination of browse production, browsing capacity and implications on bush encroachment and livestock feed resources in rangelands of Southern Ethiopia

Abule, G; Alemayehu, M[1]; Bedasa, E[2]

[1]Ethiopian Society of Animal production, Addis Ababa, Ethiopia; abuleebro@gmail.com

[2]International Livestock Research Institute, Addis Ababa, Ethiopia

Key words: Leaf biomass; canopy volume; browsing height, Goat, Kudu

Abstract

Rangelands covering about 61 to 67% of the total land area of Ethiopia have herbaceous and woody vegetation layers. Browse production, browsing capacity and implications on bush encroachment and livestock feed resources have not been investigated in the Borana rangelands of Ethiopia in contrast to the many studies of biomass production and grazing capacity of the herbaceous layer. Thus, the objective of this research was to determine browse production and browsing capacity and the implications on bush encroachment and livestock feed. Eighty-six rangeland sites were identified to collect data on woody vegetation species, density, plant height, heights of maximum canopy diameters, heights of first leaves or potential leaf bearing stems, and maximum and minimum canopy diameters using plots of 20 m x 20 m or 10 m x 10 m at each site. The browse production and browsing capacity were analysed using biomass estimation from canopy volume model and browsing capacity equation. The mean browse production at peak of the growing season varied from 516 to 14,914 kg ha^{-1} with a browsing capacity ranging from 8.27 ha and 0.21 ha BU^{-1} (browser unit), respectively. The mean woody vegetation density varied between 783 to 8,800 plants ha^{-1} while the mean evapotranspiration tree equivalent (ETTE), which is a measure of the status of a woody community in terms of potential moisture use, ranged from 2,421 to 58,951 with a high degree of bush encroachment with increasing ETTE. The woody plants that contributed more to browse production and bush encroachment were mainly the acacia species. While the increase in the woody vegetation results in higher browse biomass production, the high degree of bush encroachment, which lowers the production of the herbaceous layer affects the grazers. Thus, appropriate bush management needs to be implemented while taking into consideration the feed needs of the browsing and grazing animals

Introduction

Rangelands, which are usually defined as uncultivated land that will provide the necessities of life for domestic and wild grazing and browsing animals, include grasslands, savannas, shrublands, woodlands, wetlands, and deserts. They are among the most important terrestrial ecosystems in the world, occupying 54% of the world's terrestrial area (ILRI et al. 2021). Globally, rangelands contribute about 70% and over

95% of the feed needs of domestic and wild ruminants, respectively (Holechek et al. 2014). Likewise, Ethiopia has a vast area of rangelands, 61-67% of the total land area, which is primarily used for extensive livestock production and the rangelands in Ethiopia are also rich in biodiversity, mineral, water, energy resources, cultural heritages, untapped tourist attractions, and socio-anthropological values (Getachew et al. 2024). The vegetation structure of the Ethiopian rangelands includes 50% woody-browse plants; 35% open grasslands, and 15% open bush-grassland savanna. These rangelands particularly in southern Ethiopia are experiencing increasing bush (Ibrahim, 2019). Bush encroachment, which is the spread of woody vegetation into grass-dominated areas, has led to changes in the livestock species the pastoralists keep. The number of browsing animals like camels and goat is increasing while the number of grazers like cattle and sheep is decreasing (Hassan et al. 2023). Compared to the research undertaken to determine the production and grazing capacity of the herbaceous layer, the studies undertaken to determine browse production and browsing capacity is scant. Thus, the objective of this study was to determine browse production, browsing capacity and implications of bush encroachment and on livestock feed resources.

Methods

As the Borana rangeland is very vast, the woody vegetation assessment was undertaken following a road transect sampling technique. The effect of the roadside was avoided by moving more than 50 meter from the edge of the road. Data was collected from 86 rangeland sites throughout the three sub-basins of the Borana zone, and the woody vegetation data was collected in most instances at an interval of 10-20 km. The woody vegetation was assessed at the peak of the growing season using a plot of 20 m x 20 m or 10 m x 10 m at each of the sites, and all live woody plants within the 400 or 200 m^2 plots were counted by species to determine density.

All live plants rooted in the plot were counted, and multi-stemmed plants were counted as a single plant. The measurement consisted of the following: (i) maximum height, (ii) height where the maximum canopy diameter occurs, (iii) height of first leaves or potential leaf-bearing stems, (iv) maximum canopy diameter (2 dimensions), and (v) base diameter of the foliage at the height of the first leaves (2 dimensions). The canopy volume of each woody plant was calculated using the Biomass Estimates from Canopy Volume model (Smit, 1989,1996). The number of evapotranspiration tree equivalent (ETTE) ha^{-1} was subsequently calculated from the leaf volume estimates (1 ETTE mean leaf volume of a single-stemmed tree with a height of 1.5m = 500 cm^3 leaf volume, Smit, 1989). The ETTE is a measure of the status of a woody community in terms of potential moisture use. To measure the heights and diameters of the woody plants, two calibrated aluminium poles of 2 and 4m were used. Dimensions of those woody plants too tall to measure with poles were taken using a dimension meter (Smit 1996). Estimates of the browsing capacity for the most important woody plants based on leaf DM were made from the leaf DM estimate, using the formula proposed by Smit (1999).

$$\text{ha BU}^{-1} = \frac{\text{DM x p x f}}{\text{r}}$$

BU = Browser unit defined as the metabolic equivalent of an average kudu with a mass of 140 kg (Dekker 1997)
DM = Total leaf DM yield ha^{-1}
p = Phenology (0= no leaves, 1.0 = peak biomass)
f = Utilization factor
r = Daily browse DM required per BU (3.5 kg day^{-1})

The estimated leaf phenology for the various plant groups can theoretically vary from 100% (p= 1) in the case of evergreen to 0% (p=0.0) during winter for the early deciduous group. However, there are indications that browsers may utilize the tips of shoots and twigs even if no leaves are present. Accordingly, the allocated leaf phenological values ranged from 0.2 (lowest leaf yield) to 1 (maximum leaf yield).

Furthermore, each woody plant was assigned a leaf carriage score to determine leaf phenology: where, 0= no leaves, 1= 1-10% of full leaf carriage, 2= 11-40 % of the leaf carriage, 3= 41-70% of the full leaf carriage, 4 = 71-100% of full leaf carriage (Smit 1994). A utilization factor ranging from 0.1 to 0.3 depending on the palatability of each of the woody species as perceived by the pastoralists was used in this study.

Results

The woody vegetation density (plants ha^{-1}) ranged from 700 to 11,200 with an average range of 783 to 8,800 while the ETTE ha^{-1} varied from 2,271 to 73,425 with an average value ranging from 2,421 to 58,951. The results clearly indicate a high degree of bush encroachment in the sampled sites. The higher the ETTE value, the higher the degree of bush encroachment. The browse production (kg ha^{-1}) at the peak of the growing season varied from 503 to 22,766 with an average value ranging from 516 to 14,914. The browsing capacity varied between 8.47 ha BU^{-1} and 0.003 ha BU^{-1} with a mean range of 8.27 to 0.21 BU ha^{-1}. Generally, the results indicate that with an increase in the amount of browse production, the land size required to support a browser unit for a year will decline. Removing the unpalatable woody plants, the browse production and the associated browsing capacity will decline. Acacia species are the most important woody species contributing to browse production and bush encroachment, and they varied from site to site.

Discussion/ Conclusions/Implications

Bush encroachment, one of the major problems in Sub-Saharan Africa, leads to an increase in plant cover by woody species and a decrease in grass cover, grass production, and the grazing capacity of the rangelands which corresponds with the findings of previous studies in the study area (e.g., Ayana, 2007; Chaun et al. 2018). The availability of forage/browse that can support the different livestock species is the most important factor influencing habitat selection by large herbivores (McNaughton, 1987). However, there is variability from locality to locality in terms of browse production and browsing capacities (Jarman and Sinclair, 1979). Different bush control techniques are applied by government and non-government organizations in the area. The pastoral communities own both grazers and browsers, and the number of browsers has increased in recent years. While the increase in the woody vegetation results in higher browse biomass production, the high degree of bush encroachment lowers the production of the herbaceous layer, and decreases forage for grazers. The study implies that appropriate bush management needs to be implemented while taking into consideration feed needs of the browser and grazers animals.

Acknowledgement

The authors duly acknowledge the support given by the pastoralists and extension staff during the study.

Pasture land use and planning: An example from the Mogod soum of Bulgan province, Mongolia

Bazarragchaa, A[1]; Batdorj, G[2]; Radnaa, J[3]

[2] Vector Map LLC, Chingeltei District, V khoroo, VI Micro district, Bld-34, 1th floor, part 2-A, Ulaanbaatar Mongolia

Key words: Pasture use; pasture land planning; pasture carrying capacity; pure pasture; pasture irrigation; affected pasture land; soum, bag

Abstract
The pressure on soil and vegetation of pastureland has drastically increased in recent years and the tendency to desertification has increased due to overgrazing and non-rotational grazing. We aimed to evaluate the possibility of developing a pastureland use plan based on suitabiliy assessment and citizens' survey of pasture use and its future, as well as an assessment of the current condition of the pastureland, in Mogod soum[6] of Bulgan province. Our study shows that as of 2020, Mogod soum contains a total of 243,789 ha of pastureland that includes 1,073 camps. Camp registrations show that these comprise 366 camps used for winter, 402 for spring, 272 for winter-spring, 28 for summer-autumn, 2 for autumn and 3 all-season camps. Some 28,500 ha of pastureland (11.7 per cent of the toal) is affected or changed of which 68.7 % is affected moderately and 31.3% strongly; rodents are widespread on 6,499 ha, overlapping both moderately and strongly affected pastures. Over the total soum pasture area the total number of livestock exceeds the carrying capacity by 3.7 times, indicating the dire need to take immediate actions to improve pasturelands in the region. It is planned to use 19.8% of the total pasturelands in summer and autumn, 18.6% in spring, 51.3% in winter and spring and 10.3% in winter under a rotational use scheme, with livestock numbers reduced to the approproiate seasonal carrying capacity. For improvement of affected areas, we plan 3.6% for fallowing, 7.8% for rotational use only, 2.6% for rodent control, and 88.6% for seasonal rotation without exceeding the carrying capacity.

[6] A small administrative unit within a province, further divided in 'bag', the smallest administrative unit.

Introduction

Since the last century, land that was used solely for agricultural purposes is now being used for various purposes. In recent years the pressure on the soil and vegetation of agricultural land has increased dramatically due to overgrazing on pastureland, with negative effects of grazing including pastureland degradation and increased tendency for desertification.

Therefore, we need a plan that balances the two factors: (i) increase the economic benefits of using the land and livelihood improvements of the residents and (ii) encouraging appropriate use of land based on the natural resources and conditions of the area and their relationships. Right balance aimed at maintaining the sustainability will ensure creation of wealth in the area and better life quality for the residents.

Methods

The current situation of the Bulgan province of the Mogod soum's pasture land was determined, and pasture land plan was developed based on the land suitability assessment and local citizens' opinion. We used the methods outlined in the Methodical Instructions for Monitoring the State and Quality of Pastureland (MoCU, Order 34 of 2019) as well as reports related to Mogod soum's pastureland use, unified land fund, land cadastral database, surface water inventory, pasture condition and its state quality control and photo monitoring activities.

Results

The "2020 report of the United Land Fund" shows that Mogod soum has pasture land totalling more than 237,000ha, which is 97.3% of the total agricultural land. The report further indicates that 35.6% or 84,533.4 hectares of pasture lands belong to summer-autumn pastures, and 64.4% or 152,750.5 hectares of pasture lands belong to winter-spring pastures as shown in Figure1. There is a difference of 6,037.7 hectares compared to the result of the study of the unified land fund report. In this study, pasture area was calculated as pure pasture used by livestock.

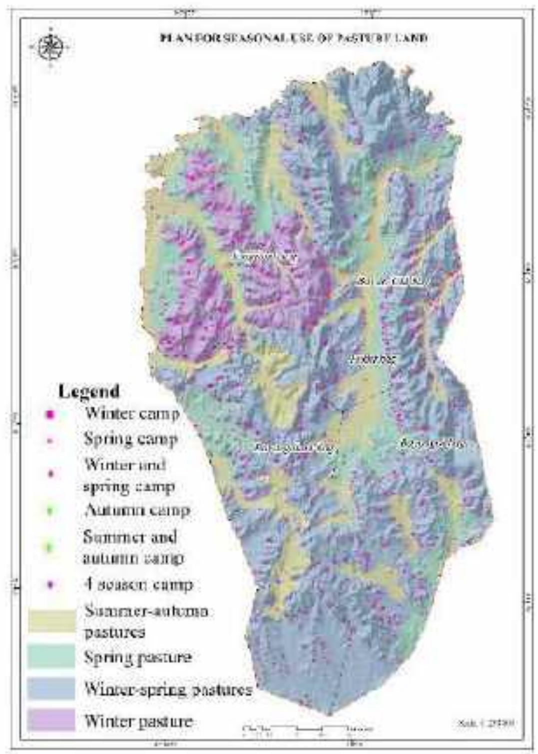

Figure 1. Plan for seasonal use of pasture land

Pasture lands affected by use: Based on the analysis and quality comparison of the Mogod soum's pasture land pasture quality inspection reports, as well as the survey of soum citizen opinions, 28,500hectares of pasture land were affected (11.4 percent of the total pasture land). The degradation of pastureland in Mogod soum is related to the rapid growth of animal husbandry and non-rotational use throughout a year. About 68.7% or 19,558.2 ha of changed or affected pasturelands are moderately grazed, and 31.3% or 8,899.0 ha are strongly grazed and rodents are spread in 6,498.5 ha of pastures, which coincides with moderately and strongly grazed pastures as shown in Figure 2.

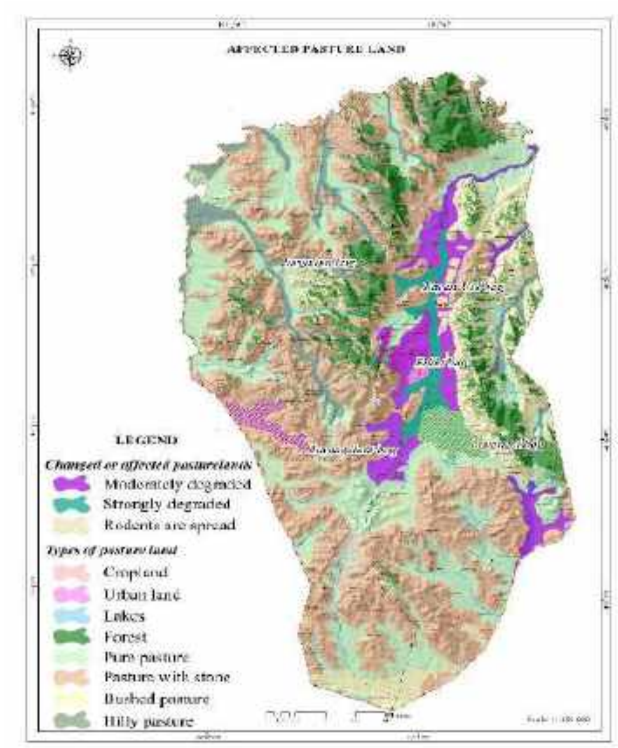

Figure 2. Affected pasture land

Carrying capacity of pasture in Mogod soum: The carrying capacity of pasture was calculated by the "Integrated method for calculating the carrying capacity of livestock pastures", which was approved in 2019, and is being implemented nationwide.

The total number of livestock is compared with the total soum pasture area, the carrying capacity of the pasture is exceeded 3.7 times the maximum limit. Taking further actions to improve pasture lands in Mogod soum is necessary.

Pasture land improvement, and conservation plan: As the number of livestock increases in Mogod soum, traditional types of grazing pastures are lost, and the number of winter and spring shelters increase dramatically.

Therefore, based on the suitability assessment of the pastures and citizens' opinion and features of the surface landscape, seasonal pastures are planned for 4-year use, that allows the use of 19.8% of total pasture lands in summer and autumn for all 4 years, 18.6% in spring only in year 1 and 3, 51.3% in winter and spring in year 2 and 4, and 10.3% in winter for year 1 and 3. In this way, it is possible to use the pasture with seasonal rotation and reduce the carrying load of the pasture to maintain the appropriate number of livestock for that season.

Plan for affected pastures: In accordance with regeneration capacity of pastures, measures like summer and autumn pastures to be alternated between months and seasons, rest periods, taking improvement measures, and fighting rodents in the pastures are planned.

Table 1. Modified Pasture

№	Measures to be taken on the pasture	Area, ha	Normal condition	Affected degree		
				Overgazed strongly	Overgrazed moderately	
1	Rest pasture	11,659.7		8,899	2,760.7	
2	Rotational timely grazing	16,797.5				16,797.5
3	Seasonal rotation according to carrying capacity	221,369.3	221,369.3			
4	Destroy pests and rodents	6,498.4		3,737.7	2,760.7	

It is planned to take measures to improve pastures covering all soum pasture land. For rest pastures 3.6%, for replacement pastures 7.8%, for rodent control 2.6%, and for seasonal rotational pastures 88.6% of total grazing measures are planned as shown in Table 1.

Measures for seasonal rotation according to carrying capacity: This measure is planned for 221,369.3 hectares of pastures in normal condition. To sustainably use and protect pasture land for a long period of time, it is necessary to herd animals suitable for the carrying capacity of the pasture, and to use it with seasonal rotation and sell the surplus animals to the market. Thus, it is advisable to introduce to the herders the right practices and methods to use pastures in groups under contract and ensure its proper practices. The following actions are required:

- Adjusting the number of animals to the carrying capacity of the pasture;
- Optimizing the herd structure;
- Separating long legged animals and male animals into remote herds;
- Improving the quality of animals and intensifying the sale of male and female animals.

Rest measures: Rest pastures are planned 2,556.5 hectares of spring pastures in the area of Suuj Ukhaa, which is a strongly overgrazed pasture, 6,342.5 ha of pastures along the Khulj, which is summer and autumn pasture, and 2,760.7 hectares of pastures in Ikh Khujirt and Suuj khundii are moderately overgrazed spring pastures.

It is necessary to calculate the load to be 10 percent lower than the possible bearing capacity, and it is necessary to make a long migration to rest when visiting the pasture. When making a long distance migration, we planned to move along the Bumbat river and Rashaantyn khoshuu.

Alternative use measures: Total of 1,679,765 hectares of moderately degraded pastures, so these pastures will be released from use during the growing season until the vegetation cover recovers. The load should be calculated at less than 10% of the potential capacity and should be used during the growing season of plants for 2 years in a row.

Measures to control pasture pests and rodents: Total of 6,498.5 hectares of pastures are planned to be controlled by voles. During the implementation of the measure, it is planned to use many methods, such as poison spraying, biological control, fumigation, and water pouring, based on the characteristics and capabilities of the ammunition.

Discussion

By implementing the above plan for 5-7 years, the following results are expected:

1. Herders in Mogod soum will adapt the rotational use of pastureland.
2. By letting 3.6% of pasture rest as per plan, and 7.8% used by rotation, and fight against rodents on 2.6% of the pasture, the floral cover of the pasture will be rehabilitated causing more types of plants to emerge, thus the pasture will be restored naturally.

3. At the end of the implementation period, a study on affected pastureland conditions and quality shall be conducted and compared to the data before the implementation of the plan.
4. AS a result of implementation of the plan, severely degraded pasture conditions should be restored bringing its level up to medium level of degradation.
5. Implementing the plan requires close cooperation of the loval government and herders to reduce the number and types of animals and keep it suitable to the carrying capacity of the pastureland.

Developing a national kangaroo strategy

Bracks, J[1]; Wilson, G[1, 2]

[1]Fenner School of Environment & Society, Australian National University; [2]Australian Wildlife Services

Key words: Macropod; kangaroo; wildlife management; policy.

Abstract

Macropods are important and treasured Australian animals. Several kangaroo species have increased due to land changes since European settlement, and overabundant populations require management to conserve biodiversity, production, and to protect human safety and property. Management is also necessary to avoid boom-bust cycles which have extremely poor animal welfare outcomes with mass starvation events and road trauma.

Current management practices, however, can also result in animal welfare, conservation and waste issues. A National Statement: Improving Kangaroo Management was developed from the symposia of two 2019 conferences, supported by a special edition of *Ecological Management & Restoration: Optimum management of overabundant macropods* (Read et al. 2021b). The key recommendation was for a National Kangaroo Taskforce to work with stakeholders to develop a National Kangaroo Strategy which will improve animal welfare, human safety, sustainability and reduce waste.

This research project, commencing March 2025, will expand on recommendations outlined in the National Statement to develop the case for a National Kangaroo Strategy. It will include consultation and engagement to integrate Indigenous, animal welfare, industry and conservation stakeholder priorities, set unified objectives, along with analysis of population dynamics, identification of appropriate foraging densities, steps to prevent extreme population cycles, non-lethal management options where appropriate, ethical standards to be maintained and included in a single National Code of Practice, opportunities to better integrate kangaroos into rangeland production systems, and recommendations to overcome barriers associated with regulatory limitations, lack of unified practices, and resource constraints.

Introduction

Conservation and management of macropods, particularly kangaroos, is complex with varying objectives across jurisdictions and diverse views amongst stakeholders.

In some developed areas kangaroo populations are under threat due to loss of habitat and safe connectivity. This can result in a range of animal welfare and human-wildlife conflict issues including morbidity, road strikes and problematic individuals in places where dispersal opportunities are limited, such as golf courses and schools.

Across much of Australia, kangaroos have benefited from land use changes in the past 200 years with additional grazing habitat and watering points, reduction in dingo numbers and reduced traditional hunting. In these areas boom-and-bust cycles can occur, with periods of almost exponential growth in favourable conditions followed by mass starvation events in times of drought (see Figure 1). An overabundance of kangaroos can result in overgrazing, damage to vegetation and pastures, competition with other fauna and livestock, and an increased risk to road safety, food security and property damage.

Population management is therefore required to avoid animal welfare impacts in starvation events, conserve biodiversity, protect agricultural land and human safety.

A Joint National Statement was prepared by scientists experienced in applied ecology, conservation biology, primary production, veterinary science and environmental policy advocating for a coordinated national approach to management (Read et al. 2021a). Motivation for this was a shared belief that current kangaroo management is leading to detrimental consequences for kangaroo welfare, landscape sustainability, biodiversity conservation, resilient agricultural production and cultural values. They asserted that there is a need for a credible, collaborative approach to represent diverse stakeholders and challenge the viewpoint that commercial harvesting of overabundant macropods is contrary to welfare, conservation and cultural values, while acknowledging that treating kangaroos as pests to meet management objectives limits the values of managing kangaroos as a resource. The key recommendation was for a National Kangaroo Taskforce to work with ecologists and stakeholders to develop a National Kangaroo Strategy to support government and other stakeholders in decision-making.

A suite of other issues and topics are canvased in the 2021 paper including the implication for managers that overabundant kangaroo populations, along with other herbivores, must be managed to conserve minimum forage resources, such as grass cover, and to enhance conservation, production and for animal welfare outcomes. Where dingoes are not compatible with other land uses, regulated and accredited harvesting of overabundant macropods (as a resource) is preferable to culling (and wasting) or death by starvation. Kangaroo populations are best managed by informed, proactive and adaptive management at property, regional and national scales, so that waste is minimised and resources are used sustainably.

This research project aims to develop the case and considerations for a National Kangaroo Strategy.

Methods

This research program, supporting the development of a National Kangaroo Strategy, commenced in March 2025 and seeks feedback from attendees at IRC XII as priorities, scope and questions are refined. The options are numerous, and not all can be included. Potential topics include:

- Engaging with Indigenous, animal welfare, industry and conservation stakeholders to integrate the priorities of all stakeholders, establish unified objectives and practices, and build on existing successful initiatives.
- Analysing population dynamics including harvest quotas and factors contributing to population fluctuations over time (Figure 1), investigating foraging densities and thresholds to maintain healthy populations and landscapes.
- Identifying steps to prevent extreme population cycles including objectives, roles and responsibilities of stakeholders.

- Identifying when non-lethal management options are practical and appropriate.
- Detailing ethical and humane standards during harvesting/culling for a single National Code of Practice.
- Identifying opportunities to better integrate kangaroos into rangeland production systems in a complementary way with domestic stock as a low carbon, healthy protein with low impact on soils and vegetation. This climate-friendly income stream could mitigate income fluctuations by participating in programs for emissions reduction, soil carbon sequestration, and biodiversity stewardship. Sustainable harvesting can also limit future demand for intensive, factory-style farming practices which often have poor animal welfare outcomes. These opportunities could be promoted through a public awareness campaign.
- Identifying barriers to be addressed including regulatory limitations, lack of unified practices, and resource constraints, with recommendations for overcoming them.

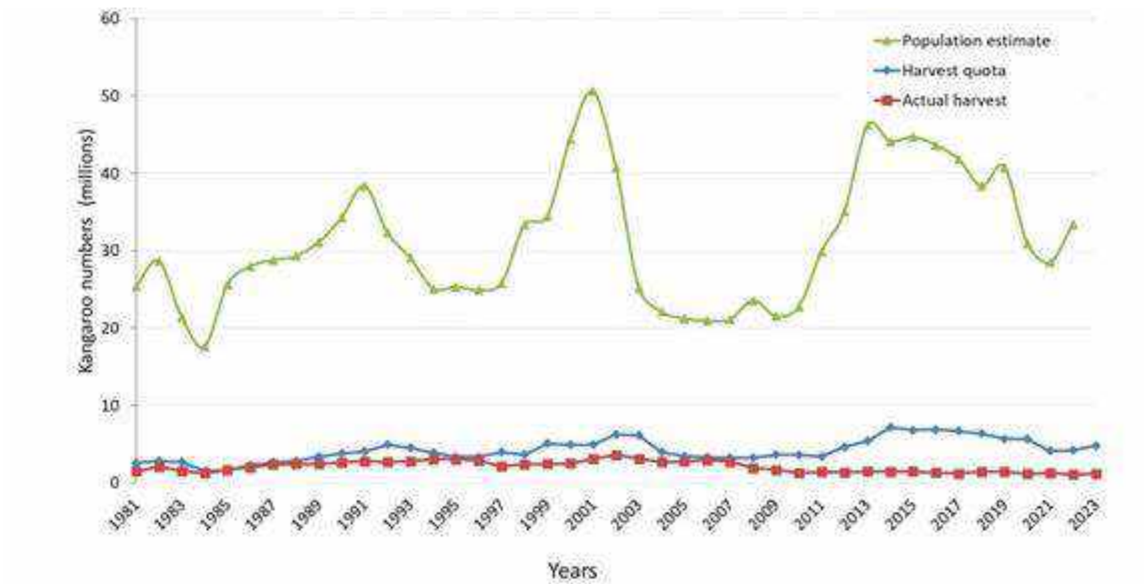

Figure 1 National Kangaroo Population and Harvest Statistics (Edwards & Wilson 2023).

Discussion

This research will contribute to a National Kangaroo Strategy integrating all stakeholder needs and objectives to enhance consistency, efficiency, ethical standards and sustainability in kangaroo management across Australia. Contributions by a broad range of government and non-government stakeholders will be critical to the success of the project. A national, collaborative approach, featuring evidenced-based decision making and education of the public is needed to build a broad social mandate for improved management of kangaroos in Australia.

Local flora for ecological restoration: the FLoRE project

Carita, T[1]; Simões, N[1]; Carneiro, JP [1]; Reis, P [2]

[1] National Institute of Agricultural and Veterinary Reseache - Elvas, Ap 6, 7351-901 Elvas, Portugal; [2] National Institute of Agricultural and Veterinary Reseache - Oeiras, Av. da República, Quinta do Marquês, 2780-157 Oeiras, Portugal

Key words: native seeds; restoring nature; Mediterranean region

Abstract

The territories of south-western Europe are still recognised as a biodiversity hotspot. However, it is very much subject to the dangerous consequences of the intensification of human activities, climate change, wild fires and the abandonment of the agricultural and forestry activities in marginal land areas, with the consequent degradation of the land, vegetation and the ecosystems. There, the Interreg SUDOE FLoRE project, started in January 2024, is being implemented to test, analyse and scale-up the implementation of different ecological restoration solutions based on native and locally sourced herbaceous plant seeds. We develop: a) practical tools adapted to the current needs of the target groups; b) create a network of pilot projects in sites with diverse environments and land degradation (due to wildfires, overgrazing, mining, invasive vegetation); and c) lead a multi-stakeholder participatory process to design and test new models of economic cooperation, aimed at the self-production of seeds by users or the supply of products and services to sector players. The project will engage public authorities, non-profit private organization and private companies with the ambition of introduce this type of species into their restoration processes and organise dissemination days for the general public.

Three working groups (WG) were created: WG1 - Operationalise and disseminate existing knowledge on ecological restoration using local seeds, to facilitate the information and learning process by stakeholders, and encourage their commitment and the implementation of good practices.; WG2-Test, monitor and evaluate different ecological restoration solutions from local seeds; and WG3-Develop a strategy to involve all the stakeholders in large-scale actions to support the sustainability of the ecological restoration solutions tested, and formulate recommendations for professionals and decision-makers on the different means of action available to them.

Introduction

Our lives depend on nature, but we are degrading it, and it is imperative that we reverse this trend. A number of factors are putting pressure on ecosystems and species populations, including: pollution, climate change, habitat loss and invasive species (80% of habitats are in poor condition, 10% of bee and butterfly species are in risk of extinction and 70% of soils are in an unhealthy state) (European Council 2024). Soil degradation represents a major threat to ecosystem services and biodiversity conservation. In addition, degradation processes are continuing and worsening (EC 2023).

The semi-enclosed nature of the Mediterranean Sea and the complex topography result in unique physiographic and ecological features. The latest IPCC results show an increasingly arid future for the Mediterranean, with less rainfall and more frequent and longer heat waves (Ali et al. 2022). Some of the consequences of climate change are: reduction of river low flows and annual runoff by 5-70%; yields of rainfed crops may decrease by 64% in some places; desertification will affect more areas, especially in the south and south-east.

The EU Environmental Council adopted the Nature Restoration Law (NRL). They intend to intervene in at least 20 per cent of the EU's land and sea areas by 2030. Restoration plans are intended to cover the period up to 2050. One of the measures envisaged is to restore of at least 30% of the habitats that are in poor condition.

In this context, the FLoRE project was created as part of the INTERREG-SUDOE programme, which aims to consolidate South-West Europe as an area of territorial cooperation in the of innovation, competitiveness and environmental protection. The major challenge of the FLoRE project is to ensure the preservation of the quality of life and the attractiveness of rural areas by demonstrating the economic and organisational viability of scale-change in the implementation of various ecological restoration techniques aimed at valuing native and local wild herbaceous species.

Project Workplan

The Interreg SUDOE FLoRE project, started in January 2024 and will finish in December 2026. The consortium is made up of eight partners (three in France: Conservatoire d'Espaces Naturels d'Occitanie (project leader), FAB'LIM - Le Labo des Territoires Alimentaires Méditerranéens, Conservatoire d'espaces naturels d'Auvergne; three in Spain: Comunidad Autónoma de la Región de Murcia, Asociación Forestal de Soria, Cámara Oficial de Comercio, Industria y Servicios de Badajoz and two in Portugal: National Institute of Agricultural and Veterinary Research, MORE CoLAB on mountain regions. Three groups of tasks were drawn up into three working groups (WG 1, WG 2 and WG 3); all the beneficiaries will take part in each WG, but one beneficiary is responsible for coordinating each WG.

WG 1 - Operationalisation and dissemination of existing knowledge on ecological restoration

Here, the focus is disseminating and applying existing knowledge on ecological restoration techniques using native and locally sourced wild herbaceous species, to facilitate their use by stakeholders (professionals in the sector, landowners, managers, national bodies), in order to encourage their involvement in changing practices and identify the remaining gaps in technical and socio-economic knowledge. To do this, we will update the current state of knowledge on initiatives, scientific publications and public policies aimed at supporting ecological restoration. Then, to facilitate access to information, the most frequently asked questions by stakeholders will be identified and answered, along with other types of dissemination actions. The deficits and gaps in knowledge identified will be revealed and addressed at a later stage of the project. (INIAV is the responsible beneficiary).

WG 2 - Experimentation and evaluation of different solutions for seed production and ecological restoration

A network of demonstration sites is being set up in different environments to publicise different solutions (including different restoration and seed multiplication techniques). Most of our pilot sites are already in place and are located in:

- Occitanie: representing altered agricultural systems and highly anthropized environments and Auvergne: representative of wetlands, meadows and pastures in Auvergne (France)
- Soria: captures truffle farms, recently cleared environments and forest environments and Murcia: degraded natural spaces and eroded areas (Spain)
- Serra da Estrela: I an example of mountain burnt areas in the centre of Portugal and the left bank of the Guadiana river- south-east Portugal represent grasslands (Portugal). This last pilot site is the responsibility of INIAV.

Based on the mapping of grasslands of ecological interest carried out, different techniques for obtaining and recovering seeds will be developed (brushing, mowing, hay transfer). Transnational co-operation will enable us to provide a range of restoration solutions adapted to the regulatory contexts of each country and the realities of each territory, given the diversity of environments representative of the SUDOE area[7]. The experiments carried out and their monitoring (based on indicators developed by the consortium) will make it possible to consolidate protocols and identify the relevant adaptations to be made depending on the contexts and restoration objectives. We will also measure the real benefit or added value, as well as the possible impacts of the restoration operations carried out. (*Asociación Forestal de Soria* is the responsible beneficiary)

WG 3 - Development of a strategy to involve stakeholders in a large-scale action

A medium/long-term strategy (from three to eight years) will be developed jointly based on the sharing of results from the multi-stakeholder group animation work at a transnational level, i.e., from the workshops involving different types of stakeholders (from scientific researchers and public decision-makers to seed vendors and farmers) from various countries, specifically from the SUDOE European region (southwest of France, Spain, and Portugal). Its main objective will be to guide professionals (landscapers, consultants, public and private buyers, scientists, local development associations, site managers) and decision makers (elected representatives, company managers, etc.) towards the means of action available to them supporting long-term viability of the technical solutions tested during the project (collection, planting and monitoring of native and locally sourced wild herbaceous species, etc.). This strategy will define realistic objectives (taking into account the constraints of these stakeholders) but ambitious enough to support the development of the proposed solutions. This may be broken down into several action plans, tailored to each type of public concerned and their respective areas of competence. We will identify a number of economic and public policy levers that can support this strategy. To facilitate its implementation, the strategy will be accompanied by a number of resources available in open access e.g. training modules for field workers and decision makers, awareness-raising content, a letter of engagement, feedback from multi-stakeholder groups, etc. (*FAB'LIM* is the responsible beneficiary).

Goals to be achieved

By carrying out the different tasks (WG1-3), we aim to achieve the following goals:

-1.Obtain commitment from: (i) the managers of the pilot ecological restoration fields to guarantee the sustainability of the solutions tested, (ii) the professionals to collectively implement the economic and organisational models co-constructed in accordance with the initial ethics, (iii) the beneficiaries of the multiplied seeds for use in projects of collective interest and (iv) the communities and companies to introduce this type of seed in their ecological restoration processes in favour of biodiversity.

---

[7] Interreg Sudoe is a European Union funding programme to support regional development and cohesion in the regions of south-west Europe.

-2.Training organisations that adopt the tested solutions to manage them independently over time.

Acknowledgements
This work is being carried out with funding from the Interreg Sudoe FLoRE- Local flora for ecological restoration project.

Characterization of pastures legumes with potential for biomass production and for mediterranean pastures restoration

Carita, T[1]; Pereira, G[1,2]

[1]National Institute of Agricultural and Veterinary Research-Elvas, Ap 6, 7351-901 Elvas, Portugal

[2]GeoBiotec, NOVA School of Science and Technology, Caparica, Portugal

Key words: Pastures; Pré-breeding; Genetic resources

Abstract

True extensive livestock systems - those based on the use of permanent pastures and grazable agricultural co-products, with low use of external production factors, and which promote ecosystem services, combat desertification and create economic conditions for the population to settle in the territory - are probably one of the most vital ecosystems in the world, particularly in the Mediterranean. These agrarian systems provide us high quality products, fodder, ecosystem services and harbour a great plant and animal biodiversity, both above and below the soil surface.

In some regions of the world, the area of permanent pasture has decreased and changes in land use continue to threaten its extent. In Portugal, many of these pastures (which occupy > 50% of the utilised agricultural area) need to be restored, preferably using nature itself, and thus increase agricultural productivity and soil health, as well as improving land management.

INIAV-Elvas (southern Portugal) has morphologically and phenologically characterised a collection of 66 ecotypes belonging to the genera *Ornithopus* and *Trifolium* genera. The aim is to evaluate ecotypes of native legume species of mainland Portugal which have the potential to successfully establish and develop under very limiting agro-ecological conditions. Descriptors developed by INIAV-Elvas, based on those developed by "Bioversity International" and UPOV-International Union for the Protection of New Varieties of Plants for species in the same group, were used to characterise this plant material. High winter growth and early flowering are important descriptors for the improvement of the Mediterranean agro-sylvo-pastoral sector. So, the ecotypes considered to have the best potential are: Ornitopus compressus 15692 e 15682; Ornithopus pinnatus 13563; *Trifolium cherleri* 15710; *Trifolium glomeratum* 15648 and *Trifolium lappaceum* 14174.

Introduction

Permanent pastures are a key feature of the European rural landscape, representing not only a significant agricultural resource but also supporting multiple non-provisioning ecosystem service. However, this vital farming system is at risk of loss or degradation due to changes in agricultural land use and management practices (Elliot et al., 2024). Schils et al. (2022) emphasize that, despite apparent shifts in the dietary preferences of the European population, prioritizing the protection of permanent grasslands in Europe is essential to prevent further losses in area and to safeguard the provision of ecosystem services. In Portugal, 52% of agricultural land consisted of permanent pastures. Meadows and permanent pastures covered approximately 2 million hectares, 68% of which consisted of unimproved pastures, lacking interventions such as sowing, fertilizing, watering, or drainage (INE, 2019). Many of these pastures are either natural (characterized by low and irregular yields) or degraded. It is necessary to intervene in permanent pastures to enhance their productivity and quality, enabling increased stocking densities and reducing the need for supplemental feed.

When faced with the challenge of restoring poorly productive or degraded permanent pastures, sustainability must be a central consideration. One effective strategy to enhance pasture functionality involves improving its floristic composition. This can be achieved through appropriate grazing management and/or the introduction of seeds from species well adapted to the specific environmental conditions. The introduction of new plant genetics, particularly legumes offers numerous benefits, including increased biodiversity, improved grass yield and quality, reduced dependence on fertilisers, lower greenhouse gas emissions, and enhanced landscape aesthetics. The addition of legumes, in particular, plays a crucial role in improving soil fertility by enriching it with mineral elements (especially nitrogen) and organic matter, creating conditions that support the development of other high-quality species.

For many years, INIAV-Elvas has been developing programs focused on the conservation and improvement of various legume species suitable for grasslands. These programs aim to contribute to the economic and environmental sustainability of Mediterranean farming systems.

In this study, we aimed to evaluate ecotypes of native legume species from mainland Portugal that have the potential to successfully establish and develop under highly limiting agro-ecological conditions.

Methods

The Portuguese ecotypes used were collected in the wild, in uncultivated fields; the prospecting and germplasm collection missions followed the rules laid down in the 'Seed Collecting Manual for wild species' published by the 'European Native Seed Conservation Network' (ENSCONET 2009).

Caraterizaram-se um total de 66 ecótipos, pertencente aos géneros *Ornithopus* e *Trifolium*. As espécies consideradas foram: *Ornithopus compressus*-Ocom ((90% Hard seeds; Deep root system; Well adapted to light-textured, acidic soils), *Ornithopus pinnatus* (Opin), *Trifolium cherleri* (Tche), *Trifolium glomeratum* (Tglo) e *Trifolium lappaceum* (Tlap).

Each ecotype was characterised for 2 consecutive years. To characterise this plant material (10 plants/access/year), several descriptors developed by INIAV-Elvas were used, based on those of Bioversity International and UPOV (International Union for the Protection of New Varieties of Plants) for species in the same group: Winter vigour; Spring vigour; No. of days to flowering (Flo-I); No. of days to end of flowering (Flo-F); Duration of flowering (Durflor); Plant size; No. of internodes; Longest stem including flower head; Leaf colour; Length; No. of internodes; Stem pubescence; Length of longest stem including flower head; Stem thickness; Stem anthocyanin colouration; Leaf colour; Length (normally developed centre leaflet immediately below terminal flower; Frequency of plants with coloured leaflet markings; Centre leaflet length; Centre leaflet width; Flower colour; Seed colour; Seed weight 1000 seeds and seed yield.

The data were analysed by numerical taxonomy techniques, using the NTSYS-pc (Numerical Taxonomy and Multivariate System) programme.

Results

A wide range of variation was registered among the ecotypes of the five annual herbaceous legume species, particularly in flowering period and cycle duration.

O. compressus is the earliest species, requiring approximately 152 days from transplanting to the start of flowering, whereas *T. lappaceum* is the latest, taking an average of 170 days. Regarding flowering duration, *O. pinnatus* exhibited the longest average flowering period (42 days) but showed the weakest vegetative vigour. The species characterised exhibited significant differences in their cycle duration. For example, the average cycle duration of *O. pinnatus* is 50 days, while that of *T. lappaceum* is only 19 days (Table 1). Additionally, there is substantial intraspecific variability.

Discussion and Implications

The species evaluated in this study exhibit the characteristics of pioneer species, meaning they are plants capable of growing in inhospitable environments with unfavorable conditions, being the first to colonize areas where many other plants cannot survive. When analysing the results, it is important to consider that the long-term goal is to identify and select species and ecotypes with the ability to adapt to challenging soil and climatic conditions (e.g., light-textured, shallow soils with acidic pH, and a Mediterranean climate characterized by increasingly shorter and warmer springs).

The ecotypes identified as having the greatest genetic potential were: Ocom_15692, Ocom_15682, Opin_13563, Tche_15710, Tglo_15648, and Tlap_14174. These ecotypes demonstrated the most stable performance over two years of characterization and exhibited reproductive and vegetative cycles suitable for Mediterranean dryland farming, including high winter vegetative vigor and an early growth cycle.

INIAV should continue to develop programs for the conservation and characterization of plant genetic resources in consistent way, given the extensive collection of forage accessions that have been preserved and which hold significant potential. This approach will enable the identification of new solutions capable of addressing the needs of diverse national agricultural systems in the face of constant environmental changes.

Key words: *Nassella tenuissima*; Mexican feathergrass; shortgrass prairie; invasion mechanisms

Abstract

Mexican feathergrass (*Nassella tenuissima* (Trin.) Barkworth) is a C_3 bunchgrass native to the Trans-Pecos region of West Texas and south-central New Mexico in the United States but has been planted as an ornamental in many other regions. *N. tenuissima* can escape from landscaping areas and become a weedy species on disturbed rangelands. To understand any physiological advantages this species may over native species, we surveyed three *N. tenuissima* colonies throughout a remnant 54-ha native shortgrass prairie within the limits of Lubbock, Texas, USA in the summer of 2022. We selected *N. tenuissima* from three locations within the colonies: inner, edge, and outer for physiological (i.e., leaf-level gas exchange) and morphological (i.e., basal area) measurements. We also monitored two 'companion' native grasses adjacent to *N. tenuissima* in the outer location: blue grama (*Bouteloua gracilis* (Kunth) Lag. ex Griffiths) and purple threeawn (*Aristida purpurea* Nutt.). *N. tenuissima* photosynthesis rates were greater than those of *A. purpurea* and *B. gracilis*, while stomatal conductance and transpiration rates were similar among species. No significant differences were seen in photosynthesis, stomatal conductance, or transpiration rates across the three colony locations for *N. tenuissima*. *N. tenuissima* cover and biomass was greatest in inner locations and decreased with distance away from the center of colonies. In contrast, warm-season grass and forb cover increased with distance away from the center of colonies. N. *tenuissima* appears to exhibit physiological and morphological advantages over native warm-season grasses, which likely contribute to its expansion in the local region, particularly at degraded and overgrazed sites.

Introduction

Mexican feathergrass (*Nassella tenuissima* (Trin.) Barkworth) is a perennial C_3 bunchgrass native to the Trans-Pecos region of West Texas and south-central New Mexico in the United States (Shaw et al. 2011), Mexico, Argentina, and Chile (Jacobs et al. 1998), but has been planted as an ornamental in many regions. *N. tenuissima* is escaping landscaping plantings and becoming a weedy species in shortgrass and midgrass prairies in western Texas and the Texas panhandle (Russell and Rector 2017). In South America where the species is native, overgrazing of desirable forage species and fire suppression are attributed to its spread (Distel and Boo 1996). Additionally, leaf litter of this species has high amounts of lignin, a high C:N ratio, and is slow to decompose (Moretto et al. 2001), further exacerbating competition with native grass and forb species. *N. tenuissima* has been reported since 1998 to be a potential threat to biodiversity in Australia (Jacobs et al. 1998).

N. tenuissima has long, narrow, tightly-rolled leaves (Jacobs et al. 1998). The foliage is considered to be unpalatable due to low N and P content, high lignin (Moretto and Distel 2002), and high amounts of silica (Russell and Rector 2017). At the field site used in this study, wildlife seem to prefer other grass species to *N. tenuissima*. Horticultural guides advertise the species as "deer resistant" (Chapman and Salwitz 2017). Additionally, a lack of grazing or prescribed burning contributes to large amounts of *N. tenuissima* litter on the soil surface. *N. tenuissima* is drought tolerant and adapted to hot and dry regions (Hillock et al. 2022), with a shallow root system well adapted to capturing soil moisture close to the soil surface following intermittent rainfall events (Humphries and Florentine 2021). The species germinates readily in vegetation gaps (Moretto and Distel 1998) and prefers full sun (Hillock et al. 2022). It also seeds freely, and a single plant can produce up to 100,000 seeds annually (Humphries and Florentine 2021).

Little is known about *Nassella tenuissima*'s physiology. In West Central Texas, the majority of its growth occurs in the late spring through early summer, with seed set continuing into the fall (Russell and Rector 2017). In the Texas High Plains, *N. tenuissima* retains a considerable amount of green tissue into late November. Though it is a C_3 species, its life cycle suggests that it behaves similarly to warm-season C_4 grasses in many ways (Russell and Rector 2017).

Our study was conducted due to a lack of information on *N. tenuissima*'s invasion mechanisms and effects on native warm-season species in the shortgrass prairie of the Texas High Plains. Objectives were to assess: 1) the relationship between *N. tenuissima* cover and biomass and those of native warm-season grasses and forbs, 2) *N. tenuissima* physiognomy relative to location within a colony, 3) leaf-level physiological characteristics of *N. tenuissima* relative to common native warm season-grasses.

Methods

This study took place at a ~53-ha remnant shortgrass prairie located within the city limits of Lubbock (33.60327 N, -101.9003 W) and used for research and teaching by Texas Tech University. Historically, the dominant vegetation was short grass prairie. Today the site has some shortgrass prairie species such as blue grama (*Bouteloua gracilis* (Kunth) Lag. ex Griffiths), and buffalograss (*Bouteloua dactyloides* (Nutt.) Columbus) but with high densities of encroaching honey mesquite (*Prosopis glandulosa* Torr.) and annual Chenopodiaceae forbs (Jackson et al. 2020). The region is semi-arid, with hot summers and mild winters. Local temperatures range from –2.8°C in January to 34.4°C in July, with an average annual precipitation of 466 mm. The site has not been grazed by livestock in ~20 years, though overgrazing occurs via high populations of cottontail rabbits (*Sylvilagus* spp.) and black-tailed jackrabbits (*Lepus californicus*). *N. tenuissima* has been planted in many locations in Lubbock and is thought to have established on the site following escape from planted locations nearby.

We selected three *N. tenuissima* colonies at the site. Colonies ranged in size from ~10 to 20 m in diameter. From the center of each colony, three transects were established in random directions to well beyond the colony margin. Total transect lengths ranged from 20 m at the smallest colony to 40 m at the largest. In November 2024, beginning at the 5 m mark, canopy cover was measured in a 0.1-m^2 frame every 5 m along each transect. Cover was classified into bare ground, litter, *N. tenuissima*, warm-season grasses, and forbs. On the opposite side of the transect from where we collected cover, we measured the height and diameter of the nearest *N. tenuissima* plant. Heights were measured to the nearest cm and diameters to the nearest 0.5 cm. If no *N. tenuissima* plants were within 2.5 m, no *N. tenuissima* morphology measurements were taken there. For analysis, data were pooled from the four to eight locations along a transect into three colony zones: 1) *inner colony* consisting of distances nearest the colony center to 1x the distance of the colony radius, 2) *mid colony* which contained locations > 1x the colony radius and < 3x the colony radius, and 3) *outer colony* which contained locations > 3x the colony radius. The number of locations varied in each zone across colonies, but this method provided a standardization for colonies of different sizes.

In summer 2022, we selected three *N. tenuissima* plants from the three colony locations for physiological (i.e., leaf-level gas exchange) measurements. We also monitored three adjacent plants of blue grama and purple threeawn (*Aristida purpurea* Nutt.) in the outer location of each colony. Leaf-level gas exchange [photosynthesis (*A*; µmol CO_2 m^{-2} s^{-1}), stomatal conductance (g_s; mol H_2O m^{-2} s^{-1}), and transpiration (*E*; mol H_2O m^{-2} s^{-1})] was assessed using an open-flow infrared gas analyzer system (LI-6800, Li-Cor, Lincoln, NE, USA). Measurements were taken in May 2022 at midday. Due to the number of colonies, gas exchange measurements were conducted over three consecutive days with similar cloud-free weather. During gas exchange measurements, three fully expanded leaves of each plant were placed parallel in the chamber. Other studies assessing gas exchange of narrow-leaved grass species have used sections from multiple leaves simultaneously as well (Ramirez et al. 2008, Perez-Anta et al. 2024). Following the gas exchange measurement, we measured and recorded the width of each leaf section in the chamber. Widths were multiplied by the length of the chamber cuvette to calculate leaf areas which were then used to normalize gas exchange data. Due to the rolled nature of *N. tenuissima*'s leaves, we were required to use the projected (rolled) leaf area to determine leaf-area corrected gas exchange rates (Haase et al. 1999, Perez-Anta et al. 2024).

Linear mixed models (SAS 9.4) were used to test the effects of colony location on *N. tenuissima* height, basal area, and leaf-level physiological parameters. The interaction of colony location and cover type was tested on canopy cover in colonies. In the outer colony location, the effect of species was tested on leaf-level physiological parameters. Differences were considered significant at $P \leq 0.05$ and tendencies assumed at $0.10 \geq P > 0.05$. Means separation of significant effects and interactions were performed using Tukey's HSD.

Results

N. tenuissima photosynthesis rates, 11.8 µmol CO_2 m^{-2} s^{-1}, were greater than those of *A. purpurea,* 4.1 µmol CO_2 m^{-2} s^{-1}, and tended to be greater than those of *B. gracilis*, 5.8 µmol CO_2 m^{-2} s^{-1} ($P = 0.06$). Stomatal conductance and transpiration rates were similar among species. No significant differences were seen in photosynthesis, stomatal conductance or transpiration rates across the three colony locations for *N. tenuissima*.

N. tenuissima basal area tended to be related to colony position, with plants in inner colony positions tending to have greater basal areas ($P = 0.052$). *N. tenuissima* height was greatest at inner colony locations. Colony position interacted with cover type to influence ground cover. *N. tenuissima* cover was greater in inner colony locations (40.4%) than mid (10.8%) and outer (3.8%) locations. In contrast, cover by native warm-season grasses and litter was lowest in inner colony locations. Forb cover and amounts of bare ground were not affected by colony position and were low in all colony locations. In every colony location, litter comprised a large portion of the cover, 55.6 – 75.2%. Within inner colony locations, *N. tenuissima* comprised a larger portion of cover (40.4%) than warm-season grasses (1.5%) and forbs (5.2%). In mid colony positions, *N. tenuissima*, warm-season grasses, and forbs had similar cover. In outer colony positions, however, warm-season grasses (17.6%) had greater cover than *N. tenuissima* (3.8%).

Discussion, Conclusions, and Implications

Though *N. tenuissima* is a C_3 species, it maintains actively growing tissue throughout the summer and fall, directly competing with warm-season native shortgrass prairie species during their active-growth period. Gas exchange measurements suggested that, at least early in the summer, *N. tenuissima* had greater intrinsic water use efficiency than warm-season native species at the site. *N. tenuissima's* drought tolerance and low water consumption has been reported in other studies (Asin et al. 2021), though we did not observe lower transpiration rates or stomatal conductance in *N. tenuissima* than *B. gracilis* or *A. purpurea*. The summer of 2022 was exceptionally dry, which limited our ability to measure gas exchange accurately following May 2022 measurements. Thus, further tests are needed to assess *N. tenuissima*'s gas exchange rates relative to the C_4 grasses under a wider range of soil moisture conditions.

We believe that the combination of the large quantities of durable litter produced by *N. tenuissima* in addition to the live cover from this species results in the suppression of the local warm-season grasses. Following honey mesquite invasion across much of the site, warm-season species have been restricted to areas of low mesquite cover. Those areas are now experiencing encroachment from *N. tenuissima* despite *N. tenuissima* being reported to be a poor competitor against native species in well-managed locations (Amme 2003, Mapaura et al. 2020). Stress from overgrazing by wildlife coupled with the unpalatable nature of *N. tenuissima* and build-up of litter appears to have resulted in warm-season species being displaced in the areas of low mesquite density. Further studies are needed to assess the effects of woody canopy cover on *N. tenuissima* growth and the degree to which it can tolerate high cover of summer-active shortgrass prairie grasses and forbs.

Rangeland Management Practices Used to Increase Usable Habitat Space: A Case Study with Greater Sage-Grouse

Dahlgren, D. K.[1]; Thacker, E. T. [1], Carter, R. [1]

Key words: Sagebrush, Forb and Grass Response, Shrub Canopy, Spike, Dixie Harrow, Lawson Aerator

Abstract
Greater sage-grouse (*Centrocercus urophasianus*) need forbs, and the associated insects, for chick diet and growth in sagebrush habitat. In some cases, sagebrush cover may limit the abundance of forbs in the understory. Sage-grouse require sagebrush and large-scale shrub treatments are detrimental to sage-grouse populations. We implemented small (40.5 ha) shrub-management treatments of Dixie Harrow, Lawson Aerator, and Tebuthiuron (Spike) in a replicated plot design with control and monitored the response of herbaceous cover and grouse. We found that spike treatments demonstrated the strongest forb response, especially forbs that are known to be consumed by sage-grouse, and greater grouse use. This long-term response of forbs and grouse shows that small-scale shrub management may provide rangeland managers with methods to improving sage-grouse brooding habitat when needed.

Introduction
Greater sage-grouse (*Centrocercus urophasianus*; hereinafter sage-grouse) depend upon sagebrush-dominated rangelands throughout western North America (Connelly et al. 2000). Sage-grouse populations have been experiencing declines due to loss or degradation of sagebrush (*Artemesia* spp.) communities (Braun 1998, Schroeder et al. 2004). Additionally, in some big sagebrush (*A. tridentata*) communities shrub canopy cover has increased and can limit herbaceous understory cover and diversity, which may negatively impact sage-grouse brooding habitat. For brood-rearing habitat, sage-grouse prefer more open shrub canopy cover (~15% cover) with plentiful grasses and forbs, which typically provide arthropods - an important component of chicks' diet - and an indication of high-quality brood-rearing habitat (Connelly et al. 2000).

The scale of habitat management is critical to predicting whether an action would be positive, negative or neutral. Sage-grouse are a landscape species, dependent on large expanses (i.e., thousands of km^2) of sagebrush-dominated rangelands (Connelly et al. 2000). However, more information is needed regarding the appropriate management techniques and scale of management activity within these areas to improve specific seasonal habitats, such as brooding areas, for sage-grouse. Within the context of a large intact sagebrush landscape, small-scale habitat manipulations may provide an effective rangeland management tool for improving herbaceous cover and associated arthropod resources, while not adding large-scale fragmentation that is known to be detrimental to sage-grouse.

Our objectives were to assess the vegetation and sage-grouse response to small-scale sagebrush canopy reduction treatments in mountain big sagebrush communities (*A. t. vaseyana*) in a replicated (i.e., n=4) and controlled design. We predicted that treated areas would exhibit improved brooding habitat conditions and sage-grouse would select for treated areas more than controls.

Methods

Study Area

Our study occurred on Parker Mountain, south-central Utah, USA. Parker Mountain is a 120,000-ha high elevation (~ 2500 – 3000 m) plateau dominated by sagebrush, with Wyoming big sagebrush (*A. t. wyomingensis*) at lower elevation, black sagebrush (*A. nova*) at mid-elevation, and mountain big sagebrush at higher elevation (Dahlgren et al. 2006). The study area has one of the largest and relatively stable populations of sage-grouse in Utah. There is relatively little to no development on Parker Mountain, except for some graded gravel and two-track roads. The study area typically receives 400-500 mm of precipitation annually, primarily in the form of winter snow and late-summer monsoons.

Shrub Removal Treatments

In 2000 and 2001, we implemented small-scale (n = 16, 40.5-ha square plots) shrub canopy reduction treatments with three methods – mechanical treatments of Dixie Harrow and Lawson Aerator, a chemical treatment of Tebuthiuron (i.e., Spike), and control plots (Figure 1). The Dixie harrow is dragged behind a large tractor and has connected pipes with alternating harrows that rip up sagebrush and scarify the bare soil when dragged in two opposing directions (i.e., double harrow treatment). The Lawson aerator is a large drum aerator dragged behind a tractor that crushes larger, woodier sagebrush without impacting the soil. The 40.5-ha plots were square and delineated to contain as much mountain big sagebrush cover as possible, but each plot also contained areas of black sagebrush. Only mountain big sagebrush was treated. Mechanical treatments were completed in a mosaic design to leave some intact big sagebrush adjacent to treated areas (Figure 2). Spiked plots received 0.75 lbs. per ha active ingredient resulting in a mosaic of varying levels of defoliation and kill to the mountain big sagebrush due to varying soil depths and other conditions within the plots.

Vegetation and Grouse Monitoring

From 2001 to 2009, we sampled n = 5 randomly placed permanent 20-m vegetation transects in each plot and measured shrub and herbaceous canopy cover using a variation of the line intercept method (Canfield 1941) and Daubenmire frames (Daubenmire 1959) centered on every meter, respectively. We recorded genus and species, when known, of shrubs, forbs, and grasses. To evaluate sage-grouse use of plots, we used trained pointing dogs to locate, point, and flush grouse using the plots from mid-July to the end of August (Dahlgren et al. 2006). A handler would cast the dog through the plots to search the entire plot. Each plot was sampled at least twice per field season.

Results

Sagebrush canopy cover was relatively high (~ 40%) in our plots pre-treatment (Figure 3). All treatments reduced sagebrush cover and increased grasses and forbs the first couple years post-treatment. However, spiked plots showed the strongest long-term herbaceous response to treatment (Figure 4). When we separated forb species into those known (i.e., reported in the published literature) to be consumed by sage-grouse we found the strongest long-term treatment response. Sage-grouse responded positively to all treatment plots, with more use (grouse flushed per plot) compared to control plots. However, grouse had nearly double the flush rate in spiked plots when conducting pointing dog surveys than the mechanical treatments (Figure 5).

Conclusions and Implications

All treatment types reduced shrub canopy cover and mechanical treatments showed a small herbaceous response for the first few years post-management. Spike treatments demonstrated a long-term increase in herbaceous cover, especially forbs that sage-grouse eat. Sage-grouse use, especially broods, was correlated with the strong forb response in spiked plots. Spike plots also demonstrated a longer recovery period for sagebrush canopy cover, likely associated with the long-term increase in herbaceous cover. The Dixie harrow and Lawson aerator plots initially showed a significant decrease in shrub canopy cover, but they also returned to pre-treatment shrub canopy cover levels within our 10-year study period.

Spatial and temporal scales are critical to consider when planning and implementing sagebrush canopy cover reduction treatments (Connelly et al. 2000). Our small (40.5 ha) treatment areas were placed within a large intact sagebrush landscape. Such prescriptive small-scale rangeland treatments may provide an opportunity for managers to address seasonal habitat needs for sage-grouse, such as forb and grass cover in brood-rearing habitat, and other sagebrush-associated species. Shrub canopy reductions conducted at large scales (100's to 1000's of ha) have been shown to be detrimental to sage-grouse. Sagebrush canopy reductions would not be advisable in sage-grouse habitat that is highly fragmented or within landscapes with limited sagebrush dominated areas (Braun et al. 1977). Additionally, we placed these treatments in high-elevation mountain big sagebrush known to be brooding habitat. Sagebrush canopy cover reduction in nesting or wintering habitat, and/or in lower-elevation Wyoming big sagebrush, have been shown to have only neutral or detrimental impacts to sage-grouse habitat and populations. The recovery time frame of treated sagebrush communities is another important consideration when it comes to how often an area might be treated and predicting potential impacts to sage-grouse.

Our results may seem somewhat counterintuitive. We provide novel findings concerning how, when, and where sagebrush treatments may benefit a sagebrush obligate species to help them meet specific seasonal habitat conditions, such as increased forbs during the brooding period. While sagebrush treatments have become highly discouraged over time as the sage-grouse conservation issue has grown since the mid-1990s, our study offers a way to continue to manage sagebrush rangelands, even potentially increasing forage for livestock and other species, while continuing to conserve and support sage-grouse populations into the future.

Cacti biocontrol in the South Australian Arid Lands

Eager, C

South Australian Arid Lands Landscape Board (SAAL LB)

Key words: cacti; biocontrol; cochineal; arid

Abstract

All Opuntioid cacti species in Australia are introduced and are Weeds of National Significance (WONS) and declared under the Landscape South Australia Act 2019 (except *O. ficus-indica*). Significant time, money and effort has been spent trying to control infestations using herbicide and physical removal. Despite this, Opuntioid cacti have resisted control efforts and continued to infest rangelands.

Since 2016, with the support of Biosecurity Queensland (Queensland Department of Primary Industries), we have developed an Opuntioid cacti biocontrol program. The biocontrol agent we use is cochineal, species of mealybugs that are cactus specific. As a result, we have biocontrol agents that assist in controlling 12 of the 15 species of Opuntioid cacti found in the SAAL LB region (Map of infestation locations included). Cochineal has been a game changer in helping to get on top of some of the worst infestations of Opuntioid cacti in our region. Before and after photos in this paper demonstrate how successful this biocontrol has been.

Biosecurity Queensland have provided cochineal species, that SAAL LB previously didn't have, that were suited to many species of Opuntioid cacti in our region. In return, we have provided samples of cactus and cochineal that they have used to further develop their Opuntioid cacti biocontrol program through trials and DNA testing of cochineal.

The SAAL LB have also been supported by the Port Augusta City Council who agreed to house the SAAL LB Cochineal Nursery on their Australian Arid Lands Botanic Garden site. The Cochineal Nursery was established in 2021 and breeds four species of cochineal, which work on six species of cacti. Cochineal from this facility has been used on infestations on numerous properties in SAAL and other Landscape Boards.

Introduction

Many cacti are invasive species globally, posing a risk to native species via competition, impeding access to natural areas, and causing harm to animal and humans due to physical attributes such as sharp spines. In Australia, Opuntioid cacti in particular, are Weeds of National Significance (WONS), with many declared species under the Landscape South Australia Act 2019 (except *O. ficus-indica*), requiring control. Opuntioid cacti are mainly found in low rainfall areas, such as the South Australian Arid Lands Landscape Board (SAAL LB) region which covers more than half of South Australia, and shares borders with three other States: New South Wales, Queensland and the Northern Territory. The vastness of this region with inaccessible terrain and a sparse population, poses a challenge to the logistics of implementing chemical control and follow-up treatments. Biocontrol is an effective management tool for cacti and entails the use of a plants' natural enemies to control populations in introduced ranges. There are several varieties of Opuntia species present in our region, including Wheel cactus (*Opuntia robusta)*, Prickly pear *(O. stricta),* Engelmann's cactus (*O. engelmannii)*, Devil's rope (*Cylindropuntia imbricata),* jumping cholla (*Cylindropuntia prolifera*), Coral cactus (*Cylindropuntia fulgida var. mamillata)* and Red-flowered prickly pear *(Opuntia elatior)* for which there are effective biocontrol agents available.

Methods

The SAAL LB initiated an Opuntioid cacti biocontrol program in 2016. The biocontrol agents we use are collectively called cochineal (*Dactylopius sp.)*, of which there are several species of mealybugs belonging to the genus *Dactylopius*. Research has identified which *Dactylopius* species to release on targeted cactus species (see table 1). Biosecurity Queensland's Cacti Biocontrol Research program has provided support through the provision of suitable cochineal that the SAAL LB didn't previously have, but that were suited to many species of Opuntioid cacti in our region (*e.g.* Jumping Cholla (*Cylindropuntia prolifera*) and Coral cactus (*Cylindropuntia fulgida var. mamillata).*

In return, we provided samples of local cactus plants and cochineal that they have used to further develop their Opuntioid cacti biocontrol program through trials and DNA testing of cochineal.

Another aspect to ensure the success of any biocontrol program, is the mass-rearing of suitable agents to ensure a smooth supply-demand cycle. This involves distribution of cochineal to new plant populations infield, and collection and replenishing of fresh plant material for agents to feed on. In partnership with the local Port Augusta City Council, a cochineal nursery was established at the Australian Arid Lands Botanic Garden property in 2021.

Results

Cochineal has been a game changer in helping to get on top of some of the worst infestations of Opuntioid cacti in the SAAL LB region. (See Fig. 1 for an example of a Before and after image that demonstrates how successful biocontrol has been). We now have cochineal released against 12 of 15 Opuntoid cacti present in the region. In the 2023-2024 financial year alone, cochineal was released at 23 sites in the SAAL LB region, targeting seven cacti species. Thirteen of these were new release sites (see Table 1).

This cochineal nursery is crucial to the success of the biocontrol program, four strains are bred at the facility that are specific to six cacti species found in region: Wheel cactus (*Opuntia robusta*), Red-flowered prickly pear (*Opuntia elatior*), Engelmann's cactus (*Opuntia engelmannii*), Devil's rope cactus (*Cylindropuntia imbricata*), Coral cactus (*Cylindropunta fulgida var. mamillata*) and Jumping cholla (*Cylindropuntia prolifera*).cacti. Cochineal from this facility has been used on infestations on numerous properties in the SAAL LB and other Landscape Board regions. Maintaining the nursery to ensure adequate stock is a shared responsibility amongst many SAAL LB staff (See Fig.2 below).

Discussion

The SAAL LB prides itself in harnessing partnerships that benefit the landscape, and this is evident through the delivery of many collaborative natural resource management projects in the region, possible through a combination of internal (levy) and external (project) funding. The SAAL LB Opuntioid cacti biocontrol program is a prime example of this. This project has been a success so far, due to the building and maintaining of partnerships, including with landowners, volunteers, and other stakeholders who participate in collaborative planning and also distribution and spread of cochineal.

For example, landholders and volunteers were engaged to map out control work that had already been completed and the scale of remaining cactus infestations, coming up with a plan of when and where to use cochineal versus chemical control. This led to the Northern Flinders Opuntia control strategy and bringing a group like this together allowed for better cross-property collaboration. Volunteers made up of 4WD, bushwalking and cycling clubs have also played a crucial role in spreading cochineal in the North Flinders for over a decade (~4,000 hours of volunteer hours annually).

Biocontrol agents are able to establish and spread by themselves infield, reducing time, effort and capacity required. Human-aided spread of agents can enhance the success of such programs, which have minimal costs involved. However, biocontrol should not be viewed as a stand-alone "golden ticket" and is often required to be used as a management tool in conjunction with other treatment methods *e.g.* herbicide control. Integrated pest weed and animal management reaps benefits, and biocontrol can be used for example, in reducing populations sizes to a more manageable level for a targeted chemical control program to reduce costs.

The Opuntioid cacti biocontrol program is directly linked to at least three SAAL LB Board priorities; Sustainable land management, Protecting and enhancing biodiversity, and People and partnerships. It is envisaged that this program will expand in future years to include a more structured post-release monitoring protocol, and collection of more in-field population data to demonstrate its effectiveness over time.

The Koonamore Project: 100 years of research in a short-term rangeland ecology study

Facelli, JM[1]; Ladd, D[1]; Sinclair, R[1]

[1] School of Biological Sciences. The University of Adelaide

Key words: LTER; Chenopod shrublands; stock exclusion, long lived plants.

Abstract
The Koonamore project is based at the Osborn Vegetation Reserve, located in arid lands of South Australia, 350 km NNE from Adelaide. The site was established in a badly degraded corner of a paddock that was fenced off to exclude stock and rabbit grazing in 1925. A series of permanent plots and photopoints have been established at the site and resurveyed regularly.

The data collected (which is available for research on request) include location and sizes of trees and long-lived shrubs in several permanent plots, and sequences of photographs for over 40 permanent photopoints.

The accumulated information provides important insights on the changes that occur in rangelands when stock and feral grazers are excluded. It also informs us on the dynamic associated to weather fluctuations and trends of climate change.

To our knowledge this is the longest running ecological study of rangelands in Australia and one of the oldest in the world. However, as the data shows, this period encompasses just a few generations of several species (e.g. *Maireana sedifolia*, *Sena artemisifolia*) and even less than one generation for some of them (e.g. *Acacia aneura*, *Myoporum platycarpum*). Given the long life span of key species in the system, and the long term nature of climatic variation, we argue that a century is a relatively short term, and that the project warrants to be continued for at least another 100 years.

Introduction
The Koonamore Project was started in 1925 with the aim of obtaining information about the recovery of rangelands in extremely degraded conditions, when stock grazing was removed. This objective was framed within Clement's recently formalised ideas about ecological succession. The project was started by Professor T.G.B Osborn by fencing off a 4 km^2 of a heavily degraded paddock in Koonamore station (between 30º07'S, 139º20′E, in the centre of the Koonamore Station) (Figure 1). This area is now the TGB Osborn/ Koonamore Vegetation Reserve (KVR). Several permanent plots and photopoints continue to be monitored (albeit with some temporal gaps) to this day, which make this project (to our knowledge the oldest Long Term Ecological study in Australia, and one of the oldest in the world.

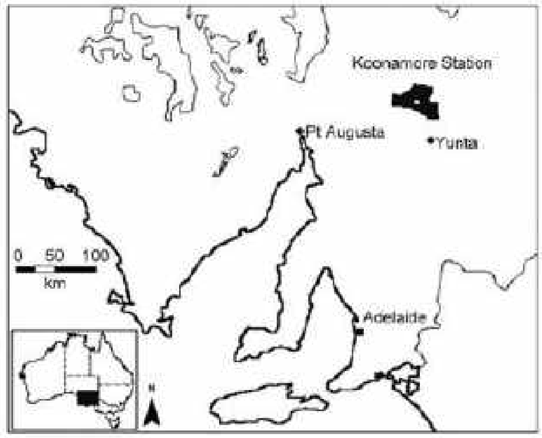

Figure 1: location of the T.G.B Osborn Vegetation Reserve, where the Koonamore Project is based.

The System

The whole area can be described as an open woodland with chenopod understorey, comprising a combination of low sand dunes alternating with sand plains and harder loam soils with travertine limestone at various depths on the intervening flats (Osborn, 1925). The annual rainfall, averages 200 mm, but shows substantial variability (between 50 and 850 mm during the period of the project). Vegetation is predominantly low open-woodland, with an sparse tree storey dominated by *Acacia aneura*, *Myoporum platycarpum* and *Alectryon oleifolius*. The tall shrub stratum include *Eremophila* spp., and *Senna artemisioides* (various subspecies). The low shrub stratum is dominated by *Atriplex vesicaria*, *Maireana sedifolia*, and *Maireana pyramidata*. Other shorter-lived chenopod shrubs grasses and ephemeral vegetation make up the lower stratum.

Central to the Koonamore Project are permanent plots where individuals of long lived plant species are mapped (x & y coordinates recorded) and, since the 1970's, dimensions of the canopy (diameters in N-S and W-E directions, and height) recorded. The main quadrat are four 100 m x 100 m areas representing the main types of vegetation (as understood when the site was established). (For more details see Sinclair and Facelli 2019). The data collected is in the public domain (currently through AEKOS (http://www.aekos.org.au/), and we are in the process of enhancing accessibility and ease of use. The data is particularly valuable since not only covers the recovery of the rangelands after de-stoking, but also the response of the system to variability in climate as the data covers several El Niño and La Niña events. It also includes several decades of important changes in climate driven by human activities.

Discussion and Conclusions

Previous recent publications (Sinclair 2005, Sinclair and Facelli 2019) report changes in population sizes, organization of the community (Lawley et al. 2013), persistence of dead logs and their effects in the creation of microsites (Bowman et al. 2014), and models of growth for the most abundant tree (*Myoporum platicarpum*) (Boland and Sinclair 2014). These publications, in our opinion, only cover a small fraction of the possible areas of research that could be explored using the massive data set accumulated. Here we present some of the areas of possible research we consider worth pursuing.

The data should allow studies of the life span of several species. The presence of species with highly contrasting life history strategies is well documented. The KVR data provide opportunities to assess several aspects of their demography. For example: is there a demonstrable trade off between life span and how often conditions conducive to recruitment occur? Because several species in permanent quadrats are mapped from establishment to death, the data base provides excellent opportunities for such studies. Equally, the role of density dependence in establishment and recruitment (a contentious issue in arid lands) can be effectively addressed with the data available. The site also provides unique opportunities to explore population genetics. The recording of date of establishment together with genetic information that can be obtained with molecular techniques could shine a light on genetic dynamics of plant populations recovering after undergoing a strong reduction in the number of individuals

The second important point we want to make is questioning whether, having reached the 100 years mark, is it worth continuing the project. It could be argued that data covering 100 years should contain ample information on the dynamics of these rangelands. Two issues are relevant. Firstly, we need to consider whether (still thinking within the Clementsian conceptual framework}, successional changes have reached a stable state. An inspection of the age population structure of some of the key species suggests that this is not the case. Indeed, populations of species such as *Myoporum platicarpum* and *Acacia aneura*) show sparse numbers of old individuals and relatively large numbers of juveniles, with no individuals in intermediate age classes. This suggest that these key populations have not reached a stable state. Further, as these species are likely to act as ecological engineers, it can be expected that as young individual mature, changes in soil and microhabitat will trigger further changes in ecosystem dynamics and in other populations. Secondly, to the successional consideration it must be added the influence of climate change. Indeed, this project has run during critical times for the climate of the planet. During the period global temperatures have risen by almost 2ºC. These changes, along with associated changes in rainfall patterns, have occurred as the vegetation and the ecosystem underwent recovery from extreme degradation. Compounding this, is the possibility of time lags in responses. Time lags are pervasive in ecological systems, and may be particularly important in rangelands, They may include responses of various species to changes in the soil, either produced by organisms, or by geological processes leading to soil formation. Microbial changes in the soil are also candidates to produce time lags. As soil changes through biotic and abiotic processes, soil microorganisms respond at different rates, which in turn through can lead to further vegetation changes.

These considerations highlight that various processes can occur in short periods of time, while others can take much longer times. Even when considering population dynamics only, species with relatively short life spans may complete several generations in a couple of decades, while species with long life spans may have not completed a single generation turnover in the 100 years of the project. Indeed, *Atriplex vesicaria*, with a life span of ca. 30 years may have have some 3 or four population turnovers. On the other hand species like *A. aneura* or *M. platycarpum*, with life spans of 150-250 years have not completed a single generation turn over. Thus, while for short lived species this project can be considered a long term study, for the later mentioned species this 100 year is a short term study documenting mortality of old individuals present at the site when the reserve was established, and establishment and recruitment of new individuals in episodic events, providing a simple snapshot of how the populations change. A corollary of this is that defining long term ecological studies require explicit identification of the variables of interest, and the identification of relevant time scales. Potentially, sampling intervals could also be defined in the same study at various intervals for the different variables.

Thus, in view of the importance of long lived trees in modulating the function of ecological systems, the required long time for changes to eventuate in rangelands, and the urgent need for better understanding of the effects of climate changes, we conclude that the Koonamore Project should be continued for at least another 100 years. Achieve this will not be easy, as several issues difficult the continuity of LTERs, Under most granting programs obtaining funds for this type of project is not feasible, so alternative sources of funding must be achieved (through establishment of specific funds to support the project via fund raising bequests, etc.). Secondly, the leading of such project do not always get the recognition they deserve, both at the institutional and global academic level. Finally, it is often difficult to ensure continuity requires academic succession planning. Given the importance of this type of studies there should be enough incentive to overcome these obstacles.

Acknowledgements
Ove the century of the project numerous volunteers have contributed enormously to the continuation of this project. Particularly we thank undergrad and graduate students of the Departments of Botany, Environmental Biology and Ecology and Evolution (this reflects organizational changes over time). The School of Biological Sciences of the University of Adelaide has supported the project, as have the Rasheed family, in charge of Koonamore station, where the project is located.

What limits seed-based restoration: seeding methods or environmental constraints?

Farzam, M[1]; Chiarenza, G[1]; Vear, A[2]; Van Leeuwen, S[3]

Research Fellow, ARC Centre for Healing Country, Department of Molecular and Life Science, Curtin University, Australia.

Key words: seed-based restoration; seedling survival; seed pelleting; soil moisture

Abstract
Drylands worldwide face severe degradation, requiring restoration efforts that often rely on native plant species. However, the small seed size of some species poses challenges for conventional seeding machinery. In Western Australia, the "Comm Veg" seeder is commonly used, creating furrows to improve seedling establishment.

To address limitations in seed distribution and sowing speed, seed pelleting technology was explored to increase seed size, enabling the use of a crop seeder (Aitchison). A field experiment in Eganu, WA (July 2024), compared seedling emergence and survival of four native species (*Eucalyptus oldfieldii, Melaleuca cordata, Eremaea pauciflora*, and *Acacia pulchella*) sown as bare seeds using the Comm Veg and as pelleted seeds using the crop seeder. Seedling emergence was measured in early (September) and mid-spring (November). A glasshouse experiment assessed germination rates of bare versus pelleted seeds.

Glasshouse results showed similar germination rates for bare and pelleted seeds across species. In the field, seedling emergence was higher with the Comm Veg seeder, likely due to greater soil moisture storage in the deep soil layer (7–15 cm) in furrowed areas. Alive *Acacia* seedlings exhibited significantly longer roots than dying seedlings, indicating deeper moisture access. However, seedling mortality was high for all species by mid-spring (<2% survival), likely due to late sowing and frequent droughts. Although crop seeder showed lower effectiveness in conserving soil moisture and supporting seedling survival, integrating agricultural machinery with seed pelleting technology remains promising for cost-effective, large-scale restoration. Refining sowing techniques and pelleting methods is essential to improve restoration success in degraded drylands.

Introduction

Drylands worldwide face severe disturbances from grazing, land-use changes, fire, and drought. Vast areas with low plant productivity making large-scale restoration in drylands costly and challenging. Direct seeding of native plants is widely regarded as a cost-effective and essential approach for large-scale restoration (Merritt and Dixon, 2011). However, less than 10% of seeds typically establish successfully due to various edaphic and biotic constraints (Ceccon et al., 2016). Additionally, handling and precision seeding of multispecies mixes with diverse seed sizes and shapes present logistical challenges, requiring specialized equipment and often resulting in low seedling establishment rates (Masarei et al., 2019).

In Western Australia, the "Comm Veg" seeder is commonly used for creating furrows during seeding. While effective, this approach could be enhanced with improved seed distribution and faster sowing speeds. Adapting agricultural machinery capable of sowing seeds over large areas at higher speeds and precise soil depths could benefit large-scale restoration efforts. However, the extremely small seed size of many native plants, such as gum trees, poses a significant challenge for using conventional crop seeders.

Seed enhancement technologies, initially developed for precision seeding in agriculture and horticulture, are increasingly being applied to ecological restoration (Madsen et al., 2016). One such technique, pelleting, involves adding materials to seeds to create an oval or spherical shape, making the original seed shape indiscernible (Pedrini et al., 2020). This process increases propagule size, enabling their use with agricultural machinery.

Effective restoration requires deep ecological knowledge to create restoration niches that support seed germination and seedling establishment, emphasizing the need for cost-effective, ecologically sound, and scalable methods. This research aimed to compare the effectiveness of two seed-based restoration methods: sowing bare seeds using the commonly used Comm Veg machine and sowing pelleted seeds of the same species with a crop seeder (Atchison). We hypothesized that the crop seeder would provide more precise seed distribution, while the slower-moving Comm Veg machine, which creates furrows, would offer more favourable recruitment restoration niches for seed germination and seedling establishment.

Methods

We tested seedling emergence and survival of four native plant species and a mixed-species treatment, comparing bare and pelleted seeds sown using two different seeder machines . The species included *Eucalyptus oldfieldii*, *Melaleuca cordata*, *Eremaea pauciflora*, and *Acacia pulchella* var. *pulchella* (DBCA 2024) (henceforth we refer to them using their genus names). Seeds of all species were pelleted using azomite as the coating medium and polyvinyl alcohol (PVOH, 8% solution) as the binder (Pedrini et al., 2020), resulting in pellets with a diameter of 1.5–2 mm, similar to canola seeds.

Bare seeds were mixed with perlite and sown using a Comm Veg direct seeder (North Stirling Pallinup Natural Resources). This seeder, designed for restoration applications in Western Australia, allows simultaneous sowing of fine and coarse seeds in four separate rows, while creating deep furrows to enhance rainwater catchment. Pelleted seeds were sown using an Aitchison drill seeder (Aitchison Seed Drills, New Zealand). This machine is optimized for sowing varying size crop seeds.

Seed sowing was conducted from July 22–24, 2024. Seedling emergence and survival were assessed 60 days after sowing (September 20, 2024) and 103 days after sowing (November 5, 2024). The final rainy week of the season occurred in early September, placing the assessments approximately three weeks and two months into the dry season, respectively. Soil moisture was measured by collecting soil samples from two depths: 0–5 cm (topsoil) and 7-15 cm (subsoil). Additionally, morphological growth parameters, including root and shoot biomass, seedling height, and maximum root distribution, were measured for six *Acacia pulchella* seedlings (both alive and dead).

The experiment followed a completely randomized block design with two seeding types (bare and pelleted) and four plant species as the main factors. Each seeding type was replicated in blocks, with each block containing five rows randomly assigned to one of the four species or a mixed-species treatment. This design resulted in 30 experimental units, encompassing two sowing types, five plant treatments, and three replicates. In a glasshouse experiment, seeds of the same species were sown as either bare or pelleted, and their emergence and survival were monitored over 45 days. This allowed us to confirm that observed differences in emergence between plant species in the field were attributable to factors other than seed pelleting and dormancy.

Results

Seedling emergence and survival in glasshouse

The glasshouse experiment showed species-specific differences in seedling emergence (Figure 1). *Acacia* (58%) and *Eremaea* (52%) had the highest emergence rates for bare seeds, while *Eucalyptus* (44%) and *Melaleuca* (23%) had lower rates. Pelleting reduced emergence in *Melaleuca* (8%) and *Eremaea* (29%) but did not affect *Eucalyptus* or *Acacia*. Seedling survival from day 20 to 45 was similar for both pelleted and bare seeds.

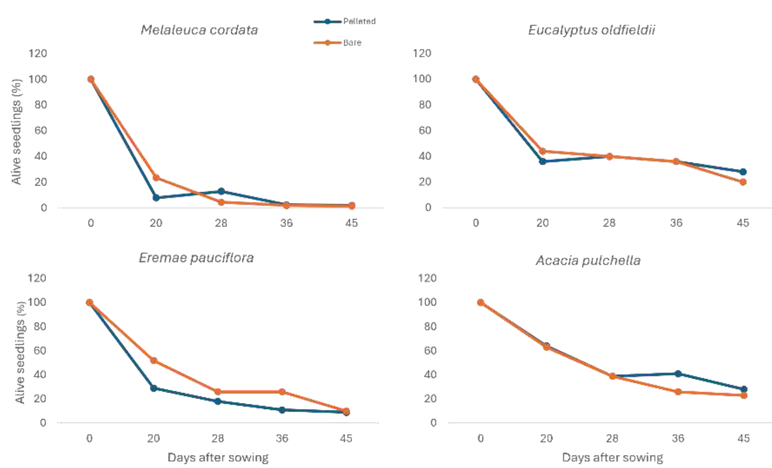

Figure 1: Seedling emergence and survival of four native species sown as bare or pelleted seeds under glasshouse conditions, means were compared by Tukey test at P<0.05).

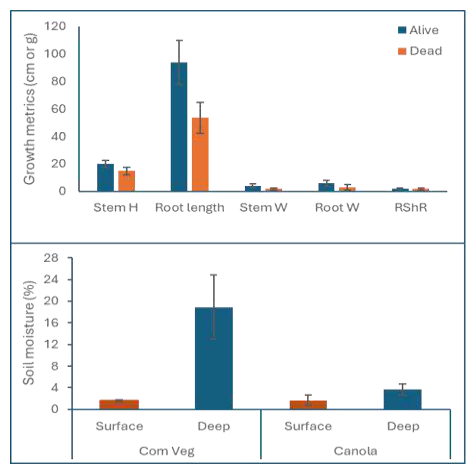

Figure 2: Comparison of growth metrics for Acacia seedlings (top) and soil moisture content across different seeding methods and soil depths (bottom), means were compared by Tukey test at P<0.05).

Soil moisture and growth metrics

Living acacia seedlings had root lengths approximately twice as long as those of dead seedlings, although their stem height and stem and shoot weights were similar. Soil moisture in the deeper soil layer (7-15 cm) was significantly higher in furrows created by the Comm Veg method compared to those created by the crop seeder, while no difference was observed in the topsoil layer (0–5 cm) between the treatments (Figure 2).

Seedling emergence and survival in field

For three of the four species (*Acacia*, *Eremae*, and *Melaleuca*), early seed emergence was significantly higher under the Comm Veg treatment, which used bare seeds sown in deep furrows, compared to the crop seeder treatment, which used pelleted seeds sown at the soil surface. In contrast, early seedling emergence for *Eucalyptus* was extremely low (<5%), with no clear difference between the methods. All species experienced severe mortality as drought intensified by mid-spring, with no difference in survival between the Comm Veg and crop seeder treatments.

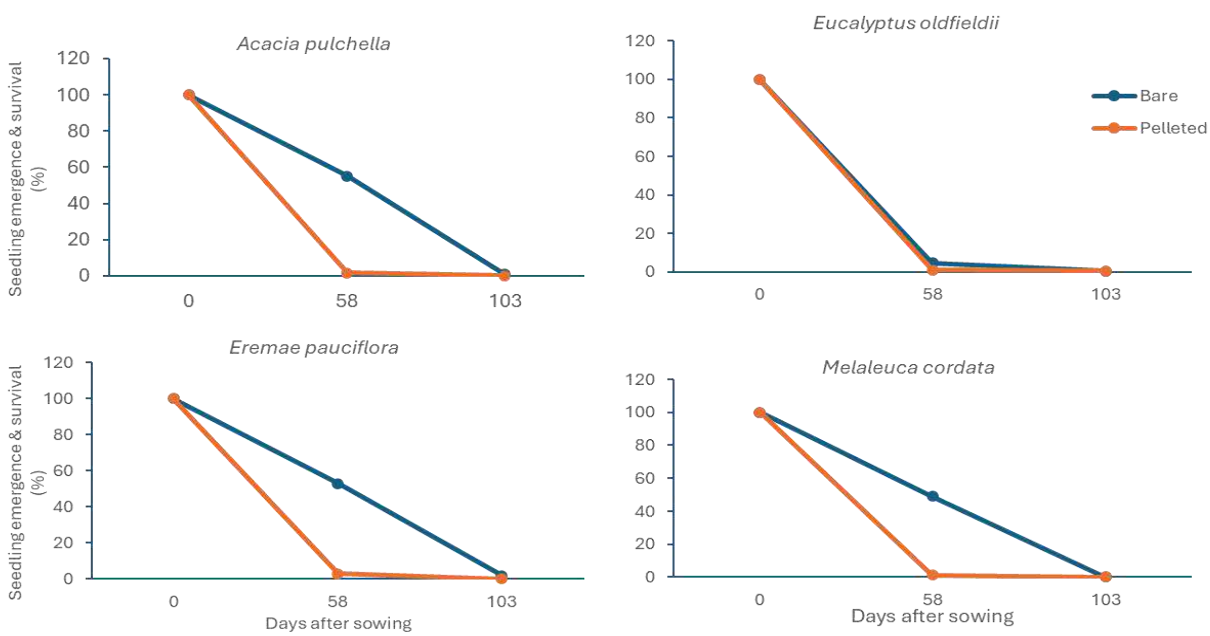

Figure 3: Seedling emergence and survival of native plant species sown as bare seeds in furrows using the Comm Veg method or as pelleted seeds using a crop seeder.

Discussion

Seed-based revegetation is widely regarded as a cost-effective and scalable solution for dryland restoration. Pelleting seeds into larger sizes offers the advantage of enabling the use of more sophisticated agricultural machinery in dryland restoration However, the results of this short-term trial highlight the pivotal role of major environmental factors—such as rainfall, soil moisture availability, and soil properties—in determining the success of restoration efforts. Late sowing and an unexpected 20-day drought in early September worsened moisture stress and led seedling mortality that was intensified by mid-summer.

Our glasshouse experiment corroborates previous studies (e.g., Pedrini et al., 2020) showing that seed germination rates were generally similar between pelleted and bare seeds. Therefore, the reduced seedling emergence observed in the field suggests that other factors, such as mechanical sowing methods, may have contributed to this outcome.

Field results demonstrated significant soil moisture retention in the deep soil layers of treatments using the Comm Veg machine, which creates deep furrows for seed placement. These furrows facilitated better moisture storage, which proved critical for seedling survival, especially under drought conditions. Morphological analysis showed that *Acacia* seedlings with longer root systems had a distinct advantage in accessing stored soil moisture within these furrows. This suggests that Comm Veg furrows, combined with the inherent root growth characteristics of *Acacia* species, enhance plant survival in water-limited environments.

In conclusion, our findings emphasize the critical importance of soil moisture storage around the root zone for seedling survival during dry seasons. Sowing techniques and timings that promote root elongation toward available moisture in the deep soil layers can significantly enhance seedling survival during dry seasons. While this small-scale trial indicated lower effectiveness of crop seeders in conserving soil moisture and improving seedling survival, the integration of agricultural machinery with seed pelleting technology remains a promising avenue for cost-effective, large-scale restoration. Further research and development on optimizing sowing techniques and machinery adjustments are warranted to enhance the efficiency and reliability of these methods.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Insights into spinifex (*Triodia* species) pastures and their management

Fletcher, M[1]; Gibson, L[2]; McDonald, M[2]; Mackay, G[2]; Wilson, N[3]

[1] Range Assist, Kununurra, Western Australia, matt@rangeassist.com.au;

[2] Kimberley Pilbara Cattlemen's Association, Broome, Western Australia, kimberleymanager@kpca.net.au; [3] Department of Primary Industries and Regional Development, Kununurra, Western Australia, noel.wilson@dpird.wa.gov.au

Key words: interviews; hummock; livestock; fire

Abstract

Interviews about various aspects of spinifex pastures were conducted with 21 pastoralists, five Traditional Owners, and seven rangeland scientists from the Pilbara, Kimberley, and central Australia regions. Interviews sought to provide insights into spinifex pastures and covered topics such as plant identification, burning, grazing systems, tree/grass balance and Indigenous uses of spinifex and burning practices; knowledge gaps were also identified.

The interviews made it clear that fire plays a significant role in spinifex pastures and is frequently used to enhance grazing productivity by removing old or moribund spinifex and allowing palatable new growth to replace it. Additionally, fire is used as a tool for wildfire mitigation by creating different-aged fire scars and subsequent variations in fuel levels across the landscape. The amount of non-spinifex material in the diet of grazing animals was also commonly discussed where, after rain, cattle primarily grazed on a non-spinifex diet by selecting the soft fresh growth of annual and perennial grasses and forbs where available.

At the conclusion of each interview, interviewees were asked what additional information they would like regarding spinifex pastures and their management. The most common request was for accurate identification of spinifex species. Interviewees also wanted more information on the nutritional value of spinifex seed heads and leaves; specifically, how nutrient content and digestibility change throughout the year and between fire intervals. Additionally, they expressed interest in comprehensive information on various aspects of spinifex biology, including growth habits, reproduction, response to fire, and the formation of spinifex rings.

Introduction

Spinifex is the common name for a group of native perennial grasses (*Triodia* species) that are found in all Australian mainland states (Australian Virtual Herbarium 2024) and cover more than 25% of the Australian continent (Allan *et al.* 2002). Spinifex plants grow predominantly on soils with low nutrient levels and low water-holding capacity. The genus *Triodia* consists of 65 species, all of which are endemic to Australia (Australian National Botanic Gardens 2024). A notable feature of many *Triodia* species is their ability to form a ring. A hummock is formed as the plant expands outwards via above-ground stolons. At some point the central growth may die and disappear leaving a distinctive ring surrounding a bare area.

Although spinifex covers a significant proportion of Australia (Fig. 1), there is limited readily available information on spinifex plants or the management of spinifex pastures in a pastoral context. The purpose of the interviews was to consolidate the collective knowledge on spinifex pastures and make this information available to land managers, pastoralists, Traditional Owners, extension officers, researchers and other interested stakeholders.

Methods

A total of 33 interviews were completed in April and May 2024; 21 with pastoralists, five with Traditional Owners, and seven with rangeland scientists. Due to the large distances and time constraints, all central Australian and rangeland scientist interviews were conducted by phone. Pastoral and rangeland scientist interviewees were asked a standard list of questions. In a small number of cases, interviewees chose not to respond to certain sections because of time constraints or their perceived lack of qualification. Of the five Traditional Owners interviewed, two were asked all interview questions, while the other three focused only on the aspects of spinifex and fire as relevant to Traditional Owners.

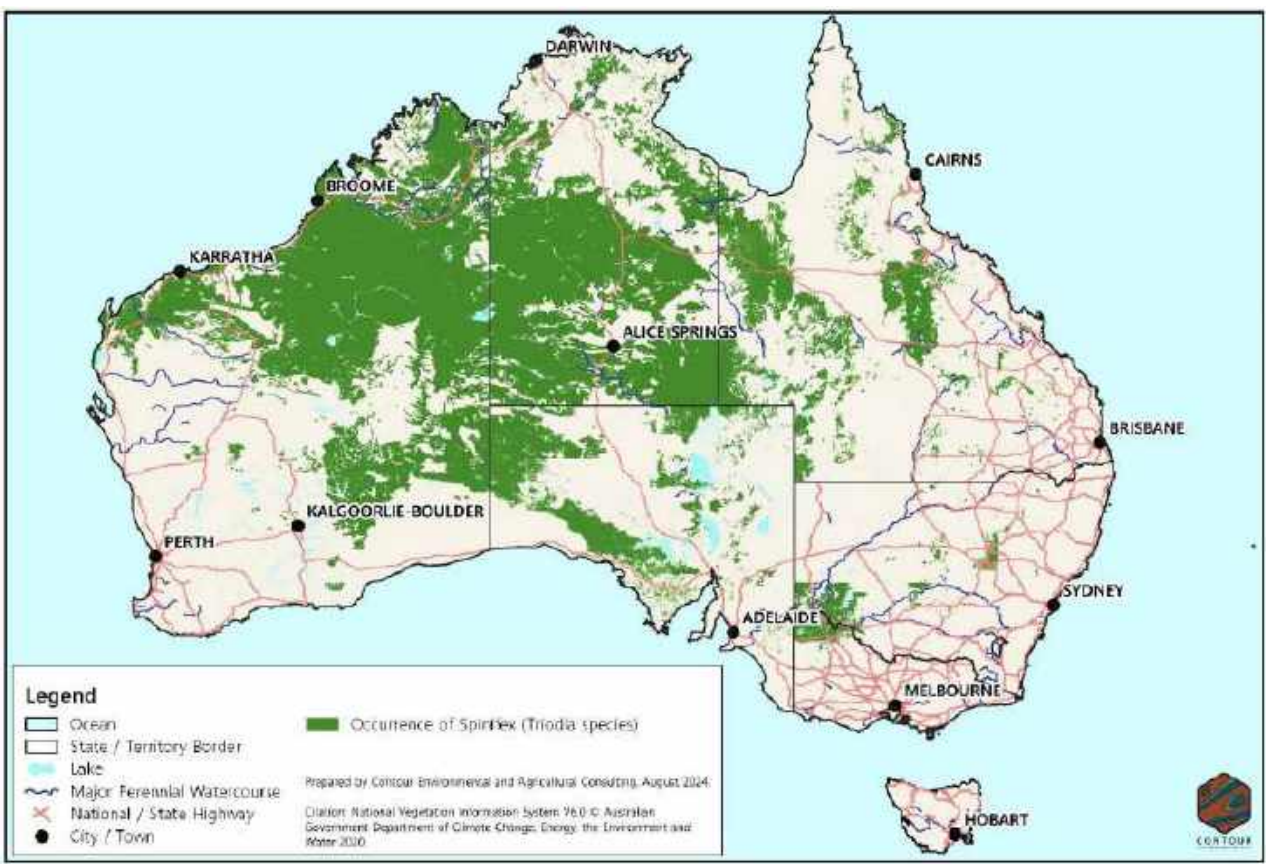

Fig. 1. Occurrence of spinifex (*Triodia* species) in Australia.

Results and Discussion

Interviewees generally referred to spinifex as being either hard or soft. Hard spinifexes included *Triodia basedowii*, *T. intermedia*, *T. irritans*, *T. secunda* and *T. wiseana* and soft spinifexes included *T. epactia*, *T. pungens* and *T. schinzii*. Hard spinifex foliage was generally considered unattractive to livestock at all stages of growth. In contrast, soft spinifex foliage is grazed by livestock and remains palatable for 3–4 years after fire, after which the feed quality deteriorates.

Spinifex and fire

Most of the interviewees preferred cool fires and emphasised the need for adequate soil moisture prior to burning. Burning after rain, when the soil and spinifex are well hydrated, is desirable because fire intensity is reduced. Importantly, pre-existing soil moisture also enables rapid regrowth of spinifex and any other perennial grasses that have not been killed by fire, typically within a week or two. Humidity was another key requirement for a cool fire. With high humidity, the fuel (particularly of cured pasture plants) absorbs moisture from the air. This increased moisture content renders the plant more difficult to ignite and slows down the rate at which it will burn. Consequently, fire intensity and its rate of spread is reduced.

In general, interviewees emphasised that they do not deliberately ignite hot fires; however, they often encountered them as a result of lightning strikes or unauthorised fires. Hot fires were typically associated with east/southeast winds, low humidity, dry fuel, and high temperatures from September to December and throughout the summer until sufficient rainfall has occurred. Many interviewees made efforts to avoid hot fires because areas affected by hot fires often take years to recover. The effectiveness of hot fires in killing spinifex, shrubs, and trees was frequently discussed.

The primary tool utilised for wildfire mitigation in spinifex is mosaic/patch burning. Creating variation in fuel levels through different-aged fire scars is considered the most effective method for mitigating wildfires. Not only does this practice minimise the risk of wildfires, it also rejuvenates the spinifex pastures by replacing old, dense spinifex with new growth. Essentially, to prevent wildfires, one must 'combat fire with fire'.

Spinifex and grazing

Cattle congregate on burnt areas. The early growth is nutritious but not abundant, so cattle also need access to other bulk feed. Getting the proportions right around how much to burn or not burn is crucial. Burning areas that are too small can lead to excessive localised grazing, while burning too much can deplete feed reserves and affect areas that should be reserved for burning in following years.

There are more annual grasses and forbs present 1–3 years after fire compared with longer time frames of four or more years, and it seems the presence or absence of these species significantly influences productivity. Similarly, young spinifex plants aged 1–3 years contain a higher concentration of nutrients compared to older plants, aged four or more years. Additionally, the leaves are more digestible when actively growing than when dormant. Interviewees were aware of the benefits to animal performance provided by increased amounts of annual grasses and forbs and appreciated the importance of varying nutrient concentrations and digestibility of spinifex.

The practice of patch burning enables cattle to have access to spinifex at various stages of regeneration. This way, cattle may never need to graze pastures that are considered rank (4–6 years old), as there are always some available areas that have been burnt more recently (in the last 1–3 years). As a result, cattle may only graze areas of rank spinifex for a short time; grazing the seed heads for a couple of weeks each wet season.

Beef production

All pastoralists keep breeders in their spinifex country; mainly older cows that have had at least two calves. Where possible, weaners, steers, and heifers are moved onto the more productive buffel (Cenchrus spp.) and Mitchell grass (*Astrebla* spp.) pastures. Some interviewees can grow their cattle out on the more productive pastures of their lease, while others have farms in the agricultural areas of Western Australia, where all growing and sale cattle are transferred for finishing. A common response from those interviewed was that dry or spayed cows will fatten on spinifex, however wet cows or growing cattle will not.

Additional information needs

At the end of each session, interviewees were asked what further information they wanted on spinifex. While some were satisfied with their current knowledge, others had many unanswered questions. The most common areas of interest were spinifex identification, understanding nutrient mobilisation between rainfall and fire events, and a basic '101' introduction covering growth habits, reproduction, response to fire, and the formation of rings.

There was also interest in exploring whether non-spinifex species form the bulk of an animal's diet through faecal DNA sampling. Additionally, interviewees were keen to learn about cattle movement patterns across different aged fire scars and between seasons and the potential of high-density, short-duration grazing strategies to manage rank growth without relying on fire.

Conclusion

This work provides insights into spinifex pastures and their management and is based on 33 interviews with experienced practitioners from the Pilbara, Kimberley and central Australia.

Notably, fire plays a significant role in spinifex pastures and is frequently used to enhance grazing productivity by removing old or moribund spinifex and allowing palatable new growth to replace it. Additionally, fire is used as a tool for wildfire mitigation by creating different-aged fire scars and subsequent variations in fuel levels across the landscape.

The amount of non-spinifex material in the diet of grazing animals was a commonly discussed topic. Interviewees reported stock preferences for available annual and perennial grasses and forbs as well as browse species – predominantly wattles.

Many of the interviewees would like more information on spinifex identification, and nutrient levels relative to time of year as well as time since fire. There was support for developing a '101' of spinifex dealing with spinifex biology, response to fire, and other plants found in spinifex pastures. Over the next 3–4 years, the Kimberley Pilbara Cattlemen's Association proposes to address identified knowledge gaps and produce a more comprehensive and in-depth document outlining spinifex ecology and best practices for managing spinifex pastures.

It is envisaged that this report will provide industry, industry bodies, and government agencies with information to guide future research, extension, and development activities to benefit all those working with spinifex pastures.

Acknowledgements

A sincere thanks to the pastoralists, Traditional Owners and rangeland scientists who willingly provided their time, information and support to this project. Their willingness to participate in quite lengthy and detailed interviews was appreciated.

This project was managed by the Kimberley Pilbara Cattlemen's Association with support from the Department of Primary Industries and Regional Development WA and the Department of Industry, Tourism and Trade NT. The project was jointly funded by the Department of Primary Industries and Regional Development WA and the Northern Hub through funding from the Australian Government's Future Drought Fund.

A book on the rangelands of Libya

Gintzburger, G[1]; Saïdi, S[2]

[1]BadiaConsulting@gmail.com, & [2]Slim.saidi@cirad.fr

Key words: Agricultural systems; steppe; desertification; rehabilitation

Abstract

Our book cut across all aspects of arid Libyan rangelands. It addresses climate – bioclimates with statistical analysis on climate change trends and droughts recurrences, geomorphology and landforms, soils, vegetation types and landscapes, rangeland production and stocking rates, livestock systems, traditional rainfed barley cropping and Australian ley-farming implemented on large scale, common water use and valorisation by water harvesting and flood farming, forest - afforestation and charcoal manufacturing, past and present wildlife, historical tribal rangeland use, degradation and desertification, restoration and rehabilitation techniques applied to large areas all over northern Libya from passive rangeland protection to fodder shrubs /trees plantations, and agro-ecological zoning to identify land capability and suitability for rainfed barley and olive trees without encroaching current land use.

Our monograph is unique and without equivalent from Morocco to Mongolia. It is relevant to the challenges affecting the arid rangelands of North Africa, the Middle East and Central Asia. It explains the transition from subsistence arid rangeland systems to current trends in livestock feeding with imported and subsidized feed stimulating rangeland degradation and desertification. We explain rangeland degradation and recovery, and agro-ecological zoning using the most up-to-date remote sensing and GIS techniques. It covers arid rangeland rehabilitation and afforestation projects with appropriate plant material, operations unfortunately failing most time due to lack of rangeland communities' involvement.

Our Libyan book is abundantly illustrated with 759 photos including 561 photos of 220 plants with their description and pastoral use, 48 figures, 37 tables and 35 original maps. The bibliography covers Mediterranean arid zones publications with some 630 references in English, French, Arabic, and Latin.

We expect that our book will encourage pastoralists colleagues, decision makers and politicians of North Africa, the Middle East and Central Asia to act wisely before it is too late.

The Libyan Rangelands Under Siege

The Libyan rangelands, inhabited by nomads and livestock, are facing significant challenges from land clearing, hazardous rainfed cropping, unsustainable irrigation projects, expanding human and livestock populations, urbanization, and modernity, particularly in the 100-500 mm rainfall zones, leading to degradation and desertification (Fig. 1).

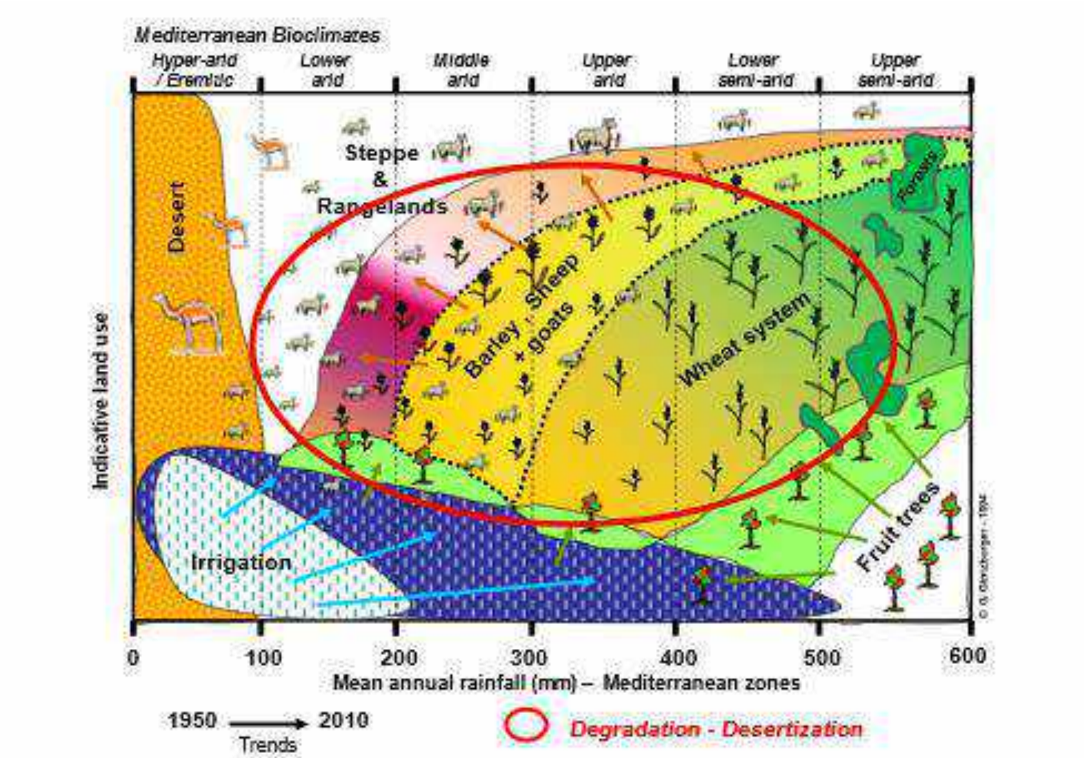

Fig. 1. Land use trends in West Asia and North Africa (Gintzburger, 1996)

Climate, Bioclimates And Droughts

Our study analyses Libyan climatic data from 1945 to 2010, revealing differences in spring rainfall between the northwest and northeast regions and rainfall variability. It examines climatic factors affecting native vegetation and rainfed cropping. Libya was not immune from long-past climatic oscillations, with evidence from paleoclimatology and archaeology.

Geomorphology And Landforms

Geomorphology is crucial for understanding arid zones' ecology and vegetation distribution. Northern Libya is dominated by Cretaceous limestone altered over millions of years. The Sirte region results from long-past marine transgressions. Quaternary terraces, saline coastal endoreic depressions, thick loess deposits, and sand deposits are common features. Wind and water erosion, along with land clearing and overgrazing, continue to alter and chisel landforms and soils.

The Libyan Soils

Based on research in southern Tunisia, we identify and classify the main Libyan soils based on the topsoil and upper horizons supporting native vegetation. Our soil description and classifications remain easily accessible to rangeland ecologists and land developers. It provides for easy soil interpretation and identification from vegetation type, ecological group, plant association, or presence of specific indicator plants. We produced a synthetic soil map of Northern Libya based on our classification and field experience.

The Vegetation Types
Libyan landscapes are shaped by geology and geomorphology, resulting in various vegetation types, and ecological groups modelled by climate, soil types, and land use, creating specific plant associations altered by land use and grazing pressure. Vegetation surveys require detailed phyto-sociological studies necessitating a deep understanding of environmental parameters and plant taxonomy. It necessitates incessant field trips and surveys, herbarium collection and accurate plant identification, complemented with local knowledge collected from shepherds and farmers.

The Most Common Libyan Rangeland Plants
We illustrate 262 plants from 51 families commonly found on Libyan rangelands with their scientific and vernacular names, life form, description and morphology, reproduction, pastoral importance, palatability and fodder value, toxicity, economic interest, habitat, distribution, and endemism.

From Rangeland Vegetation Standing Biomass To Stocking Rates
Sustainable rangeland management necessitates biomass field measurements, Rain-Use-Efficiency evaluation, satellite imagery processing and GIS. However, grazing decisions based on western concepts of carrying capacity and stocking rates are not suitable for shepherding in arid zones due to logistical constraints, water availability, flock management, and land tenure issues.

The Rainfed Ley-Farming System On Rangelands In Western Libya
The Australian ley-farming system, implemented from 1973 to 1984 on 50,000 hectares of Western Libyan rangelands, improved rainfed cereal yield and sheep production compared to the traditional system as long as annual rainfall was about 250-275mm. However, the Australian system was difficult to manage due to low erratic rainfall and required constant Australian expertise and Libyan colleagues' training. The technology transfer to private farmers failed due to lack of community participation, small farm size, and complexity of the input system. It was abandoned for more profitable irrigated vegetable and fruit tree production or reverting to free rangeland grazing.

Livestock On Libyan Rangelands
For centuries, Libyan rangelands have been home to herded small ruminants and dromedaries supported by native vegetation and scanty water resources, both limiting livestock numbers. Droughts would occasionally reduce their numbers, taking years to restock. Today, degraded Libyan rangelands are not producing the necessary feed to sustain rocketing livestock numbers. Feed and barley grain production are insufficient despite expanding rainfed cropping targeting the best rangelands. Livestock are now mostly artificially fed under open-air feedlots using subsidised imported barley grain. With overstocking causing desertification, it also stimulates the spread of infectious diseases barely controlled. The livestock situation is dire and cannot be solely attributed to climate change.

Water On Rangelands
Water availability is vital for arid rangelands communities. Since antiquity, they dug shallow wells, built cisterns and developed efficient water harvesting and flood farming. Widely spaced watering facilities was the norm up to the end of WWII, but perceived as a limitation to modern rangelands management, hence uncontrolled implementation of legal and illegal wells and cisterns. Modern drilling and pumping stations accessing deep aquifers with hauling water to the most remote rangelands accelerated rangeland degradation. Without strict control and policing water resources, Libyan rangelands will be totally degraded, leading livestock to be exclusively fed on stationary open-air feedlots.

Tribes And Territories

Berber and Arab Libyan tribes managed their rangelands despite endless battles, invasions and colonisations, fiercely defending and controlling their territories. Each tribal territory covers a diversity of landscapes and rainfall zones allowing for balanced resources and sustainable land management. Tribal rules about territory and shared resources are reviewed with examples from the West, Sirte and the East extending deep into the southern desert. With the discovery of oil reserves by 1959, the Libyan tribal system and economy gradually evolved, leading impoverished nomads and semi-nomads to quit the rangelands for financially secure but humble employment. Yet, the *esprit de corps*, traditions and rules within and between tribes remains strong to these days. The weaving art composing the elements of the customary bedouin tent is portrayed as steadily disappearing.

Forests, Afforestation, Fuelwood And Charcoal

Libya still benefits from a wealth native trees and shrubs. The use of fuelwood and charcoal is a part of Libyan culture. Native forests, woody shrubs, and afforestation are relentlessly threatened from illegal logging and charcoal manufacturing. Current forestry and rangelands legislations are inefficient. Without policing, accurate mapping and monitoring, fuelwood resources will continue to be plundered. Alternatives to fuelwood harvesting and charcoal manufacturing are reviewed. Afforestation projects must be encouraged using native and appropriate exotic species. Without immediate actions to remedy illegal logging and charcoal manufacturing, Libya will soon see its native forests, exceptionally drought resistant trees, and forestry plantations decline, widening already rampant rangeland desertification.

Past And Present Wildlife On Libyan Rangelands

Wildlife is an essential element of rangelands and forests, and a sign of good health of the ecosystems. These days, in Libya, even in the most desert remote areas, native herbivores, carnivores and birds are mercilessly hunted. Hunting, not anymore a vital necessity, is replaced with indiscriminate illegal sport hunting leading to wildlife massacres. We review, describe and illustrate the Libyan wildlife from prehistoric to modern time.

Assessing Rangeland Recovery, Degradation And Desertification

Rangeland bio-physical recovery, degradation or desertification are azonal and affect all arid Libyan rangelands. The anthropogenic reasons are well known with climatic high variability and possible climate changes. We review the methods and tools to assess rangeland health from simple site- and date-specific measurements to the most advanced complex satellite imagery time-series processing allowing monitoring and mapping trends over large areas. Rangeland degradation, often over emphasised in media, is not inescapable as many examples confirm rangeland recovery. Libyan rangeland managers, decision makers and scientists could benefit from these technologies to accurately identify, locate rangelands recovering and prioritise treatments of degraded areas under threat of desertification.

Recovery, Restoration And Rehabilitation Of Degraded Rangeland

Rangeland rehabilitation techniques were implemented on tens of thousands of hectares in Northern Libya. Rangeland passive protection and deferred grazing remain the cheapest and most efficient techniques well accepted by shepherds. Active means of rehabilitation, such multipurpose shrub plantations combined with water harvesting techniques and phosphate fertilization may be necessary. Reseeding with native rangeland species remains to be explored, especially with annual *Medicago* sp. (Medics) pods. Reallocating the best rangelands to fodder shrubs plantations is labour-intensive, and expensive, and is neither valued nor accepted by rangeland communities. Rangeland protection, multipurpose shrubs plantations, reseeding, low-cost water harvesting techniques, and minimal fertilisation produced satisfactory technical results on Libyan rangelands. They remain doomed unless supported by local communities.

Agro-Ecological Zoning Of Libya: The Case Of Barley And Olive Tree

Considering the barley grain deficit and current plans to expand olive tree production, is there some agricultural land still available for rainfed farming in Libya ? We developed an agro-ecological zoning methodology based on algorithms and GIS mapping filtering limiting climatic, soils, and barley and olive tree agro-ecological and agro-biological factors. We produced maps of western and eastern Libya excluding current land use and accurately locating suitable land for the two crops. The methodology could be improved providing up-dated land use map and refined limiting factors. Cropping, planting new trees on additional suitable land would have to remain with identified communities, property rights and traditional laws.

Overall Conclusions

Despite their apparent monotony, the Libyan rangelands are ecologically extremely diverse due to a rich geology and climate shaping landscapes supporting various soil types, in turn defining plants associations. For centuries, plant associations provided free feed and wildlife resources to rangeland communities. There was a fragile equilibrium between resources and demand. This equilibrium, often broken by droughts or unrest, tilted towards creeping land degradation past WWII and accelerated by 1970 with the oil discovery, increasing human and livestock population, wealth and urbanisation. The Libyan rangelands are these days in a crisis, unable to sustain the current livestock numbers. This is unsustainable without importing vast quantity of complementary subsidized feed, illegally drilling wells and constructing countless new watering places, all contributing to more rangeland desertification. The culprit is not climate change, but simply the man.

Grassland restoration in the face of invasive species: A British Columbia, Canada case study

Gardner, WC[1]; Robinson, MJ[2]; Gordon, K[1]

[1] Thompson Rivers University, Kamloops, BC, Canada; [2] BC Ministry of Forests, William Lake, BC, Canada

Key words: invasive species management; spotted knapweed; grassland restoration; temperate grasslands

Abstract

The preservation and ecological integrity of temperate grasslands globally are under threat, making the effective control of invasive species crucial. The spread of spotted knapweed (*Centaurea stoebe,* spp. *Micranthos*) endangers native plant biodiversity and the functioning of grassland ecosystems in British Columbia, Canada, where temperate grasslands cover less than 1% of the province's total area but contain more than 30% of the province's threatened species. To combat this threat, a project was launched in 2022 on Red Hill within Lac du Bois, the second-largest protected grassland area in British Columbia, to test various knapweed treatments and evaluate grassland restoration success. This project employed a randomized block design to compare six treatments: a control, hand pulling, mowing using a weed whacker, spraying Milestone^{TM} (broadleaf selective herbicide with active ingredient aminopyralid) at high (0.5 l/ha) and low (0.29 L/ha) concentrations during the bolting (just prior to flowering) stage of knapweed, and spraying Milestone^{TM} in the fall at a high (0.5 L/ha) concentration. Percent cover data were collected and analyzed using a nonparametric Kruskal-Wallis test, with a post hoc pairwise comparison to further investigate differences between treatments. Variables examined included the cover of knapweed, bare ground, native and non-native forbs, native and non-native grasses, native shrubs, and species richness. Spray treatments proved highly effective in eliminating spotted knapweed, significantly decreasing both non-native and native forbs while increasing native grass cover. Hand pulling and mowing were less effective in reducing knapweed and had limited effect on native grass cover. These findings offer valuable insights for efforts to restore native grassland by managing invasive species. Ongoing data collection at this site will continue, making it an effective demonstration site for raising awareness about grassland restoration.

Introduction

Invasive plants pose significant threats to British Columbia's landscapes, particularly its native grasslands, which account for less than 1% of the province’s land area (GCC 2017). Lac du Bois, a protected area adjacent to Kamloops, is a vital grassland reserve but faces numerous threats, including recreation, overgrazing, climate change, and invasive species. Among these invasives, spotted knapweed (*Centaurea stoebe spp. micranthos*) is of major concern. Originally introduced from Europe in the 1890s, this aggressive plant spreads easily and forms monocultures that outcompete native species (Marrs et al. 2008), reducing biodiversity, forage availability and resulting in other negative impacts (Sheley et al. 2001, Tyser and Key 1988). Despite its protected status, Lac du Bois is at high risk of further knapweed invasion, exacerbated by disturbances like overgrazing and climate change.

Efforts to control spotted knapweed at Lac du Bois, specifically in the Red Hill Demonstration area, involve a range of methods, including herbicide, hand pulling, weed whacking, and seeding. Each technique has its own advantages and challenges, with herbicides being necessary for large infestations and hand-pulling effective for smaller ones. Integrating these control methods is essential for successful long-term management. Restoration is also key, with strategies focusing on reintroducing native plants and managing competition from weeds. The current project aims to compare six treatments, evaluating their effects on knapweed cover, native vegetation, and species richness in order to inform future management practices in the region.

Methods

The study was conducted in the Thompson-Pavilion grassland region, specifically at Red Hill in the Lac du Bois protected area. This region is influenced by a dry climate due to the rain shadow from coastal mountains, with cold winters and hot summers. Red Hill, located in the Bunchgrass Nicola Very Dry Warm (BG xw1) biogeoclimatic zone, represents middle grasslands with an elevational range of 700-1000 meters. Dominant plant species in this zone include bluebunch wheatgrass (*Pseudoroegneria spicata*), rough fescue (*Festuca campestris*), and flowering plants such as mariposa lily (*Calochortus macrocarpus*) and yarrow (*Achillea millefolium*). Red Hill is known for its distinct reddish soil and rocky terrain, and prior to protection, was heavily impacted by motorized vehicles. The area, which also serves as grazing land for cattle, has been the focus of various restoration efforts, including invasive plant removal and grassland enclosures to monitor recovery.

The experimental plots for the Red Hill project were established in the summer of 2022, and treatments were applied on June 27, 2022, with post-treatment data collected a year later. The study utilized a randomized block design, with the site divided into two sections to avoid previously seeded alfalfa strips. A total of 24 plots, each 7.5x7.5 meters, were used to compare six treatments: control (C), high-concentration (o.5 L/ha) Milestone™ herbicide during bolting (SH), low-concentration (0.29 L/ha) Milestone™ during bolting (SL), high-concentration (0.5 L/ha) Milestone™ in the fall (SF), hand pulling (HP), and mowing using a weed whacker (WW). Milestone™ has the active ingredient aminopyralid and is selective for broadleaf plants. Each plot was marked with fluorescent stakes and had a central 2x2-meter monitoring plot. Data collection included estimating percent canopy cover in categories such as grasses, forbs, shrubs, bare soil, and species richness was determined by counting different plant species within the plots.

Statistical analysis was conducted using a nonparametric Kruskal-Wallis test to assess whether the treatments had significant effects on the variables measured, including knapweed cover, bare ground, and native and non-native vegetation. Post hoc pairwise comparisons were used to analyze differences between treatments. The results were considered statistically significant if the p-value was less than 0.05, with SPSS used for all data analysis. Three replicates were used for most treatments, while hand-pulling and weed-whacking had six replicates each to assess treatment effectiveness.

Results

The results of the study indicated significant differences in knapweed cover across the various treatments ($p = 0.001$). Specifically, the spray treatments (high fall concentration, high bolting concentration, and low bolting concentration) successfully eliminated spotted knapweed, resulting in zero cover in those plots, as shown by the absence of error bars in the data (Figure 1a). In contrast, the hand pulling (HP) and weed whacking (WW) treatments did not produce a significant decrease in knapweed cover. The study also found differences in native grass cover among the treatments ($p = 0.026$), with the spray treatments demonstrating significantly higher native grass cover compared to the control, while HP and WW treatments did not yield significant changes in native grass cover (Figure 1b).

Additionally, the treatments impacted non-native and native forbs differently, with non-native forb cover showing significant reductions in the spray treatments (p = 0.008), including zero cover in the high bolting concentration. Although HP and WW treatments did not show a significant decrease in non-native forbs, they exhibited a higher mean cover of native forbs compared to the spray treatments (p = 0.004), albeit without significant differences from the control (Figure 1c). Species richness varied across treatments (p = 0.006), with spray treatments having lower species richness than the control, though not significantly different (Figure 1d). HP and WW treatments had higher species richness but also did not show significant differences from the control. Overall, the findings highlight the effectiveness of spray treatments in controlling knapweed and their implications for native plant recovery.

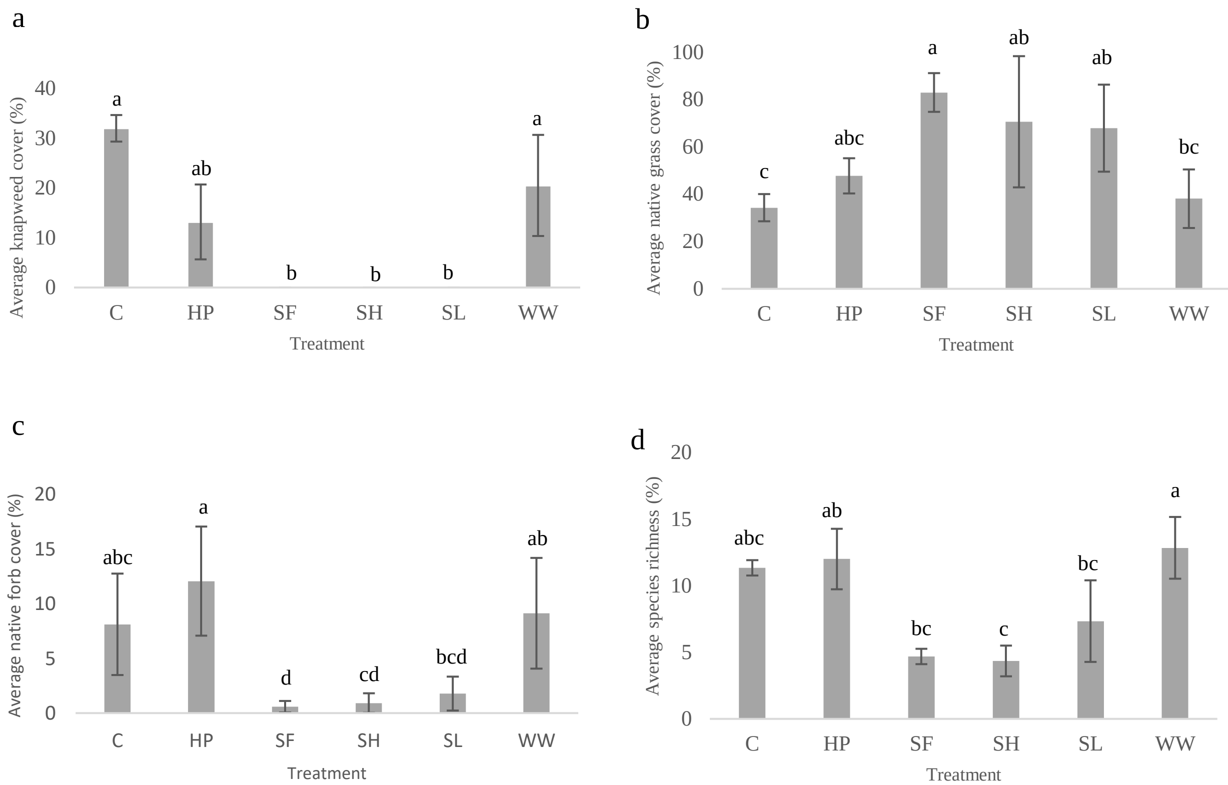

Figure 1. Mean percent cover in 2023 by treatment of a) spotted knapweed; b) native grass cover; c) native forb cover; and d) species richness. Treatments: control C, hand pull HP, spray Milestone™ high concentration fall SF, spray Milestone™ high concentration at bolt SH, spray Milestone™ low concentration at bolt SL and weed whack WW. Variables with different letters are significantly different ($p<0.05$) and error bars represent 1 standard deviation.

Discussion [Conclusions/Implications]

This study investigated the impact of various treatments on the management of invasive spotted knapweed and the subsequent recovery of native plant communities, focusing on bare soil cover, vegetation cover, species richness, and future management considerations. Findings revealed that the treatments resulted in low levels of exposed bare soil, all under 3%, aligning with reference conditions for grassland communities (Delesalle et al. 2009). While hand-pulling was expected to disturb the soil more than other methods, it did not significantly affect bare soil cover, allowing natural vegetation to recover over time. Overall, there was no excessive bare ground post-treatment, suggesting that the techniques employed did not lead to significant disturbance to the site.

In terms of vegetation cover, the herbicide Milestone™ proved to be the most effective treatment for controlling knapweed, achieving complete elimination in spray plots after a single application supporting the findings of Malone (2015) and Jacobs (2017). This treatment notably increased native grass cover to over 67%, a positive outcome in contrast to previous studies where herbicides led to increased non-native grass dominance (Skurski et al. 2013, Whitehouse 2021). Although the hand-pulling and weed-whacking methods did not demonstrate significant effectiveness in reducing knapweed density, they maintained a high cover of native forbs. The lack of notable changes in species richness across treatments suggests that while herbicide use facilitated native grass recovery, the overall species diversity remained stable.

The study acknowledges the limitations inherent in its design, such as the small number of replicates and the timing of treatments. The results indicate that in this specific setting Milestone™ herbicide can facilitate a return of native species without the need for additional seeding or restoration efforts, a promising result given concerns about invasive species dominance in similar contexts. However, it is important to emphasize the necessity of continued monitoring and treatment, particularly for hand-pulling and weed-whacking methods, which require repeated applications to be effective. Recommendations for future management include planting a native seed mix to promote biodiversity, investigating the introduction of biological control agents to complement existing treatment strategies, the application of treatments for at least two more years, the use of lower concentrations of Milestone™, and the development of a long-term monitoring plan to track the recovery of plant communities and the potential emergence of invasive species from the seed bank. Overall, the findings provide a solid foundation for enhancing grassland restoration efforts and addressing the challenges posed by invasive species like spotted knapweed.

Native Pasture Restoration in the Kimberley Rangelands, Western Australia – Seed Production Areas

Golos, PJ[1]; Revell, CK[2].

[1] Kings Park Science - Department of Biodiversity, Conservation and Attractions; [2] Department of Primary Industries and Regional Development.

Key words: seed; grass; revegetation

Abstract

The pastoral industry in the Kimberley region is an important economic contributor to Western Australia. However, as a result of past land management practices, there has been a decline of the more desirable native pasture grasses resulting in a loss of feed-base productivity. To reverse this decline, research is being conducted to help restore important native pasture grasses in this region.

In the Kimberley region, access to native grass seed for restoration is limited as wild-harvest is opportunistic, typically un-mechanised and ripe seed collection sites can be difficult to access during the wet season. Establishing a Seed Production Area (SPA) close to existing all weather roads will allow access to seed at the optimum harvesting time, and planting of single species on flat terrain will allow rapid and efficient collection of seed especially if using mechanical harvesters. Also, the use of fertiliser and irrigation could improve seed quality and increase seed production. This should improve the availability and reduce the cost of native grass seed for use in restoration of native grasses to degraded rangelands and mine-sites.

Six native grass species have been planted out on a small scale to trial a SPA located in Perth, Western Australia. Plants were fertilised and irrigated during summer. Plant growth and phenology were monitored and seed quality compared to wild-harvested seed. Irrigation extended the flowering period and hence seed production. Seed fill (a measure of seed viability) from the SPA was equal to or significantly greater than for wild-harvested seed. There was a trend towards increased seed yield and seed fill in the SPA when grasses were cut before summer re-growth, and with increased irrigation.

Introduction

The pastoral beef industry in the Kimberley region is an important economic contributor to Western Australia. The climate is tropical savanna, with hot wet summers (wet season) and dry winters (BOM 2024). Native grasses are the main forage resource for cattle (Chilcott *et al.* 2020), but the extremes of rainfall create seasonal patterns in forage quality. Extended periods of average and above average rainfall can encourage managers to increase livestock numbers. When seasons return to average or below average, these higher livestock numbers are often retained, which can result in overgrazing of preferred pasture plants, resulting in a loss of soil cover and therefore increased potential for degradation and a decline in productivity.

Seeding is one of the most used methods of restoring vegetation to degraded sites. Sourcing of seed for restoration largely relies on harvesting from wild plant populations (Neville *et al.* 2016). However, sourcing of seeds can be problematic, especially in remote areas like the Kimberley region of Western Australia. Access to seed is limited by a lack of suppliers and difficulty to access ripe seed after wet season rains due to road closures. The authors have noted after three years of seed collecting in the Kimberley, that seed ripening can be spatially and temporally heterogenous, requiring extensive resources and time to search large areas to find plants where seed has not dispersed or is ripe for collection. In addition, much of the rangelands are grazed or have experienced late wet season/early dry season burns reducing the available area for seed collection and requiring further travel. Also, seed collecting by foot can be hazardous especially on cracking-clay plains, where deep “crab holes” are concealed by long grass.

Establishing a Seed Production Area (SPA) close to existing all weather roads will allow access to seed at the optimum time, and planting of a single species on flat terrain will allow rapid and efficient collection of seed especially if using mechanical harvesters. Also, implementing horticultural practices like irrigation, the use of fertilizer and annual cutting of grasses could increase seed production and seed quality.

Methods

Wild seed was collected from a range of grass species growing on Napier Downs and Mt House Stations located in the Shire of Derby-West Kimberley in Western Australia during May, after the end of the wet season when road access was available. All six species chosen for this study (Table 1.) can be found growing in clay and/or loam soils with three species also found growing in sandy soils (Ryan et al. 2013).

Due to logistical and accessibility issues in setting up a SPA in the Kimberley, it was decided to trial a site at the University of Western Australia (UWA) research facility in Shenton Park, Perth. The soils are yellow-brown sands of the Spearwood dune system of the Swan Coastal Plain (McArthur and Bettenay 1960). The climate is subtropical, with a warm dry summer and cold wet winter (BOM 2024).

Tubestock was propagated from wild collected seed germinated in petri dishes and transplanted into tubes about 2-3 weeks after germination. Grasses were grown in a proprietary potting mix (supplied by Richgro, Jandakot, Western Australia) and in nursery conditions for 10 months before planting.

The SPA trial site at Shenton Park was established in late November 2022. The original planting comprised 206 plants consisting of five perennial and one annual grass (*Iseilema vaginiflorum*) species. In 2023, the trial was reduced to five perennial species of 176 plants (40 *Dichanthium fecundum*, 52 *Dichanthium sericeum*, 40 *Heteropogon contortus*, 18 *Panicum decompositum*, and 26 *Sehima nervosum*).

Each species was planted in separate plots. Within each plot, tubestock was planted in 3 rows 35 cm apart, with plants planted 40 cm apart in each row and offset with the adjacent row by 20 cm (6 plants/m^2). Fertiliser (Seamungus® by Neutrog) was added (1 handful) to the planting hole and mixed with soil before planting tubestock. All plants were hand watered for the first two weeks. Once established all plants were fertilised with NPK Blue (Cresco), one handful/m^2 on the 5 November 2023 and 26 February 2024. Overhead irrigation (approximately 30 minutes, 2-3 times/week) commenced 27th November 2023 with the volume applied doubling on the 20th of March 2024. To measure the effect of defoliation on future growth and seed production, approximately half of each perennial grass plot was cut (to a height of 10-15 cm) on the 11 September 2023. Seed was collected separately from cut and uncut sections of the plot every 1-2 weeks depending on the quantity of seed produced.

All seed harvesting, from the wild and SPA, was done by hand by lightly pulling at inflorescences to remove ripe florets and dropping into a bucket. Weights harvested are inclusive of florets for all grasses except for *P. decompositum* as seed readily fell out of florets during harvesting. Grass florets/seed were x-rayed to determine seed fill using a Faxitron Specimen Radiography System (MX-20 Cabinet X-ray Unit) (Faxitron, Wheeling, Illinois, USA).

Results

Wild seed was collected in May 2021, 2022, and 2023. While seed was found at Napier Downs every year, no or very little seed was found at Mount House in two of the three years. Seed collecting in the SPA commenced in February 2023 and seed was still being collected in June for *D. sericeum* and *S. nervosum*. While there was an extended period of seed production there was a peak of seed production in May for all species. Seed fill of grasses harvested in SPA was equal to or greater than wild-harvested seed (Table 1). In the SPA, seed yield and seed fill was greater when grasses were cut before summer growth. Also, following an increase in irrigation volume, seed yield increased by 3 to 50-fold and seed fill more than doubled for most species (Figures 1 and 2). There was an interaction between grass cutting and irrigation with the effect of cutting grass on seed yield and fill greater with low irrigation than high irrigation. For *H. contortus* there was no seed produced from uncut grass until after the irrigation volume was increased.

Table 1. Seed fill (%) of seed harvested from the wild (Wild) and the Seed Production Area (SPA) in Perth, (n = number of collections).

			Seed fill (%)			
Species	Common name	Soil type	SPA	n	Wild	n
Dichanthium fecundum	Bundle-Bundle	sand, loam, clay	12-51	5	12-39	3
Dichanthium sericeum	Blue grass	clay	48-87	5	43-63	3
Heteropogon contortus	Black Speargrass	sand, loam, clay	36-74	4	17-32	2
Iseilema vaginiflorum	Red Flinders grass	clay	32	1	21	1
Panicum decompositum	Native Millet	loam, clay	88-99	5	56-94	2
Sehima nervosum	White grass	sand, loam, clay	29-60	5	23-37	2

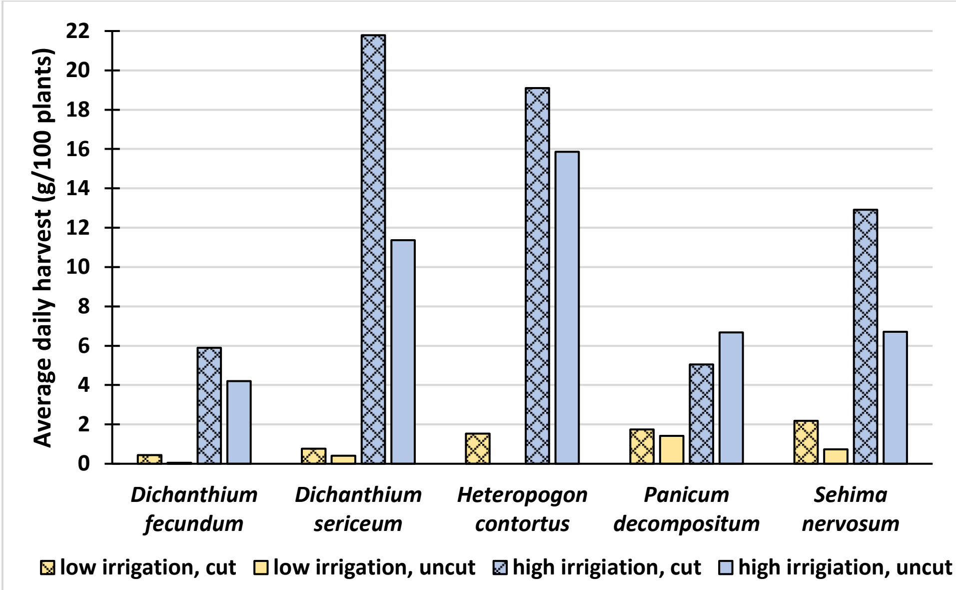

Figure 1. Average daily quantity of seed (g) collected from cut and uncut grasses grown in the SPA at Shenton Park, Perth before and after the increase in irrigation.

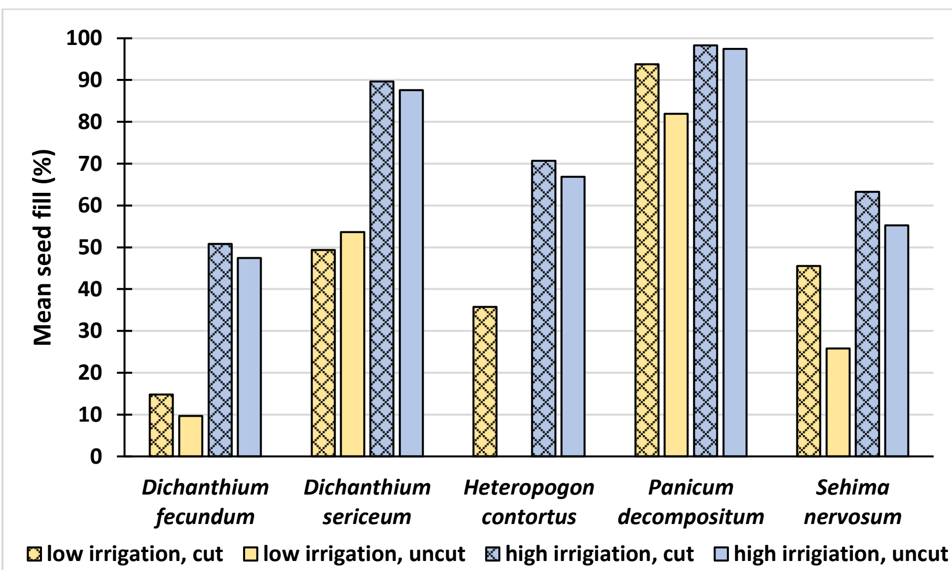

Figure 2. Mean seed fill (%) of seed collected from cut and uncut grasses grown in the SPA at Shenton Park, Perth before and after the increase in irrigation volume.

Discussion

This small-scale seed production area (SPA) in Perth demonstrated that the grass species trialled in this experiment can be successfully grown in climatic and soil conditions that differ to that of wild populations. Also, with irrigation and fertiliser, the SPA can produce larger quantities of viable seed by extending the period of flowering and hence seed production, and of higher quality (% seed fill) than seed collected from wild populations. Although the grasses were planted in soil and climate conditions quite different to wild populations, seed quality and productivity were not negatively impacted. The broad adaptability of these grasses to a range of site conditions, will enable the establishment of SPA close to population centres and infrastructure that will allow access to all weather roads, improve monitoring of plant growth and seed development, and allow the use of mechanized seed harvesting technology which will all lead to faster and more efficient harvesting of seed. We suggest the establishment of SPA is a feasible approach to improve the reliability of supply, quality of seed and potentially reduce the cost of supplying seed for use in restoring native pasture grasses in rangeland landscapes.

Key words: Crested wheatgrass; AUM; Grazing; Forage; Livestock

Abstract
Almost half the total land area of the United States is used for pasture and grazing, and nearly all of it is infested with weeds (Monaco et al., 2002) Rangeland pastures worldwide are often invaded by various weed species (Vasques et al., 2010). These invasions cause significant biological (Christensen et al., 2011) and economic loss (Whitesides, 2004). In the Mountain West region of Utah, cheatgrass, knapweed, medusa head, and hoary cress are just a few of the numerous invaders. Even though weeds are a serious problem and are difficult to control, it is possible to manage weeds (Jones et al, 2010) and restore pasture health and productivity.

We undertook a pasture renovation project in 2012 at the Y Ranch in Tooele County and Juab County, Utah in the Great Basin Region of the western United States. Invasive weeds, primarily knapweed, had degraded Y Ranch pastures. We aerially sprayed herbicide to kill weeds in a 728-hectare pasture then later fertilized the pasture; we did no seeding. Two years later AUMs had increased by 200. We wanted to measure forage production after ten years of livestock grazing to see how many AUMs were currently available twelve years after the renovation.

A forage production sample taken in May 2024 showed 91 kg/ha. The primary forage species was Crested Wheatgrass, *Agropyron cristatum.* Although crested wheatgrass is an introduced species in the Great Basin, it has shown an ability to establish when and where other species struggle. This pasture currently provides 225 AUMs of grazing where before the treatment it provided virtually no AUMs.

Introduction
Many rangeland pastures are infested with weeds that reduce their usefulness and productivity. Livestock grazing and wildlife diversity and numbers are diminished when non-useable plant species dominate. Squarrose knapweed (Centaurea virgata ssp. squarrosa) is particularly troublesome as it is a long-lived, tap

rooted perennial (Whitson et al. 2006). It can often form dense stands that crowd out useful plant species. Mature plants are from 30 to 46 centimetres tall and are very rough and abrasive. Wildlife will avoid moving through impenetrable patches. Knapweed and other invasive weed species can be eliminated by using the right herbicide and with proper application timing. Pastures can be restored and maintained in a productive state for several years if managed properly (Bidwell and Woods, 2017). The objective of this project was to eliminate Squarrose knapweed with herbicide so that useful forage species would have a chance to re-establish and grow. Our objective for the present study was to see how much forage production was available twelve years after our initial herbicide and fertilization treatment of Y Ranch pastures.

Methods

An area of 728 ha of rangeland pastures on Y Ranch, Tooele/Juab Counties, Utah was treated with Milestone® herbicide (Active ingredient: Aminopyralid, an auxin type growth hormone) and LINK® 30L foliar fertilizer (30-0-0, 30% polymer-based Nitrogen). Milestone® was applied aerially at the rate of 0.198 kg/ha in May 2012. LINK® 30L was applied with a ground rig boom sprayer in November 2012 at the rate of 14 L/ha.

Results

Dense stands of Squarrose knapweed were eliminated and by November 2012 we were able to apply fertilizer to encourage forage growth for the following season. Forage grass species, primarily Crested Wheatgrass, *Agropyron cristatum,* grew in abundance. Grazing of livestock on the treated area was deferred for two growing seasons. In the summer of 2014 AUMs of available forage had increased from 25 to 200 (Figure 1). After ten years of grazing, forage species were still abundant (Figure 2). Samples taken in May 2024 showed forage levels of 91 kg/ha and 225 AUMs. There was no sign of Squarrose knapweed on the treated area.

Figure 1. Before and after treatment of Squarrose Knapweed

Discussion and Conclusions

Much emphasis has been placed on reseeding with native plant species to restore rangeland, however many native species are unable to establish successfully because of aggressive invasive annual species. Downy brome, *Bromus tectorum* L., is especially troublesome on rangelands of the western United States. It is a prolific seed producer with a high rate of germination as both an annual and winter annual (meaning it can germinate in either late fall or early spring) and is an early maturer prone to ignition from sparks, lightning, and other sources of fire. It has been responsible for many failed seedings.

Crested Wheatgrass is known for resilience to weed invasion (Looman and Heinrichs 1973). It has shown potential (Hulet et al. 2010) to be a transition species by out competing invasives such as Downy brome and allowing other species, especially natives, to establish.

Because forage production on treated Y Ranch land has remained high for ten years and because knapweed is non-existent, Crested Wheatgrass may also be effective in preventing re-establishment of invasive perennials.

In this project it has also demonstrated its longevity. It is known to have a 15–20-year lifespan (Looman and Heinrichs 1973).

Steps can be taken to reverse the effects of weeds and pasture productivity can be restored. Use of an effective herbicide combined with proper timing of application can bring about positive results. In our project a combination of herbicide and fertilizer proved to be very effective. No reseeding was necessary.

A century of livestock exclusion reveals soil microbiome impacts in arid Australia.

Greening, RR[1]; Delean, S[1]; Facelli, JM[1]

[1] The University of Adelaide

Key words: soil ; microbiome; grazing

Abstract

Soil microbiome responses to disturbance in arid ecosystems remains a critical knowledge gap. This study examines the soil microbiome in the north-east pastoral zone of South Australia, comparing the TGB Osborn Vegetation Reserve, established in 1925 with livestock and rabbit-proof fencing, to the adjacent grazed Koonamore Station, a merino sheep-grazing lease. Soil bacterial and fungal community compositions were analysed through amplicon sequencing, revealing that livestock grazing is associated with specific microbial abundances and community structure, with distinct spatial patterns between bare soil areas and soil under perennial vegetation. Soils from open spaces in livestock grazing areas showed more disparity through reduced microbial abundances compared to soils ungrazed for 98 years. However, soils underneath shrub canopies in grazed areas showed increased abundances and taxonomic differences in comparison to ungrazed. Further research is needed to understand the functional consequences of these soil microbiome shifts on ecosystem function and services.

Introduction

Our understanding of soil microbiome responses to disturbance in arid ecosystems remains limited, as well as the timescales required for functional rehabilitation following disturbance (Toledo et al. 2021; Zhang et al. 2023). Soil microbes form complex, highly diverse communities with significant roles in ecosystem function, yet are largely undescribed and understudied, especially in arid systems (Liu et al. 2023). Within a landscape, different microsites are conducive of different microbial communities, and as such contribute to important processes such as nutrient cycling and soil surface stabilisation. Arid lands are water and nutrient limited, so perennial vegetation which can alter the distribution of resources play vital roles in the functioning of the system (Ludwig and Tongway 1995; Morton et al. 2011). Individual perennial plants create small-scale areas of high fertility beneath the canopy surrounded by lower fertility soil, called "fertile islands" (Garcia-Moya and McKell 1970). Microbial abundance, diversity, and activity have been found to be higher in fertile islands (Goberna et al. 2007). The ameliorated conditions combined with higher substrate levels in fertile islands directly contribute to enhanced nutrient cycling by microbes when compared to open spaces (Macdonald et al. 2015). Soil microbial communities that form biological soil crusts also play major roles in ecosystem services provisioned in the open spaces as well by stabilising the soil surface and fixing atmospheric nitrogen (Belnap and Lange 2003; Castillo-Monroy et al. 2011). Identifying the differences in soil microbiomes where livestock are present and excluded in both open and within fertile islands is crucial for assessing the system wide consequences of livestock grazing. Alongside limitations in identifying microbial species and function, another significant barrier in our understanding of soil restoration and impacts of livestock grazing on soil microbial communities is that there is only a small number of long-term grazing exclusion study sites for comparison (Allington and Valone 2014). This study conducts a cross-fence comparison between a unique 98 year ungrazed reserve and adjacent livestock grazed arid rangelands to address these critical knowledge gaps. The main hypotheses to be tested are: 1) perennial vegetation fertile islands will foster unique microbial communities in comparison to open spaces, and 2) 98 years of grazing exclusion will result in substantive differences in microbial communities compared to livestock grazed areas, and the impacts will be more substantive in open spaces compared to those under plant canopies.

Methods

Sampling was conducted in chenopod shrublands of the arid north-east pastoral zone of South Australia within the TGB Osborn Vegetation Reserve (32°07′S, 139°20′E), established in 1925 with a livestock and rabbit-proof fence, and the surrounding merino sheep-grazing lease on Koonamore Station.

Soil sampling and microbiome extraction and sequencing

Three soil cores (10cm diameter to 5cm depth) were taken beneath the 'Canopy' of selected *Eremophila sturtii* shrubs (that are unpalatable to livestock) within 10m of the TGB Osborn Vegetation Reserve (hereafter "reserve") exclusion fence and combined to make a single sample. The same approach was used to provide a composite soil sample from a randomly chosen paired site on 'Open' ground approximately 5 metres away. Composite samples were homogenised, sub-sampled into 5g tubes and stored in a -18°C freezer. Sampling was replicated for both ungrazed sites inside the 'Ungrazed' reserve and at 'Grazed' sites outside the reserve in May 2023 (Autumn; n=24) an in September 2023 (Spring; n=41).

PCR amplification and sequencing of soil samples was conducted by the Australian Genomic Research Facility (AGRF, Adelaide, Australia) on the Illumina NextSeq2000 platform (San Diego, CA, USA). DNA was extracted using the PowerSoil Soil DNA Isolation Kit (MoBio Laboratories, Solana Beach, CA, USA). Two regions of ribosomal DNA, 16S and ITS, were amplified to assay the bacterial and fungal communities using the forward and reverse primers, 341F - 806R for bacteria, and ITS1F - ITS2R for fungi. Fungi and bacterial communities were sequenced from Autumn samples (n=24) and only fungi was sequenced from Spring samples (n=41) for logistical reasons.

Bioinformatic pipeline and statistical analysis

The bioinformatics analysis involved demultiplexing, quality control, Amplicon Sequence Variant (ASV) calling, and taxonomic classification. The demultiplexed raw reads are primer trimmed and quality filtered using the cutadapt plugin followed by denoising with DADA2 (Callahan *et al.* 2016) (via q2-dada2). Taxonomy was assigned to ASVs using the q2-feature-classifier classify-sklearn naïve Bayes taxonomy classifier (Bokulich *et al.* 2018). Diversity profiling analysis was performed using QIIME 2 2019.7 (Bolyen *et al.* 2019). To assess the multivariate response of microbes to grazing and canopy cover, multivariate permutational analysis of variance was used to model the ASV inter-sample Bray-Curtis dissimilarities as a function of Canopy/Open and Grazed/Ungrazed treatments while accounting for spatial clusters (i.e., blocks) and random spatial site-pairs (shrub Canopy-Open ground pairs). To determine microbial community compositon patterns between grazing and canopy treatments and sampling date, the assigned taxonomy of fungal (at Class level) and bacterial (at Phylum level) ASVs were aggregated to visualise the broad patterns of the read counts, representing the relative abundances, of these taxa at easily distinguishable taxonomic levels. To determine if ASV's are indicative of any multivariate treatment differences, Indicator Species Analysis (De Cáceres and Legendre 2009) was conducted on the read counts, representing the relative abundances, of the fungal and on the bacterial data and the Phylum and Class compositions as a proportion of the indicator species were plotted for visualisation.

Results

Fungal community

There were 4002 fungal amplicon sequence variants (ASVs) identified across 24 Autumn-sampled sites; the most abundant Phyla were Ascomycota and Basidiomycota, by majority, and Chytridiomycota, Mortierellomycota and Rozellomycota. Fungal abundance was higher under Canopy in the Grazed compared to Ungrazed Canopy, whereas in Open sites there was considerably higher fungal abundance in the Ungrazed compared to Grazed Open soils. This result was consistent across the two seasons (**Figure 1**). The multivariate response differed between Canopy and Open sites (*p-value* = 0.001) as well as between the Ungrazed and Grazed sites (*p-value* = 0.03). The same Phyla were rank-ordered most abundant in 3911 fungal ASVs identified across 41 sites sampled in Spring, with the exception that Glomeromycota replaced Rozellomycota as the fifth-ranked taxon. The multivariate ASV abundances differed between Canopy and Open (*p-value* < 0.0001) in Spring, though these fungal community differences were not the same across all surveyed blocks (microsite*block *p-value* = 0.01). Similarly, average differences among the blocks varied between the Ungrazed and Grazed sites (block*grazing (*p-value* < 0.05)).

There were 72 fungi ASVs identified as indicators for differences between Canopy and Open sites and an additional 38 indicator ASVs for Grazing-Ungrazed differences in Autumn. The number of indicator ASVs differed only slightly for the Spring data; 62 Canopy-Open indicators and 35 Grazing-Ungrazed indicators.

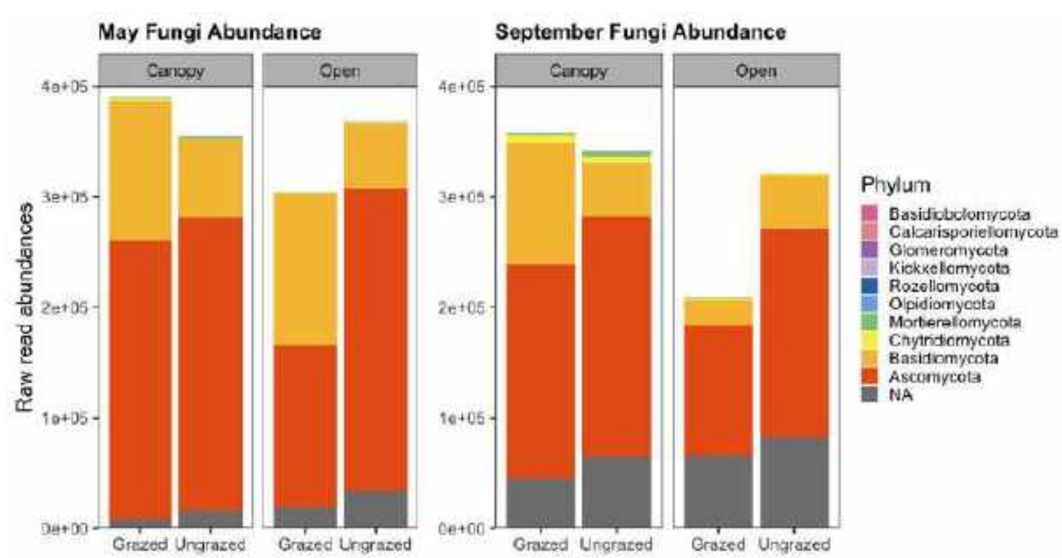

Figure 1. The raw read abundances of fungal Amplicon Sequence Variants (ASV) identified to Phylum across microsites and grazing treatment between sampling periods in May and September in 2023 at Koonamore, South Australia.

Bacteria and archaea community

There were 8412 ASVs (of which 8367 were bacterial and 45 archaeal) identified across 24 Autumn-sampled sites; the most abundant Phyla were Actinobacteria by majority, followed by Chloroflexi, Proteobacteria, Acidobacteria, Gemmatimonadetes, Cyanobacteria, and Firmicutes. The only recorded archaeal Phyla were Thaumarchaeota and Euryarchaeota. Bacterial abundance was higher under Canopy and higher in the Grazed areas compared to Ungrazed (**Figure 3**). The multivariate response differed between Canopy and Open sites (p-value = 0.02) as well as between the Ungrazed and Grazed sites (p-value = 0.006).

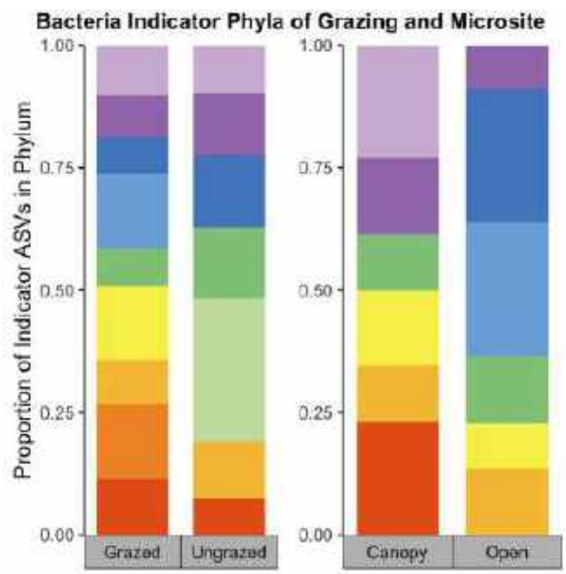

Figure 2. The proportion of bacterial Indicator species classified into Phylum plotted as a proportion of the total assigned indicator species in both grazing and microsites.

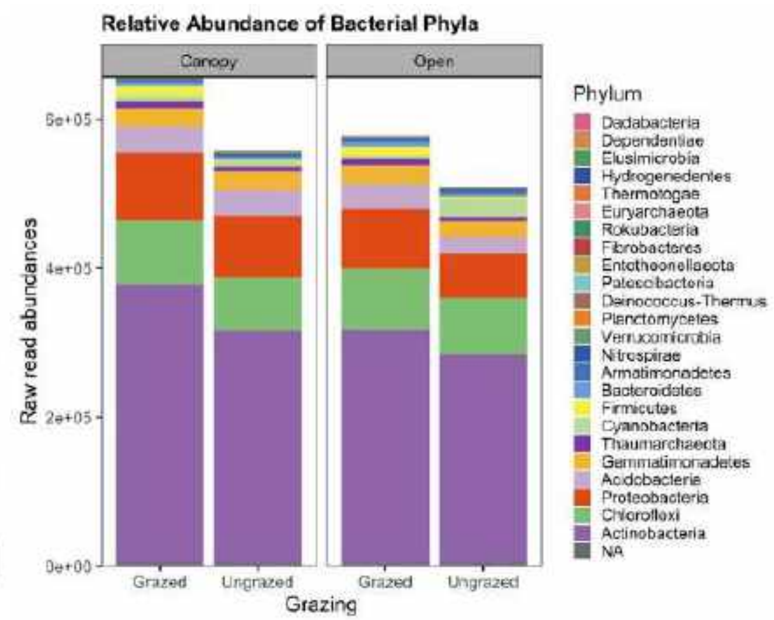

Figure 3. The raw read abundances of bacterial Amplicon Sequence Variants (ASV) identified to Phylum across microsites and grazing treatment in May 2023 at Koonamore, South Australia.

There were 61 fungi ASVs identified as indicators for differences between Canopy and Open sites and an additional 88 indicator ASVs for Grazing-Ungrazed differences in Autumn (**Figure 2**).

Discussion

This study's cross-fence comparison revealed significant differences between livestock Grazed and long-term Ungrazed soil microbiomes, with distinct variation in responses between fertile island soils and soils in open spaces. The fertile island effect was evident for bacterial taxa, with abundances higher in Canopy soils in both Grazed and Ungrazed soils compared to Open soils. Higher abundances of soil bacteria and fungi in fertile islands is well documented throughout both Australian and worldwide drylands, associated with increased substrates and ameliorated conditions under perennial vegetation (Ding and Eldridge 2021; Noy-Meir 1973). However, the distinct fertile island effect was not consistently found in both Grazed and Ungrazed soils for fungal taxa in this study. Specifically, fungal abundances in Ungrazed conditions did not consistently show a fertile island pattern, with Open soil fungal abundance higher than Canopy in May; however in September, a slight fertile island effect could be seen. Compared to the pronounced Canopy-to-Open differences in Grazed soils, it is hypothesised that this response may be due to physical disturbance of biological soil crusts by livestock. Previous studies indicate that fungi are more sensitive to physical disturbance than bacteria and that ungulates can adversely impact Australian dryland soils (Eldridge and Delgado-Baquerizo 2018; Eldridge et al. 2016; Zhang et al. 2016).

In addition to abundance differences, there are significant community composition differences between Grazed and Ungrazed soils that are hypothesised to result in differences in soil function. Bacteria were more abundant in Grazed areas, with that higher abundance mostly found in Canopy soils. Fungi were more abundant in grazed Canopy soils but considerably less abundant in open Grazed areas compared to the Ungrazed overall. For bacterial communities, the most abundant taxa remain similar across grazing treatments and between Canopy and Open, however differences emerge in taxa that form smaller proportions of the overall community. Taxa from the bacterial phylum Firmicutes were more abundant and indicative of Grazed soils, while taxa from phylum Cyanobacteria were more abundant and uniquely indicative of Ungrazed soils. These abundance and community composition shifts may impact the known spatial partitioning of ecosystem services such as nutrient cycling in arid ecosystems (Macdonald et al. 2015). While this study has identified multiple significant compositional and abundance differences, limited knowledge of the functional classifications of these taxa prevents interpretation of the processes leading to these differences without further soil functional analyses.

This study highlights the significant spatial heterogeneity of soil microbiomes, influenced not only by perennial vegetation but also by disturbance. These findings underscore the importance of considering small-scale variation to comprehend the broader impacts of disturbance and recovery in arid ecosystems.

Inhibitory effects of *Phytolacca americana* extracts of different solvents on *Pestalotiopsis microspora*: The causal agent of blueberry leaf spot

Jin-mei Guo[1,2]; Shu-qing Zhang[1,2*]; Jian-feng Li[1,2]

1. School of Geography and Resources, Guizhou Education University, Guiyang, Guizhou, 550018, China; 2. Institute of Soil and Environment Bioremediation in Karst Habitats, Guizhou Education University, Guiyang, Guizhou, 550018, China

Key words: P*hytolacca americana*, *Pestalotiopsis microspora*, inhibitory rate, EC_{50}

Abstract

Inhibitory effects of different *Phytolacca americana* L. extracts on *Pestalotiopsis microspora*, a fungal pathogen isolated from blueberry leaf spot, were determined by a growth rate method. Effects of *P. americana* extracts from different tissues (leaves, roots, stems) obtained with five different solvents on inhibitory rates of *P. microspora* were determined by measuring fungal growth. Ethanol and acetone *P. americana* extracts clearly inhibited growth of the fungal pathogen, and inhibition rate was positively correlated with treatment concentration. Inhibitory effects of ethanol extracts were significantly greater than those of the acetone extracts, and the optimal inhibitory effect (Using EC_{50} to express the median lethal concentration) was at 0.004 g mL^{-1}. Water, petroleum ether, and benzene extracts did not significantly affect *P. microspora* growth. Leaf extracts of *P. americana* had the strongest inhibitory activity, followed by that of root and stem extracts. In this study, the ethanol extract from *P. americana* leaves had the greatest inhibitory effect on *P. microspora*, the causal agent of blueberry leaf spot, and thus, ethanol might be the best choice of solvents to extract bacteriostatic substances from *P. americana*. The study provides basic data for continued research and development of biopesticides.

Introduction

Phytolacca americana is in the family Phytolaccaceae, and it has a wide range of growth, strong adaptability, easy harvest and low price(Zhang *et al.* 2020).In addition to medicinal value(Zou *et al.* 2019), P. americana has attracted much attention for its insecticidal(Wang *et al.* 2019), acaricidal, bacteriostatic, and antiviral activities.

Zhao et al. measured the inhibitory effects of Phytolacca acinosa extract on four types of bacteria by a filter paper method(Zhao *et al.* 2010). In that study, some of the Phytolacca extracts had antibacterial activity, and most of the substances with the strongest antibacterial activity were in the root system. Overall, antibacterial activities of different extracts were different against different bacteria. Ge et al. showed that extracts from fruits and branches of Phytolacca significantly inhibited proliferation of tobacco mosaic virus(Ge *et al.* 2015). Although bacteriostatic effects of Phytolacca have been reported, bioassays of Phytolacca bacteriostatic activity on pathogenic fungi are lacking.

In this study, extracts were obtained from roots, stems, and leaves of P. americana by using five different solvents: water, petroleum ether, acetone, ethanol, and benzene. Inhibitory effects of the different extracts on the pathogenic fungi P. microspora isolated from blueberry leaf spot were determined. The goal was to clarify differences in the inhibition of P. microspora activity by the different extracts to provide ideas for the development of biopesticides.

Methods

The damaged blueberry leaves were collected from Maling Township Blueberry demonstration Garden, Huaxi District, Guiyang City, Guizhou Province, China (latitude 106.594775, longitude 26.275049). For identification based on ITS(NCBI nucleotide sequences PP346193 and PP346194). The fungal pathogen was identified as *Pestalotiopsis microspora*.

Whole *P. americana* were collected from Guding Village, Xiaba Town, Wudang District, Guiyang City, Guizhou Province, China(latitude 106.898299, longitude 26.692004). Roots, stems, and leaves were dried at 38° C, crushed, and sifted through a 20-mesh screen.

Water, petroleum ether, acetone, ethanol and benzene with different polarity were selected to form a series of solvents. Five concentration gradients were set, and two different extraction methods (Yang *et al.* 2005).

Fragments of the symptomatic leaves were used for indirect isolation of the causal agent in potato dextrose agar (PDA) medium (Jéssica *et al.* 2022). Mycelial disks of Pestalotiopsis microspora was prepared by a growth rate method. And colony diameter was measured by crossing method.

Results

Inhibition rate of acetone extracts from Phytolacca americana against Pestalotiopsis microspora

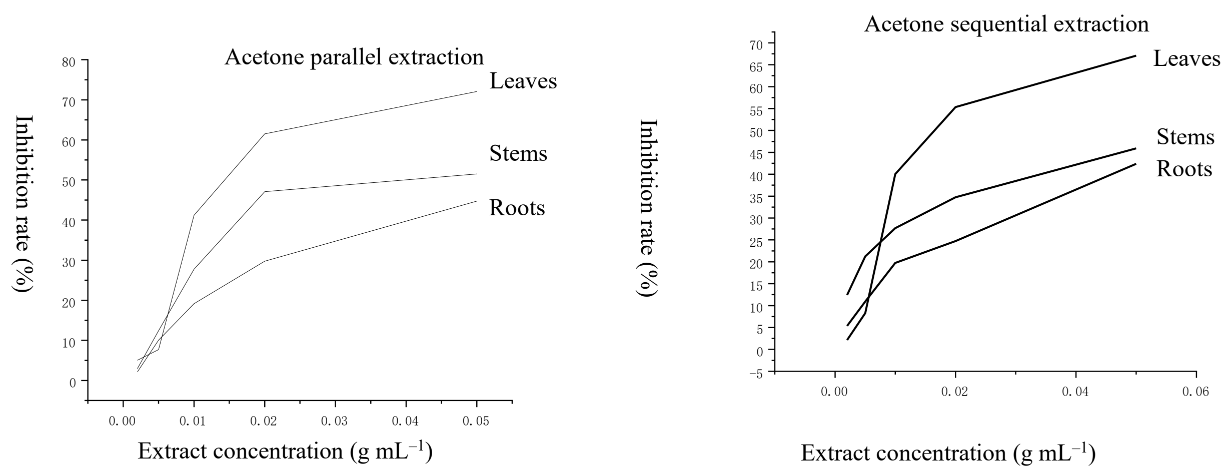

Figure 1 Comparison of inhibitory rate of *Phytolacca americana* acetone extracts from two different extraction methods

Inhibitory rate of acetone extracts from roots, stems, and leaves of *P. americana* on *P. microspora* are given in Figure 1 . When the concentration was 0.05 g mL^{-1} from parallel extraction, the leaf extract had the strongest inhibitory effect, with an inhibition rate of 72.1%. When the concentration was 0.002 g mL^{-1}, the inhibition effect of the root extract was weak, with an inhibition rate of only 2.1%. In sequential extraction, the inhibition rate of the leaf extract at 0.05 g mL^{-1} was 67.1%, which was the maximum inhibition rate of sequential extracts. Acetone extracts of both parallel and sequential extraction methods had inhibitory effects on *P.microspora* across the range of concentrations, with bacteriostatic rate increasing with increasing extract concentration. In parallel and sequential extractions, leaf extracts had the highest inhibitory rate. Overall, treatment concentration and inhibition rate were positively correlated for acetone extracts from different parts of *P. americana*.

Inhibitory rate of ethanol extracts from Phytolacca americana against Pestalotiopsis microspora

Inhibitory rate of ethanol extracts from roots, stems, and leaves of *Phytolacca americana* on *P. microspora* are shown in Figure 2 . In parallel extraction, the strongest inhibition effect was with the leaf extract at 0.05 g mL^{-1} , with the inhibition rate of 77.59%. In sequential extraction, the inhibition rate of the leaf extract at 0.05 g mL^{-1} was 71.99%, which was the maximum inhibition rate of sequential extracts. The inhibition rate of root, stem, and leaf ethanol extracts from parallel extraction increased with the concentration. Overall, treatment concentration and inhibition rate were correlated for ethanol extracts from different parts of *P. americana.*

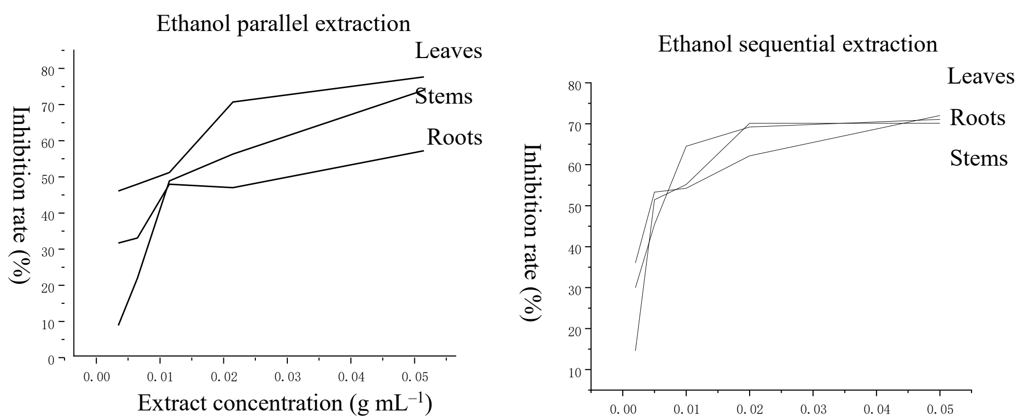

Figure 2 Comparison of inhibitory rates of *Phytolacca americana* ethanol extracts from two different extraction methods

Comparison of virulence and significance analysis of ethanol and acetone extracts of Phytolacca americana against Pestalotiopsis microspora

According to inhibition rates, virulence regression equations were established, and inhibitory medium concentrations (EC_{50}) were calculated. Virulence regression equations and correlation coefficients (r) were used to compare the toxicity of *P. americana* ethanol and acetone extracts to *P. microspora* (Figure 3). according to EC_{50} values of extracts from roots, stems, and leaves, the inhibitory effects of ethanol extracts were generally greater than those of acetone extracts, and the inhibitory effects of leaf extracts were better than those of root and stem extracts.

When acetone was used as the extractant at 0.05 g mL^{-1}, whether parallel or sequential extraction, the inhibitory rate of leaf extracts was significantly higher than that of stem and root extracts. When ethanol was used as the extractant, the inhibitory rate of the leaf extract was significantly higher than that of the stem extract with parallel extraction, but there was no significant difference among root, stem, and leaf extracts when extracted sequentially. Thus, extraction method and order affected the bacteriostatic rate.

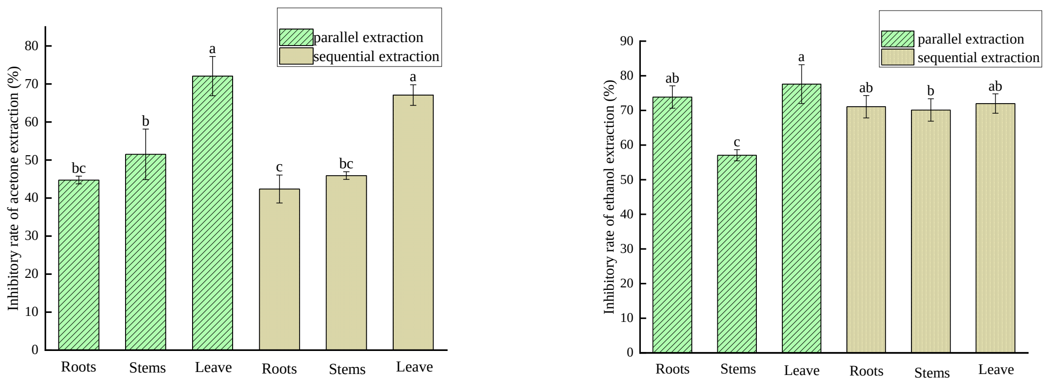

Figure 3 Comparison of inhibition rates of acetone and ethanol extracts of *Phytolacca americana* at 0.05 g mL^{-1} using two extraction methods. Acetone extract on the left and ethanol extract on the right.

Discussion

Secondary metabolites in many plants can inhibit, kill, or promote the growth of pathogenic fungi (Luo *et al.* 2022), and those of *P. americana* also have this characteristic (Li *et al.* 2021). In this study, Both ethanol and acetone extracts inhibited the growth of *P. microspora*, and the concentration of extracts was positively correlated with the inhibition rate. When the concentration of extracts increased, the effective content of the plant extract and the inhibition rate also increased. In addition, analysis of the relation between solvent polarity and bacteriostatic rate indicated that the content of active inhibition components extracted from *P. americana* was positively correlated with solvent polarity. The water extract showed no inhibitory effect, and we thought that the inhibitory components against *P.microspora* were insoluble or slightly soluble in water.

The effective inhibition components of *P. americana* were concentrated in the leaves, which is consistent with the conclusion that most secondary metabolites are primarily concentrated in leaves(Salvat *et al.* 2004). The results are in contrast to those of Zhao *et al.* who found that most substances with the strongest antibacterial activity are in roots, which may be due to Zhao et al.testing effects on bacteria. The inhibition mechanisms of extracts from different parts of *P.americana* against fungi and bacteria might be different and should be investigated in future studies.

Antibacterial substances in different parts of *P.americana* were most easily extracted by strong polar organic solvents.Ethanol extracts of leaves had the highest levels of bacteriostatic active components, which were significantly higher than those of root and stem extracts. To develop plant-derived blueberry leaf spot inhibitors from extracts of *P.americana*, strong polar organic solvents such as ethanol should be used with extraction of leaves.

Key words: faecal seeding; seed coating; endozoochory, ruminants; grazing, rangelands

Abstract

Cheatgrass *(Bromus tectorum)* has established itself as a prolific invader across the rangelands of the western United States, resulting in an abundance of fine fuel and an increased wildfire frequency. The increased frequency of fires has led to a significant reduction in native vegetation, causing degradation of wildlife habitat, forage availability, and other ecosystem services. To address this destructive wildfire cycle, cattle can be utilized to reduce cheatgrass fuel loads and mitigate cheatgrass dominance through targeted grazing. Concurrently, livestock may be used as vectors for the dispersal of desired rangeland plant species seeds through faecal seeding. Many seeds of interest are susceptible to microbial degradation in the rumen, which is why our study aimed to utilize *in situ* methods to evaluate the effects that seed coat enhancements have on the viability of seed germination post ruminal fermentation. Four target species, Indian ricegrass (*Achnatherum hymenoides*), crested wheatgrass *(Agropyron cristatum),* bottlebrush squirreltail *(Elymus elymoides),* and bluebunch wheatgrass *(Pseudoroegneria spicata)*, were coated with either Polyvinylpyrrolidone (PVP) or PVP + ethyl cellulose (Ethocel). The seeds were subjected to ruminal fermentation for 0, 6, 12, 24, 36, 48, 96 hours, after which, the seeds were placed into petri dishes and germination was monitored for five weeks. PVP and PVP + Ethocel coating treatments resulted in decreased germination rates for the 0-hour treatment across all species except Indian ricegrass. However, coated seeds exhibited greater resistance to microbial degradation through time. The exception to this was Indian ricegrass, which exhibited an increase in germination through time for PVP and control groups. Additionally, coated crested wheatgrass seeds were incubated *in vitro* for 48 hours and incorporated into faecal pats of varying depths to examine emergence. Emergence in faecal material was notable for the PVP + Ethocel group, indicating its potential to protect seeds under harsh environmental conditions.

Introduction

Rangeland ecosystems are essential for maintaining biodiversity, supporting livestock grazing, and providing ecosystem services such as carbon sequestration and water filtration. Despite their importance, these ecosystems are under increasing pressure from a variety of anthropogenic and natural factors, including habitat fragmentation, altered fire regimes, and the proliferation of invasive plant species (Baughman et al., 2022; Whisenant, 1989). Among these threats, the introduction and dominance of invasive grasses such as cheatgrass (*Bromus tectorum*) pose significant challenges, transforming native rangelands and exacerbating wildfire frequencies. As vegetative diversity declines, ecosystem resilience weakens, leading to cascading effects on trophic dynamics and ecosystem functions (Pace et al., 1999; Quijas et al., 2010).

The loss of plant community diversity in western rangelands, particularly within sagebrush steppe environments, has prompted land managers and researchers to investigate innovative methods to restore these ecosystems. Healthy rangelands depend on diverse plant communities with functional traits that enable them to adapt to challenging and fluctuating environmental conditions (McCann, 2000; Baughman et al., 2022). Restoration practices often aim to bolster this functional diversity, which enhances ecosystem resistance and adaptability to disturbances.

Restoration efforts in the western United States date back over a century, but harsh environmental conditions and logistical constraints make these efforts costly and often ineffective. Traditional reseeding methods face low success rates due to factors like poor seed-soil contact, water scarcity, and competition with invasive species (Monsen & MacArthur, 1995; Svejcar & Kildisheva, 2017). In recent years, seed coating technology has emerged as a promising solution to improve restoration outcomes. By applying physical, chemical, or biological enhancements to seeds, seed coating technologies can improve seedling establishment, viability, and resistance to environmental stressors (Davies et al., 2018; Pedrini et al., 2020). For example, surfactants added to seeds reduce soil-water repellency, enhancing water availability at the seed microsite, while coatings with abscisic acid (ABA) delay germination to align with favourable conditions (Madsen et al., 2014; Richardson et al., 2019).

The application of seed coating technologies in rangelands presents a dual opportunity: to improve the establishment of desirable native species and to suppress the dominance of invasive grasses. For example, effective reseeding with perennial grasses can reduce cheatgrass density, thereby altering fire regimes and restoring wildlife habitat (Francis & Pyke, 1996; Whisenant, 1989). Targeted grazing strategies further support this effort by reducing cheatgrass seed banks and fine fuels while avoiding harm to beneficial vegetation (Clark et al., 2023; Perryman et al., 2020). Grazing also presents a unique opportunity to leverage natural seed dispersal mechanisms through endozoochory—the spread of seeds via livestock or wildlife excrement (Teichman et al., 2013).

Faecal seeding, where seeds are dispersed in livestock faeces, is a low-impact restoration method that capitalizes on natural trophic interactions. While this approach minimizes mechanical disturbance to the soil, the digestive processes of ruminants can reduce seed viability, particularly for invasive species like cheatgrass (Holton et al., 2024). This challenge necessitates innovative solutions, such as hydrophobic seed coatings, to protect seeds during digestion and improve their establishment post-dispersal (Qoism et al., 2024; Sashi et al., 2019).

This study investigates the potential of hydrophobic seed coatings, specifically Polyvinylpyrrolidone (PVP) and PVP combined with ethyl cellulose (PVP + Ethocel), to protect seeds during ruminal digestion. Our objectives were to evaluate germination and emergence rates of coated seeds post-digestion and assess their viability under simulated rangeland conditions. We hypothesize that hydrophobic coatings will enhance seed protection during digestion and improve seedling establishment in faecal seeding applications.

Methods

In Situ Ruminal Incubation

Six rumen-cannulated Angus × Hereford steers (610 ± 54.5 kg) were fed a grain-hay diet and used to evaluate the effects of seed coatings on the viability of crested wheatgrass (*Agropyron cristatum*), bluebunch wheatgrass (*Pseudoroegneria spicata*), bottlebrush squirreltail (*Elymus elymoides*), and Indian ricegrass (*Achnatherum hymenoides*). Seeds were coated with PVP, PVP + Ethocel, or left uncoated as controls. Seed samples were placed in heat-sealed nylon bags and incubated in the rumen for varying durations (0, 6, 12, 24, 48, and 96 hours). Bags were removed at designated time points and prepared for enzymatic digestion simulations.

In Vitro Abomasum Incubation

After ruminal incubation, seeds were subjected to in vitro digestion to simulate passage through the abomasum. This process involved incubating seeds in a solution of rumen fluid, pepsin, and hydrochloric acid at 39°C for three hours. The treated seeds were then rinsed and prepared for germination trials in sterile petri dishes.

Germination Trial

Fifty seeds from each treatment group (species, coating, and incubation time) were placed in sterile petri dishes with blotting paper for moisture retention. Dishes were incubated at 20°C with a 12-hour photoperiod and monitored for germination every five days over five weeks. Germination was defined by the emergence of a 2-mm radicle.

Faecal Emergence Trial

Seeds incubated for 48 hours in the rumen were mixed into homogenized faecal material at depths of 1.3, 2.5, and 3.8 cm in greenhouse conditions. Emergence was monitored over ten weeks, beginning with five weeks of water restriction followed by watering every three days. Seedling counts were recorded every ten days.

Statistical Analysis

Generalized linear mixed models were used to analyse the effects of seed coatings, ruminal incubation time, and faecal depth on germination and emergence. Statistical significance was set at $P \leq 0.05$, with trends noted between $P < 0.1$ and $P > 0.05$.

Results

Germination Post-Incubation

Germination rates decreased as ruminal incubation time increased for all species (Figure 1). PVP + Ethocel coatings significantly improved germination for crested wheatgrass and bottlebrush squirreltail after extended incubation times, while Indian ricegrass performed poorly with this coating. Notably, Indian ricegrass treated with PVP maintained germination rates similar to the control group, with a slight increase at 24 hours of incubation (Figure 2).

Faecal Emergence

Seedling emergence varied significantly by faecal depth and coating type. Control seeds exhibited the highest emergence at shallow depths (1.3 cm), while PVP + Ethocel coatings outperformed at deeper levels (2.5 and 3.8 cm). Deeper faecal deposits provided better moisture retention, supporting greater emergence rates across treatments (Figure 3).

Discussion [Conclusions/Implications]

Our findings reveal that seed coatings, particularly PVP + Ethocel, can enhance the viability of certain rangeland species during ruminal fermentation. Species-specific responses indicate the importance of tailoring coatings to match seed morphology and dormancy characteristics. For example, Indian ricegrass, which relies on dormancy to regulate germination, exhibited poor performance with PVP + Ethocel coatings, likely due to the coating's interference with dormancy-breaking mechanisms.

The faecal emergence trial highlights the importance of environmental conditions, such as faecal depth, in seedling establishment. Deeper faecal deposits mitigated moisture loss and crusting, creating favourable conditions for emergence. However, the reduced performance of PVP-coated seeds at shallow depths underscores the need for further refinement of coating formulations to maximize their applicability across diverse rangeland environments.

This study demonstrates the potential of seed coatings to enhance restoration efforts through faecal seeding. PVP + Ethocel coatings showed promise for improving seed viability and emergence under harsh conditions, making them a viable tool for restoring degraded rangelands. However, further research is needed to optimize coatings for a broader range of species and field conditions. Tailoring coating technologies to the specific ecological and operational contexts of restoration projects will be essential for maximizing their impact.

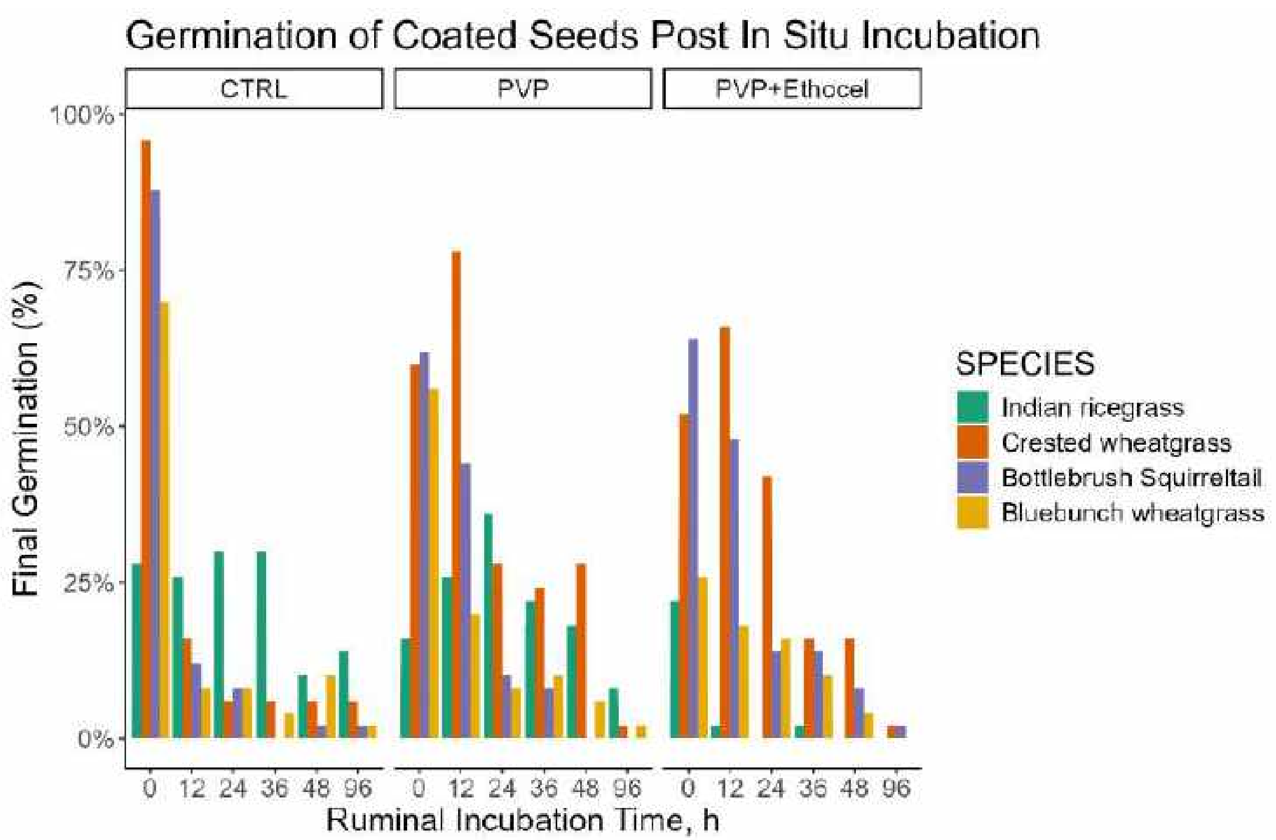

Figure 1. The evaluation of the germination potential of rangeland seed species coated with either polyvinylpyrrolidone (PVP), PVP + Ethocel, or control, after exposure to *in situ* ruminal fermentation through time (in hours) followed by 3 hours of *in vitro* abomasal enzymatic digestion. The final germination is expressed as a percentage of total seeds examined.

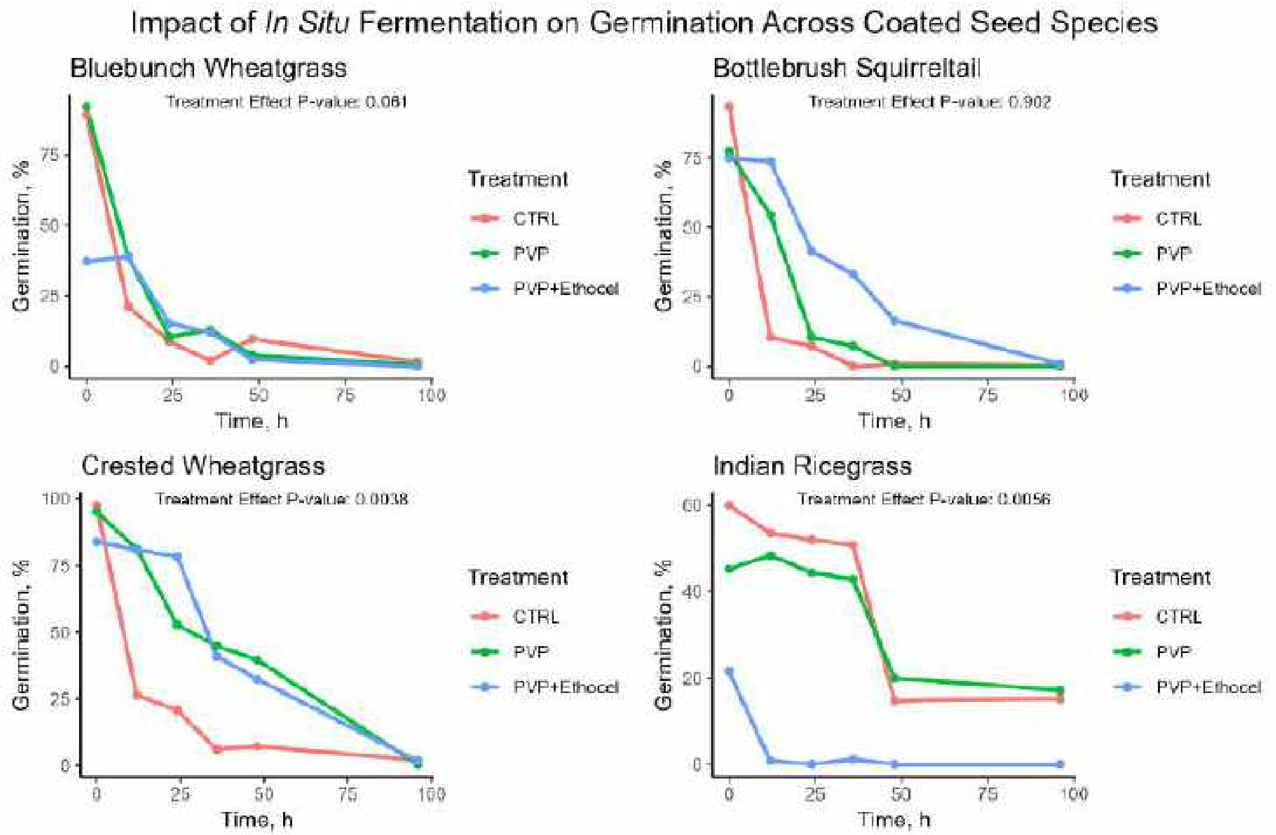

Figure 2. An examination of germination rates through time (in hours) for rangeland seed species coated with polyvinylpyrrolidone (PVP), PVP + Ethocel, and a control group. Seeds were incubated in the rumen, followed by 3 hours of *in vitro* abomasal enzymatic digestion.

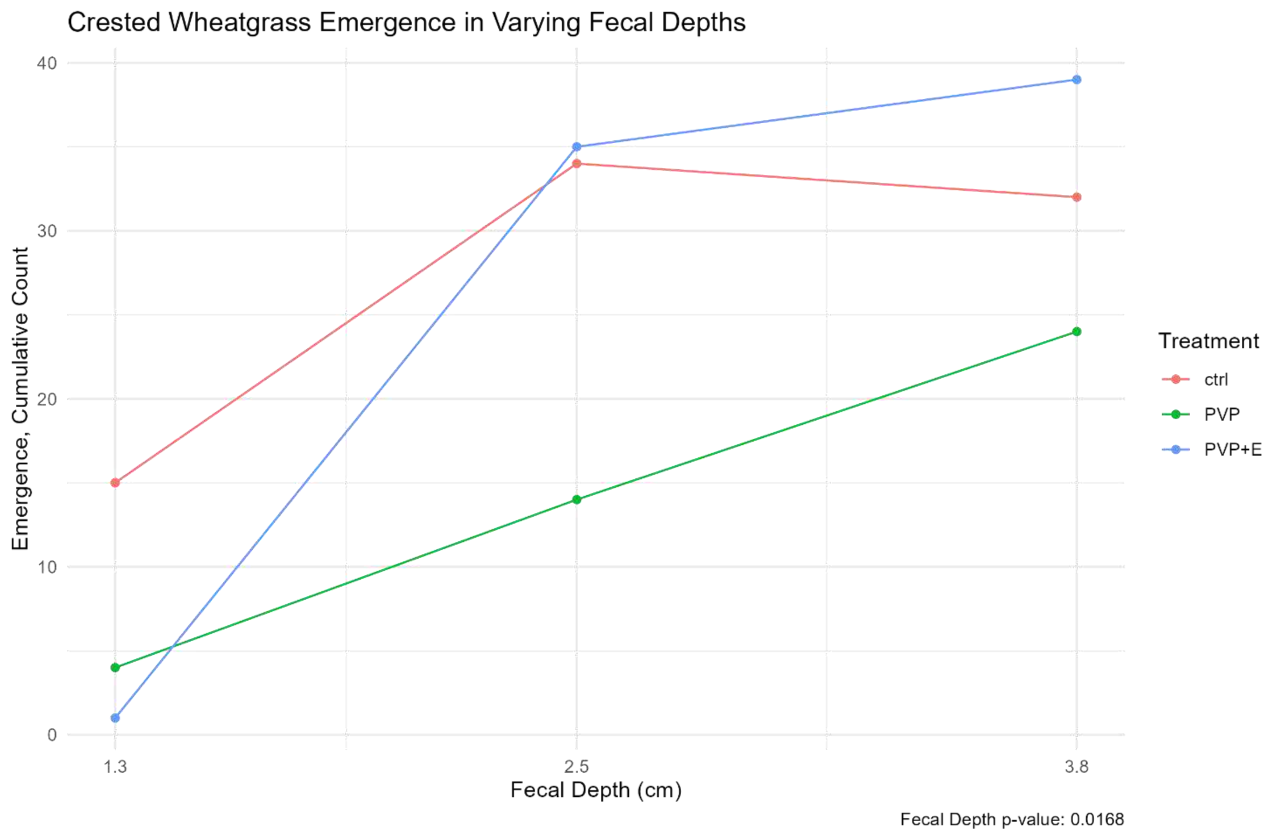

Figure 3. The evaluation of crested wheatgrass (*Agropyron cristatum*) emergence in faecal material substrate at varying depths (1.3 cm, 2.5 cm, and 3.8 cm) after seeds were coated with Polyvinylpyrrolidone (PVP), PVP + Ethocel (PVP + E), or control, and subjected to 48 hours of *in vitro* ruminal fermentation paired with 3 hours of *in vitro* abomasal enzymatic digestion. Emergence was determined by above surface expression of vegetative material.

Abstract

Large areas of short grasslands have undergone vegetational changes in northern Mexico. Overgrazing, droughts, fire reduction, and climate are among the main factors responsible for these changes. This study was conducted in Cananea, Sonora, Mexico, to compare vegetation changes in *Bouteloua-Aristida* grassland under regular conditions, with and without contour furrowing. Contour furrows, 3 m wide at the base and 1 m tall, were constructed at 30 cm elevation intervals using a disk furrower pulled by a D-6 bulldozer. The topography at the site is characterized by flat ranges with less than a 5% slope. Soils have a deep loamy sand texture. The climate is semi-warm and dry, with a mean annual precipitation of 425 mm and an average temperature of 15 °C. Changes were measured in three permanent plots of 400 m^2 each. Plant density, height, basal coverage, and forage production were monitored during the summer from 2013 to 2022 in ten permanent quadrants of 1 m^2 each per plot. A randomized block design was used, and the data were analyzed by ANOVA ($P \leq 0.05$). Precipitation was near average for 4 years, below average for 3 years, and above average for 3 years. All variables were higher ($P \leq 0.05$) in the contour furrowed areas than in the control plots. Plant density averaged 10.7 plants/m^2 in the control plots and increased by 116.8% ten summers after treatment in the contour furrowed areas. Plant cover increased by 67.5% in the same plots, and plant height increased by 47% ten summers after treatment in the contour furrowed plots. Total annual forage production averaged 635.8 kg D.M. ha^{-1} in the control and 1,546.5 kg D.M. ha^{-1} in the contour furrowed areas, resulting in an increase of 143.2%. We conclude that water harvesting through contour furrowing is an effective method to promote the establishment, development, and productivity of native grass species in short grass prairies.

Introduction

Overgrazing, climate change and severe droughts have caused strong changes in rangelands where a reduction in vegetation cover and an increase in the loss of soil and water through runoff can be seen. Grasslands are plant communities where short and medium-sized grasses predominate with few trees and shrubs (Holechek et al., 2010). They are of ecological and economic importance and constitute strategic areas for the North American livestock industry. Most grasslands are used for raising cattle, horses and large and small wildlife and are considered sources of food, fiber and fuel, contributing to climate regulation, pollination, purification and recharging of aquifers, control of invasive species and carbon sequestration (Milchunas and Lauenroth, 1993; CONABIO, 2023).

Water is a fundamental element to produce forage and for livestock farming, since it is a vital input for the nutrition of animals and for the pasture and irrigation of crops, so the availability of water and the production of food is the main concern for the future of the human population. We believe Short Grass Prairies in regular condition require only the application of water conservation practices to restore productivity. This study was conducted in Cananea, Sonora, Mexico, to compare vegetation changes in a *Bouteloua-Aristida* grassland under regular condition, with and without contour furrowing during a 10-year period.

Methods

The study was carried out during the summers of 2013 to 2022 at the Experimental Ranch of the University of Sonora, located 15 km east of the city of Cananea, Sonora, (30º 58'00" Lat. N and 110º 08'30" Long.W). In a short grass prairie in fair condition, at an elevation of 1,417 meters above sea level, with relatively uniform topography with flats and low hills, slopes that vary from 3 to 7%. The soil type corresponds to haplic chestnut with a sandy loam texture and an average depth greater than 50 cm. The climate is temperate semi-dry BS1 kw (x') (e'). The average annual precipitation and temperature is 425 mm and 15 ºC, respectively (García, 1973). The vegetation is composed of native grasses of the *Bouteloua-Aristida* genera (COTECOCA, 1988). An area of 1 ha surface was selected, where 6 experimental plots (20 x 20 m) each were randomly chosen, 3 in areas with level furrows and 3 in untreated flat areas (control), excluding grazing. The furrows 3 m at the base and 1 m high were built on contour lines at intervals of 30 cm in height, with an 8-36" diameter disk furrower pulled by a D6 bulldozer. Main grass species in the study area were: Blue grama *Bouteloua gracilis* (Willd. ex Kunth) Lag. ex Griffiths., Sideoats grama *Bouteloua curtipendula* (Michx.) Torr., Sprucetop grama *Bouteloua chondrosioides* (Kunth) Benth. ex S. Wats., Green sprangletop *Leptochloa dubia* (Kunth) Nees, Common wolfstail *Lycurus phleoides* Kunth, and Sixweeks Threeawn *Aristida adscensionis* L. (Rendowski, 2006).

Variables evaluated were plant density, basal cover, height and biomass production. Plant density, basal cover and height were monitored during the summers of 2013 to 2022, in ten permanent quadrats 1 m^2 per plot. Plant density and basal cover were estimated for each species by counting the total number of plants and the sum of their crowns, respectively. Height was determined by measuring the length of the plants from the soil surface to the apex. Forage production was estimated by clipping in 10 quadrats of 1 m^2 distributed randomly by plot, species and total production. For the determination of dry matter, the forage samples were dried in a forced air oven at 60 ºC for 72 hours. A completely randomized block design was used with two treatments and three repetitions (Steel and Torrie 1980). All variables were analyzed by ANOVA ($P \leq 0.05$), using Duncan's Multiple Range test for the comparison of means. Statistical analyzes were conducted using the SAS package (SAS, 1988).

Results

Precipitation was near average for 4 years, below average for 3 years, and above average for 3 years. All variables were higher ($P \leq 0.05$) in the contour furrowed areas than in the control plots. Plant density averaged 10.7 plants/m² in the control plots and increased by 116.8% ten summers after treatment in the contour furrowed areas. Plant cover increased by 67.5% in the same plots, and plant height increased by 47% ten summers after treatment in the contour furrowed plots. Total annual forage production averaged 635.8 kg D.M. ha^{-1} in the control and 1,546.5 kg D.M. ha^{-1} in the contour furrowed areas, resulting in an increase of 143.2% (Table 1). Forage production of main grass species was consistently greater ($P\leq0.05$) on plots where water was harvested and varied from 25.4 to 204.3 kg of dry matter (DM)/ha on untreated plots and varied from 134.4 to 318.3 kg of dry matter/ha on contour furrowing plots. Biomass of individual grass species was consistently increased from 18.9 to 64.18% on the contour furrowing plots (Table 2).

Table 1. Plant density, basal cover, plant height and biomass production of range grasses in a short grass prairie ten years after contour furrowing at Northern Sonora, Mexico.

Variables	Contour Furrowing	Untreated Check	Percent of change
Plant density (p/m^2)	23.2 a	10.7 b	116.8
Basal cover (%)	16.08 a	9.6 b	67.5
Plant height (cm)	96.46 a	65.62 b	47.0
Biomass Production (kg DM/ha^{-1})	1,546.50 a	635.8 b	143.2

** Means between treatments with different lowercase letter are different ($P\leq0.05$).

Table 2. Total Forage production (kg DM/ha^{-1}) of several grass species at a short grassland with and without contour furrowing after ten years of treatment at Northern Sonora, Mexico.

Species	Contour Furrowing	Utreated Check	Percent of change
Blue grama	264.5 a	148.6 b	56.18
Sideoats grama	318.3 a	204.3 b	64.18
Sprucetop grama	234.7 a	77.5 b	33.02

Others	134.4 a	25.4 b	18.89
Total	1,546.5	635.8	

* Means between treatments with different lowercase letter are different ($P\leq0.05$).

Discussion

The purpose of creating contour furrow is to control the surface runoff and increase vegetation establishment and forage productivity. The runoff water is stored in soil profile for plant growth during prolonged periods of moisture stress (Kugedera et al., 2018). Studies conducted with sorghum in Kenya show that the increase in soil moisture content accelerated the crop growth, leaf size, panicle length, number of tillers and above-ground biomass yield (Mwami et al., 2024). Appropriate application of *in situ* and micro-catchment techniques could improve the soil water content of the rooting zone by up to 30% (Biazin et al., 2012). It has been shown that soil and water conservation practices reduce runoff and increase the water content in the soil by 13 to 22% up to one meter deep (Mondaca et al., 2024).

In this study all grass species on disk furrowed plots showed greater plant density, height, basal cover as well as greater forage production as compared to the control. Similar results are reported by Ali et al. (2010), suggesting that water harvesting in micro-structures in the soil captures excessive runoff for subsequent use by plants, helping the development of roots and foliage and reducing the mortality rate of new seedlings. Other studies carried out in Jordan show that forage production increased from 380 to 1,151 kg ha^{-1} with the use of water retention practices (Abu-Zanat et al., 2004). Traditional in situ water harvesting improves soil moisture retention by 59% and effectively reduces runoff by 53% and soil loss by 58.66%, demonstrating their robust water and soil conservation benefits (Tefera et al., 2024). In Sudan, increases of 2.25 to 3.65 tons ha^{-1} of forage are reported in rangelands with rainwater retention, compared to the control with 0.65 tons ha^{-1} (Ezzat et al., 2013).

Conclusion

Contour furrowing in soils of Short Grass Prairies favored the density, basal growth and height of grasses, which together, increased the individual and total forage production of the pastures. The practice allowed the capture and conservation of additional water. Rainwater harvesting resulted in an increase in the biomass production of plants in soils with high runoff potential, thereby increasing soil cover and the production potential for feeding livestock and wildlife. Water harvesting through contour furrowing is an effective method to promote the establishment, development, and productivity of native grass species in Short Grass Prairies.

Challenges and opportunities for broad-scale state-and-transition model development

Johanson, JK[1]; Talbot, CJ[2]

[1, 2] United States Department of Agriculture – Natural Resources Conservation Service, Soil and Plant Science Division

Key words: ecological site; ecosystem services; soil survey; ecosystem dynamics; site potential

Abstract

State-and-transition models (STMs) provide an intuitive framework for interpreting ecological observations in support of assessment, monitoring, research, and management of rangeland ecosystems. Australian scientists proposed STMs as a non-linear alternative to the equilibrium range succession model after the latter was scrutinized during the 1984 International Rangeland Congress in Adelaide. As the Congress returns to Adelaide 40 years later, the paradigm shift away from linear succession toward a non-linear mental model is self-evident. Yet despite consensus that rangelands often exhibit multiple stable states and irreversible transitions, the broad-scale development of STM products cataloguing alternative states, transitions between states, and differences among states is lacking, thus hindering the ability of natural resource managers and researchers to fully implement the STM paradigm. Renewed efforts by the United States Department of Agriculture are incorporating new ideas to elevate future STM products. We discuss challenges of STM development and present a vision for systematic, broad-scale production of STMs based on the following principles and assertions: spatial context – ecosystem properties or classes to which an STM applies must be well defined to reasonably interpret field observations and predict the behaviour of similar areas; inclusive collaboration – STMs must represent the collective ecological knowledge of field scientists, resource managers, local and indigenous experts, and other observers; reliability – STM developers must curate knowledge and data from reputable sources and implement quality control measures; accessibility – interactive online applications must be designed to easily identify an STM of interest and address specific questions about states, transitions, risks, and opportunities; diverse interpretations – STMs must describe interpretive differences among ecological states (e.g., habitat, fire behaviour, forage, water balance) to reflect diverse management and societal priorities. In addition to these principles and assertions, we discuss a variety of mechanisms to achieve our vision of easy access to reliable ecosystem knowledge in support of rangeland management and research.

Introduction

The broad-scale development and application of state-and-transition models (STMs) has proven to be inherently challenging. The STM paradigm remains alluring to many because it systematically organizes existing knowledge about ecosystem dynamics into simple box-and-arrow diagrams (Fig. 1), and it has the potential to put reliable scientific information directly into the hands of rangeland managers and other decision-makers. The basic process of STM development is to 1) define an ecosystem of interest, 2) observe and define the ecological states that occur in that ecosystem, 3) describe the circumstances under which one ecological state transitions to another, and 4) describe the variability in ecosystem attributes and services within each ecological state. STM development is relatively simple when applied to a small area with a few distinct ecosystems, however, the complexity significantly increases when producing STMs for hundreds or thousands of ecosystems across an entire region or continent. Scientists from several countries have made commendable efforts at nationwide STM development in the 35 years since Westoby et al. (1989) proposed the framework as an alternative to the range succession model; yet each attempt has encountered some combination of conceptual, administrative, and technical impediments that stifled broad-scale development and application of STMs (Bestelmeyer et al. 2017). The STM paradigm and its products are seemingly much easier to comprehend and envision than they are to implement and produce.

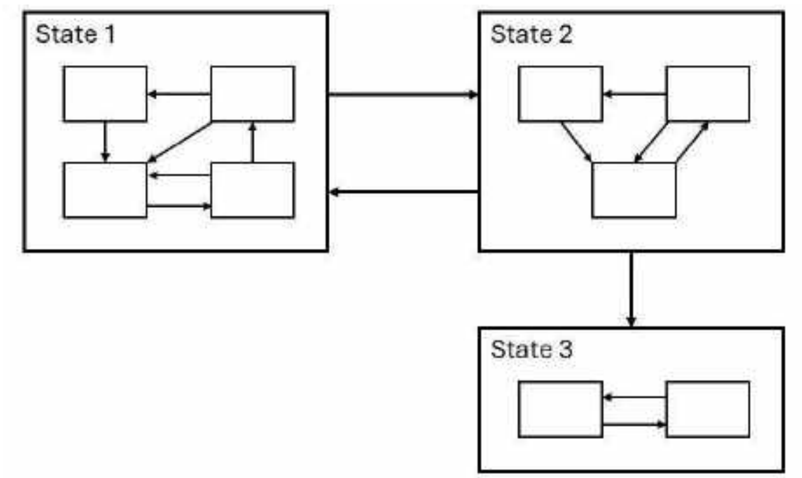

Fig. 1. A generalized STM showing three ecological states, a reversible transition between states one and two, an irreversible transition from states two to three, a lack of transition between states one and three, and community dynamics within each state. The number and nature of states and transitions in STMs varies depending on the ecosystem. To become a complete STM product, these box-and-arrow diagrams should include a legend, photos, tables, figures, and narrative descriptions that describe the variability in attributes and ecosystem services of each state, as well as the primary drivers, triggers, feedbacks, and indicators of each transition.

Despite the many challenges presented by broad-scale STM development and application, the United States (US) Department of Agriculture (USDA) is learning from past efforts and implementing the organizational structure, processes, and systems needed to tackle this complex task for the entire nation. This paper first outlines the challenges associated with broad-scale STM development and application, then outlines specific opportunities that the USDA and partners are pursuing to address each challenge.

Challenges

Impediments to nationwide STM development can be categorized as conceptual, administrative, technical, and utilitarian.

Conceptual challenges

The most significant conceptual challenge to broad-scale development efforts in many parts of the world is defining the reference domain to which each STM applies. STM development across broad regions requires a systematic ecosystem classification based on the environmental features that determine ecosystem potential and dynamics (Bestelmeyer et al. 2009). Climate, soils, physiography, hydrology, and other attributes vary across the landscape and determine the ability of each site to provide ecosystem services (i.e., site potential) and respond to natural and anthropogenic disturbances (i.e., ecosystem dynamics). For example, a peat bog may be adjacent to a well-drained sandy hillslope. Despite sharing a similar climate, these two sites have very different soils, hydrology, geomorphology, disturbance regimes, and ecosystem services associated with their distinct landscape context. These ecosystems are inherently different; thus, the STMs must reflect differences in states, transitions, and the interpretations thereof. Early efforts to produce broad-scale STMs in Australia and Argentina stalled, in part, due to a general lack of soil and other site attribute data at management-relevant scales (Bestelmeyer et al. 2017). Another conceptual challenge suggested by the STM literature is the need to systematically incorporate useful information about ecological processes and resilience into STMs, since the site-specific data needed to do so is generally lacking (Stringham et al. 2003; Briske et al. 2008).

Administrative challenges

In countries where detailed soil and site information is sufficient for systematic classification of ecosystems, administrative challenges represent the next barrier to nationwide STM development (Bestelmeyer et al. 2017). Organizational structure is necessary to develop 1) a coordinated network of experts with experience across all regions of the country, 2) coordinators responsible for bringing the experts and data together to produce useable products, and 3) clear STM product standards that include robust quality control and assurance processes. Of course, this level of organization requires sustained support and funding from institutions and individuals that value comprehensive, reliable ecosystem knowledge in support of ecosystem-based resource management. A one-time investment to develop a national STM reference library is at odds with the incremental nature of scientific knowledge generation. Instead, a sustained commitment must be procured to establish and maintain an organizational structure capable of developing and updating STMs over time as new knowledge is generated (Karl and Talbot 2016).

Technical challenges

Given administrative support and an ecological classification system, technical challenges abound when implementing a broad-scale STM development program. Most of the technical challenges stem from data management needs and training technical staff. Data systems must facilitate the efficient capture, organization, and summarization of soils, vegetation, climate, disturbance, and many other observational data types from reputable sources across all regions and ecosystem classes. While field data collection methods can be standardized for future STM refinements, first draft STMs often rely on the use of existing datasets, which can vary greatly in quality, methods, scale, and other variables. Capturing, organizing, and preprocessing new and existing data can be a monumental undertaking. Efficient workflows and processes must be designed for streamlined analysis and synthesis. Significant training is required for technical experts to learn the STM paradigm, apply standards consistently across all regions, and analyse and summarize data into useful STM products. Perhaps the greatest training challenge is for field ecologists and data analysts to become effective STM development coordinators, capable of utilizing a network of contributors with diverse experiences and perspectives in a truly collaborative process (Bruegger et al. 2016). Moderating meetings, active listening, social skills, and concise writing are critical communication skills necessary to successfully integrate our collective knowledge of ecosystem potential and dynamics into authoritative STM products.

Utilitarian challenges

The ultimate utilitarian challenge is to create STM products that are so informative and intuitive that a person would be foolish not to use them. Unfortunately, STM developers can become so enthusiastic about the science of STM development that they lose focus on the customers' fundamental need to interpret STMs for the purpose of making land management decisions in the real world. Decision-makers use STMs to assess trade-offs in ecosystem services among different ecological states as they consider the costs and benefits of managing in favour of one ecological state over another (Miller et al. 2011). Because many end users have their own work to do, it can be difficult to engage them directly to understand what information is most relevant to them, at what scales, and in what delivery format. Once customer needs are identified, new challenges arise. Software applications must be developed to deliver the STMs in an intuitive, accessible, reliable format that offers quick access to specific answers to the most common questions. A successful software application would also encourage the collection of user feedback as a method to further validate the concepts within the STM. Finally, the arithmetic of developing tables, graphs, photos, and narratives for many ecosystem services occurring on multiple ecological states and across hundreds or thousands of different ecosystems adds up to an enormous workload that requires competent teams with diverse expertise.

Opportunities

The USDA Natural Resources Conservation Service (NRCS) is poised to address each of the conceptual, administrative, technical, and utilitarian challenges facing STM development in the US today.

Conceptual opportunities

The US benefits from more than 125 years of soil survey. The US soil survey produced the spatial and edaphic data needed to develop the "range site" classification system in the mid-twentieth century. Once NRCS began adding STMs to range site descriptions in the late 1990s, the name of the classification was changed to ecological sites (ES), and the scope of ES development expanded to include all native landscapes, with the inclusion of all intensively managed lands in 2010. The ES classification system provides an ideal reference domain for STMs because ESs define the soil and site attributes that determine site potential and dynamics of ecosystems at human operative scales (Moseley et al. 2010). Shortly after the STM paradigm was adopted by NRCS, a complementary concept of dynamic soil properties (DSPs) emerged within the agency (Tugel et al. 2008). The premise of DSPs is that some soil properties change in measurable ways when an ecosystem changes to a different state. The number of DSP projects in the US has steadily increased in the past 15 years, creating new insights about soil-plant feedback process and resilience that can be incorporated into STMs as the literature suggests (Stringham et al. 2003; Briske et al. 2008).

Administrative opportunities

Even as the ES paradigm was evolving to include STMs in the US, nationwide STM development failed to accelerate due to a lack of organizational structure. Several western US states made marked progress in STM development in the first decade of the twenty-first century, yet from a national standpoint, the products were not consistent nor the coverage complete. In 2009, NRCS made administrative changes by establishing a national ES leadership team within the Soil and Plant Science Division (SPSD) to oversee nationwide STM development. Dozens of new ES specialists were hired by the SPSD to coordinate STM development work in all regions of the country. As part of the SPSD, ES specialists have sustainable funding and administrative support and have built upon the many strengths of soil survey, including access to soils experts, established networks of local technical expertise, a long history of nationwide standards, and established product quality review processes. With proper ES staffing in the SPSD, the first nationwide standard for STM development was implemented in the US in 2015 (USDA-NRCS 2014) by an initiative to develop provisional STMs for every ES in the country. Today, over 90 percent of the major soils in the US have a provisional STM product published online, and NRCS is on pace for complete nationwide coverage of provisional STM products in 2025. Many lessons were learned during this first nationwide STM effort, improvements are being made to the STM quality review processes, and new field projects have been designed to collect data for STM revisions.

Technical opportunities

Provisional STMs for the US can be accessed online via the Ecosystem Dynamics Interpretive Tool (EDIT; Bestelmeyer et al. 2016). EDIT is an STM database that houses tabular, photographic, and narrative data describing ranges in characteristics of ESs, states, transitions, and the variability in ecosystem attributes and services within each state. These ranges are summarized from observational data that is stored and analysed outside of EDIT. Since STMs must be derived from the best available information, and since vegetation plot data and experiential knowledge can take many forms, it is virtually impossible to design a single database or workflow to capture, organize, and summarize the best available information across all regions of the country. Therefore, NRCS has developed standards for determining when and how ecological plot data must be entered into the corporate soils database (the National Soils Information System: NASIS), and how to cite other data, publications, or expertise used to develop the STM. Entering vegetation plot data into NASIS should create countless analysis opportunities within the proper soil, ecological, and spatial context. One recent example is the use of NASIS vegetation plot data to forecast changes in the spatial distribution of several berry species important to indigenous Alaskan communities under different climate change scenarios (Hamilton et al. 2024). Standardized data analysis workflows are being developed to streamline STM development, which requires specialized training. NRCS and partners have developed several online training modules and instructor-led courses to expose new staff and partners to the fundamentals of STM development. Developing STM expertise, data management systems, and efficient workflows are just a few of the many opportunities to address technical challenges of nationwide STM development.

Utilitarian opportunities

Understanding how people use STMs is the key to creating a meaningful product. In 2024, NRCS established a national ES team to identify, prioritize, and address STM customer needs within the agency, as well as an interagency ES focus team with the US Forest Service, Bureau of Land Management, US Geological Survey, and Agricultural Research Service. These two new teams foster open and regular communication about how to best meet STM user needs. For example, the Bureau of Land Management would like to use STMs for landscape-scale assessment, planning, and wildfire response, but the ES scale is too detailed for these purposes. Therefore, NRCS has begun developing STMs for ES groups (ESGs) as a complementary product to the STMs already produced at the ES scale (Bestelmeyer et al. 2016). ESGs reduce the number of STMs by approximately one order of magnitude, which addresses the workload problem of developing interpretive information for many ecosystem services across multiple ecological states. With fewer total STMs, it should be easier to draft interpretations for states at the ESG scale and then apply the interpretation to similar STMs at the ES scale, for use in the short-term at least. The EDIT database includes a catalogue of STMs at the ESG scale, but unfortunately, EDIT is not designed to deliver interpretations for ecological states in a simple, intuitive format at the ESG or ES scale. As NRCS invests more resources in IT development, there may be an opportunity to redesign the EDIT data model to include tables, photos, graphs, and other functionality that better communicates interpretations of ecosystem services by ecological state (e.g., wildlife habitat, fire behaviour, water balance). The Grazing land Resource Analysis System is a software application that imports annual forage production values from EDIT directly into the conservation planning software used by NRCS planners. Similar upgrades to EDIT functionality promise to greatly improve the use of STMs.

Conclusions

Ecosystems are infinitely complex, and organizational development is complicated. It has taken several decades to work through the conceptual, administrative, technical, and utilitarian challenges facing broad-scale STM development, and now all the pieces are all in place to produce high quality STM products for the entire US. Perhaps other countries that value accessible, reliable ecosystem knowledge will benefit from these lessons learned in the 35 years of systematic STM development in the US.

Key words: Rangeland Restoration; Perennial Pastures; Regeneration; Biodiversity; Grazing

Abstract

The rangelands of NSW depend on rainfall driven native pastures to support privately managed grazing operations. The Perennial Pastures, Resilient Rangelands project aims to improve drought resilience by managing for biodiverse pastures with a focus on establishing and managing perennial species. Utilising a community of practice approach, landholders near White Cliffs collaborated with scientists and advisors to identify priority areas for restoration and implement innovative strategies to increase key perennial species. The group selected a stony plain on Yalda Downs north of White Cliffs and the landowner agreed to implement a demonstration site to trial regeneration strategies chosen by the group. Water ponding has been successfully demonstrated to improve scalded soils with low water infiltration, providing opportunities for seedling establishment leading to increased vegetation cover and plant diversity. However, establishment of key perennial grass and shrub species in these ponds is often limited. At Yalda Downs ripping, seeding of perennial grass and shrub species, and grazing exclosure treatments within water ponds were established in August 2023. Multiple rainfall events in early 2024 assisted with the early germination of perennial species (inc. *Astrebla spp*., *Panicum decompositum*, *Chloris truncata)* in the seeded treatments. The effectiveness of this trial is being monitored and species counts have shown establishment of sown seed and additional perennial species.

Introduction

Perennial species are important in the rangelands for both sustainability and productivity, protecting the soil surface during dry periods and being able to persist through dry seasonal conditions. A combination of prolonged droughts and high levels of total grazing pressure has resulted in considerable land degradation, including soil erosion and a loss of productive palatable, perennial species over extensive areas in western NSW rangelands (Green, 1989).

Regeneration strategies are often required to improve water infiltration and encourage seed germination and survival in degraded landscapes (Gintzburger, 1987; Kinloch and Friedel, 2005). Water ponding, water spreading and diversion banks have been used throughout Australia as an effective restoration method. Productivity has been reported to double within areas that have been water ponded compared to uneroded areas on the same soil (Cunningham, 1974a). Ripping and furrowing can encourage plant establishment by collecting moisture, litter, seed and reduce soil water evaporation (Gintzburger, 1987; Green, 1989; Rorive and Bainbridge, 1993). Attempts to rehabilitate semi-arid woodlands in Australia by reseeding bare areas with grasses have often been unsuccessful, and limited by seed supply (Broadhurst et al., 2015). Many studies concluded there is adequate seed naturally available to facilitate regeneration in the landscape. In addition, changes to grazing management can promote desirable plant species. In western NSW rangelands a tactical grazing approach is recommended (Hacker and McDonald, 2021) and resting after a major rainfall event allows establishment of key species (Hacker and Tunbridge, 1991; Sparrow *et al*., 2003). The aim of this study is to trial if ripping, seeding and grazing exclosure within ponding banks increase palatable perennial species density and diversity.

Methods

A demonstration site was established in 2023 located on an eroded and scalded area of Yalda Downs, ~60 km north of White Cliffs in far west NSW, Australia (30°18'28"S 143°01'28"E). The site is gently sloping, located in the Oakvale land system (Walker, 1991) with vegetation historically being primarily *Astrebla* (Mitchell Grass) grassland and chenopod shrubland, although very few perennial grasses were present. The climate is arid with an average annual rainfall of approximately 200mm.

One hundred and forty eight water ponds were established in July 2023 across ~80ha of predominately bare, stoney ground within a large (10,069ha) paddock on Yalda Downs. Ponds were constructed with a 12H Caterpillar (CAT) grader with a 14ft blade and rippers attached on the back, creating a bank ~0.5m high, ponding up to 10cm of water.

Five ponding banks of similar design were selected for monitoring in three replicate areas (15 ponds total), each receiving a different treatment:

1. Control (P), ponding only, without rip lines along the base of the pond
2. Ripping (PR), ponding with rip lines along base of pond
3. Ripping and Seeding (PRS), ponding with rip lines and seed added to ripped lines
4. Ripping and grazing exclosures (PRC), ponding with rip lines, and a 6 x 24m cage established at base of pond
5. Ripping, seeding and grazing exclosure (PRSC), ponding with rip lines and seed added to rip lines, and a 6 x 24m cage established at the base of the pond

Ripping treatments

Using a 12H Caterpillar (CAT) grader, 5 tines ripped the soil to ~30cm depth, with rows ~30cm apart, total 2m width, at the base on the topside of the ponding bank.

Seeding treatments

A list of desirable perennial species was generated for the site in collaboration with the Community of Practice and advisors. Not all desirable species were able to be sourced. Seed species sown included: *Cloris truncata, Astrebla lappacea, Astrebla pectinata, Pancium decompositum, Einadia nutans, Rhagodia spinescens, Enchylaena tomentosa, Atriplex semibaccata, Atriplex vesicaria* and *Atriplex nummularia*. For treatments with seed, seed was spread throughout the whole pond. Seeds were sown by hand, walking the length of the pond distributing seed evenly.

Cage treatments

A 6 x 24m cage was erected at the base of the pond, running parallel to the pond bank, constructed out of 5mm wire, 150mm x 100mm mesh, 1100mm high. Cages were erected in March 2024, to exclude the treatment area of being grazed by livestock and unmanaged herbivores. Although the paddock had been destocked of livestock between the time of ponding, sowing seed and the erection of the grazing exclosures.

Vegetation monitoring

At each ponded treatment (P, PR, PRS, PRC, PRSC), a permanent 20m transect was established at ~3m from the centre (top) of the bank, running parallel to the bank, with a star picket post at each end and a cattle tag denoting the treatment name and transect start. For treatments with exclusion cages, the transect was located inside the cage. The start and end points of each transect were marked on GPS and photo points (portrait and landscape) established at each transect.

Baseline monitoring of treatments was undertaken in August 2023, approximately 1-3 weeks after construction of the ponds and prior to any rainfall following the ponding. Measurements were repeated in September 2024.

Percent cover of each species present, herbage mass and percent cover of ground cover components (plant, litter, cryptogram, rock, course woody, dung, bare) was estimated in ten 0.5 x 0.5m quadrats along each 20m transect. The number of key perennial plant species within each quadrat was also recorded. All species one meter either side of the transect ($40m^2$ total) were identified, and the number of individual plants of key perennial species within this area counted.

In April 2024, ~7 months after seed was sown, establishment counts of the sown species were undertaken by recording the number of individual plants rooted within 0.5m either side of the 20m transect (total area $20m^2$).

Mixed effect models using the lme4 package in R (Bates et al. 2015; R Core Team 2021) were used to test the impact of treatment on plant and litter cover and herbage mass (log+1 transformation applied), with replicate and pond included as random effects. Anova was performed to test for significant differences between treatments ($P<0.05$).

Results

Rainfall

Summer rainfall recorded near the site resulted in totals of 54mm in December 2023, 98.5mm in January 2024 and 101mm in February 2024.

Groundcover and biomass

Overall, in September 2024, approximately 12 months after establishment of the trial, there were no significant differences in vegetative (plant+litter) ground cover ($P = 0.132$), with considerable variability depending on the pond and replicate (Fig. 1a). Herbage mass was significantly higher in the PRS treatment than the PR treatment ($P = 0.043$), but there were no other significant differences between treatments ($P>0.05$, Fig. 1b)

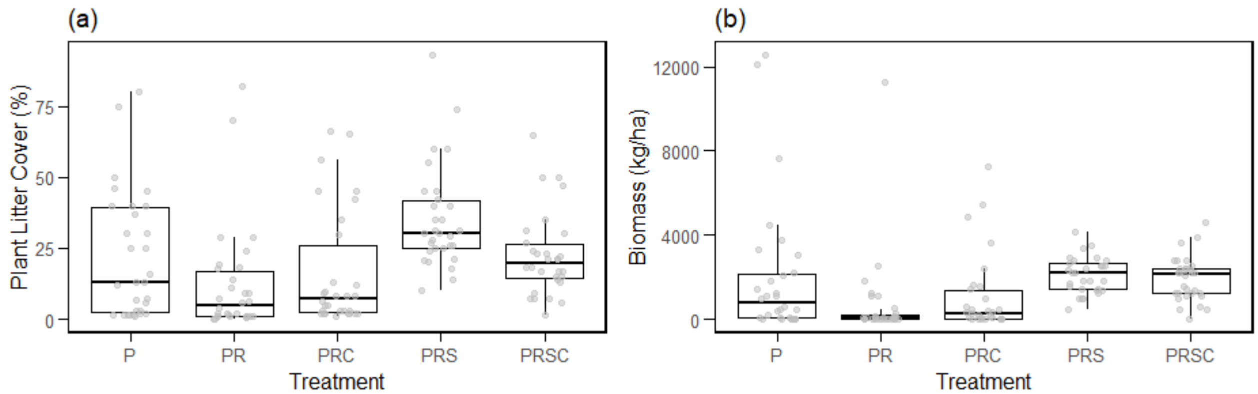

Fig 1. Boxplots of a) vegetative (plant + litter) cover and b) herbage mass across treatments in September 2024. P = ponding only, PR = Ponding and ripping, PRS = ponding, ripping and seeding, PRC = ponding, ripping and grazing exclosure, PRCS = ponding, ripping, seeding and grazing exclosure.

Species establishment

The seeded treatments (PRSC and PRS) saw *Chloris truncata* being a dominant species of sown seed with a ~9 plants per m^2 established, followed by a large count of *Panicum decompositum* and *Astrebla spp.* (Fig. 2). Other sown species, including *Einadia nutans, Rhagodia spinescens, Enchylaena tomentosa, Atriplex semibaccata, A. vesicaria* and *A. nummularia* were not present in transects in April 2024, and still had no to very low counts on assessment in September 2024.

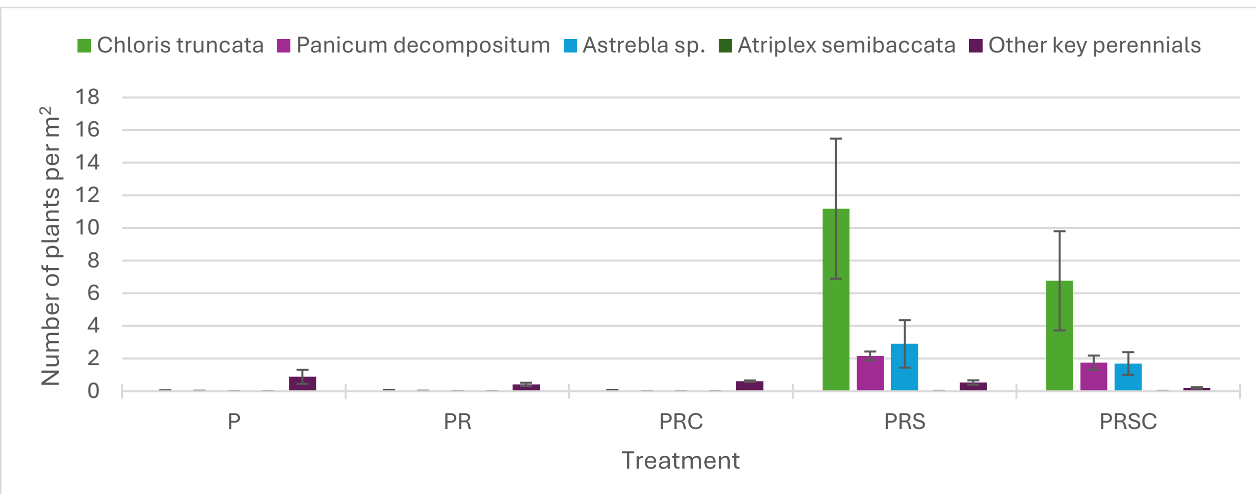

Fig 2. Average number of individual plants per m^2 of sown perennial and other perennial species recorded in different treatments in April 2024 (± 1 standard error) P = ponding only, PR = Ponding and ripping, PRS = ponding, ripping and seeding, PRC = ponding, ripping and grazing exclosure, PRCS = ponding, ripping, seeding and grazing exclosure.

Discussion

Summer rainfall in January and February of 2024 provided a germination opportunity for the seed that was sown the previous spring and continued favourable conditions throughout 2024 alongside the water ponding resulted in an increase of ground cover (>10%) in all treatments.

It has been well documented that supply and access to native species seed for large restoration projects can be limited and not efficient economically, however in this trial the treatments without seed showed a low response in perennial germination and ground cover compared to the treatments that had been seeded. Six different suppliers were required to source the quantity of seed necessary for this trial, and due to limited availability, we were unable to ensure local provenance, as would be preferable (Broadhurst *et al.* 2017). Access to limited species can also have an impact on the project outcomes and overall restoration (Broadhurst *et al.*, 2015; Broadhurst *et al.* 2017). This demonstration site used 13.51kg of seed and included differing rates of 10 different species of perennial grasses and shrubs. Although there has been success in germination and establishment of some species in the seeded treatments, the efficiencies in accessing the seed along with the economic investment should be considered alongside the risk of relying on the rainfall. By targeting seeding within water ponds this risk was reduced by increasing water availability for seed germination and establishment. Targeted seeding such as this may be a more practical and efficient approach to restoring perennial species in degraded landscapes more broadly in NSW rangelands. Early results (12 months from seeding) did not find an increase in ground cover, biomass or species germination with the removal of grazing (cage treatments). However, as the paddock was initially destocked, and later grazed by only 8 cattle, and with a favourable season reducing pressure from unmanaged herbivores within the ponded trial area, this was to be expected.

The ponding and ripping combination treatment (PR) had the lowest levels of ground cover, biomass and species establishment particularly in comparison to the ponding treatment alone (P). This was also evident when a cage was added to the treatment (PRC). Studies have shown that the effectiveness of ripping is highly dependent on the soil type and annual rainfall. Friedel at al. (1996b) found that soil disturbance techniques such as discing and pitting in the Northern Territory were successful when there was no more clay than a sandy loam.

When considering the efficiency of regeneration methods, it is important to consider the economic trade-offs and treatments across a large scale (Friedel at al.,1996b). The success of water ponding and seeding is evident in this trial however the cost relative to benefit of seeding is still in question on a broad scale application. The success of ripping should be considered alongside other treatments and soil types while a longer timeframe is required to assess the impact of the exclosures to control grazing.

Complex nature of South Australian Pastoral Lands

Maconochie, JR[1]; Humphrey, MJ[1]

[1] Pastoral Land Management Branch, Department for Environment and Water, Government of South Australia.

Key words: desert; landscape; pastoral; conservation

An overview

South Australia (SA) is the driest state in the world's driest inhabited continent. The "SA Outback" constitutes more than 80% of the State's land area or approximately 741 000 km^2. About half of this is allocated to conservation areas and Aboriginal land use – the remainder consists of pastoral stations. There are 219 stations that make up the pastoral estate in South Australia.

Socioeconomic features

The South Australian pastoral lands have long held significance as both economic resources and cultural landscapes, shaping the history, environment, and economy of the region. Covering vast semi-arid and arid regions, these lands have been utilised primarily for grazing livestock, particularly sheep and cattle, since the early 19th century. Today the many land uses occurring in the region include pastoralism, mining and petroleum extraction, conservation, renewable energy and tourism.

The pastoral estate is made up of a number of community-based districts which were originally based on Soil Conservation Boards. These districts now form the Landscape SA groups of today which link local communities to the South Australian Arid Lands Landscape Board (SAAL). There are six groups in the in the SAAL region and a seventh group in the Murrylands and Riverland Landscape Region the southernmost pastoral zone (Figure 1).

The pastoral estate is comprised of pastoral leases. Each lease is a rolling 42 year term which is reviewed every 14 years (lease assessment) and then extended to the full term of 42 years. There are 219 individual pastoral stations which may comprise of one or many pastoral leases, and cover an area of approximately 422,000 km^2. The properties or stations are operated by 160 individuals or companies and the pastoral estate (leases) is administered by the Pastoral Board of South Australia.

South Australian Dog Fence

The dingo or wild dog is Australia's only native canid, and freely roams much of inland Australia. The South Australian Dog Fence, approximately 2250 km long, runs through the pastoral lands from the New South Wales border to the east, around the North Flinders, across the middle of the state between Lake

Torrens and Kati Thanda – Lake Eyre South and then south to the cliffs of the Nullarbor Plain above the Great Australian Bight. The fence was built in sections as the pastoral estate was expanded in South Australia from the late 1800's, initially as a rabbit proof fence and then later heightened to exclude the dingo and wild dogs. In 1947 the Dog Fence Act came into operation and established a formal dog-proof fence "for the purpose of preventing the entry of wild dogs into the pastoral and agricultural areas of the State'. Today the fence creates a wild-dog free area to the south enabling grazing by both sheep and cattle, and the area north of the fence predominantly cattle and where wild dogs are still present.

Biophysical features

The geology and topography of the state consists of sandy deserts to the north and west, large inland salt lakes separated by ancient mountain ranges, saltbush and majestic tree woodlands, grassy tablelands, broad gibber plains and large free-flowing arid waterways which drain through vast lagoons and swamps into arid inland salt lakes.

The climate of the pastoral zone varies from the north to the south and east to west as South Australia is affected by weather patterns in the Pacific, Indian and Southern oceans. Both temperature and rainfall vary across the pastoral zone as a result of the latitudinal gradient affecting the weather patterns through-out the year with the north experiencing very hot summers and the east having freezing conditions in the winter.

Average annual temperatures have been gradually increasing in South Australia since the early 1970's with the highest rates of increase occurring in the north of the pastoral zone with mean annual temperatures having increased by 1.5 degrees Celsius (ºC) over the past 50 years. The hot summers in the north and north-east can see temperatures exceeding 40 ºC for a number of successive days. Climate scenarios are predicting potential average daily temperature increases of up to 2.2 ºC by 2050.

Rainfall trends vary across the pastoral zone, with averages ranging from 150 mm in the east and south, up to 300 mm on the highest reaches of the Flinders ranges in the North Flinders region. Thunderstorms and tropical inflows in the north can result in short but intense rain events that may produce a year's rainfall in one event. The northern rangelands are dominated by summer rainfall, with cyclonic weather systems of northern Australia entering SA from the north-west or occasionally from south-west Queensland. The southern portion of the rangelands is dominated by winter rainfall with cold fronts coming up from the south-west. Regional variation show that the far north of the pastoral zone is experiencing an increase in summer rainfall and the winter rainfall of the southern areas decreasing over the last 30 years. In general, the extremes in summer temperatures that occur across the pastoral zone often result in evaporation rates far exceeding rainfall.

These climatic variations across the pastoral region are reflected in the many diverse landscapes and associated vegetation communities that form the seven landscape regions.

Regional Features

Marree – Innamincka region

The Marree Innamincka region is in the far north-east of the state extending over 200 000 km2 or 20% of SA. This region contains free flowing arid rivers of the Diamantina and Cooper systems comprising the Goyder lagoon and the Coongie lakes near Innamincka. Both systems flow because of monsoonal rains in central and south-western Queensland and which, on extreme and rare rain events, will eventually empty into Kati Thanda - Lake Eyre. Sandy desert landscapes also dominate the region with the Simpson Desert, Strzelecki, and Tirari Deserts. Less extensive, the Sturt Stony Desert lies between the river channel country and is comprised of extensive flat clay dominated gibber (small, polished stones) plains with very sparse vegetation, scattered dunes and productive sand mounds. Land use is primarily pastoral with oil and gas production in the eastern parts with private and state conservation parks forming part of the increasing tourism industry.

Marla – Oodnadatta region
The Marla Oodnadatta region is in the far north of the state covering an area of 132 400 km2. The region comprises numerous landscapes, ranging from sweeping gibber plains with fertile sand lenses and dunes, tablelands with numerous drainage lines running east to Kati Thanda – Lake Eyre. There are weathered hills and plateaus forming "Breakaways" and extensive gibber plains with scattered gilgais containing perennial grasses and chenopod shrubland vegetation. Mulga woodlands scattered across the region on the sandier soils. A number of Conservation areas occur in the region and ancient mound springs of the Great Artesian Basin still occur in a number of areas. Land use is pastoralism with key resource mining, private conservation, and mining of precious stones of the Coober Pedy and Andamooka opal fields.

Kingoonya region
The Kingoonya region is in the centre of South Australia and covers 65 815 km2. This region is bounded by the Dog fence to the north and west and large salt lakes to the south and east. The national railway network crosses the region both the north-south and east-west. Vegetation is comprised of mulga and myall woodlands with chenopod shrublands, mallee dune systems and treeless undulating tablelands of low chenopod shrublands. The primary land use is sheep pastoralism with several properties running cattle enterprises. Mining and conservation are also represented with several large mines, the largest of which is Olympic dam, and one of the earliest pastoral leases purchased for private conservation, Bon Bon Station, also occurring in the region.

Gawler Ranges region
The Gawler Ranges region is 51 900 km2 in size and is comprised of several large salt lakes, including Lake Everard and Lake Gairdner and the rounded rocky hills and broad valleys of the Gawler Ranges. These ranges form the principal component of the region and are dominated by chenopod shrublands and mixed woodlands of mulga, black oak, myall and wattle. The region also has a system of parallel dunes with plains and salt lakes. Mallee, myall, sugar wood and mulga woodlands with chenopod shrublands occur across the region. The primary land use of the region is pastoralism with the first pastoral leases established in the 1850's.

North Flinders region
The North Flinders region lies between Lake Torrens, Lake Frome and south of Kati Thanda - Lake Eyre being 33 500 km2 in size and encompassing the Flinders and Gammon Ranges. The dog fence bounds the north and east of the region. This diverse landscape is comprised of plains, rugged ranges and outcrops. The complex nature of the ranges gives rise to the many landscapes of the region ranging from alluvial plains with mixed grasses and chenopods, undulating grassy gibber tablelands and plains to gentle rises and hills of annual grasses and chenopods. The ranges vary from shaley hills of mallee and pine, sandstone hills of mallee and mulga to high rugged ranges with cypress pine, spinifex and grasses and deep red gum gorges. Pastoralism began in the region in the early 1850's and continues today as the primary land use. Tourism and conservation have increased with many properties having accommodation facilities for visitors. Formal conservation in the region is supported through three national parks occurring in the region: Ikara – Flinders Ranges, Vulkathunha – Gammon Ranges, and Nilpena Ediacara National Park.

North East region

The North East pastoral region is 34 500 km2 and is bounded by the Dog fence to the north and the New South Wales / South Australian border to the east. The main feature of the region is the Olary Spur, a series of ancient hills, geologically an extension of the Flinders Ranges. The region also comprises flat to undulating plains with chenopod shrublands and areas of low woodlands and shrublands. The Olary Spur consist of chenopod plains and open woodlands with numerous water courses and river red gum lined creeks. Mallee box open woodlands can be found on hills and ridges with mallee, sugar woods, and black oaks woodlands with chenopod shrublands with mallee on the sand plains and low dunes. To the north of the region chenopod shrublands and grasslands on open plains and rises and low hills are a major feature of the landscape. The major land use of the region is pastoral grazing of sheep for wool production and some cattle enterprises. Other land uses include mining and conservation with several conservation areas previously being operational pastoral enterprises.

Eastern District region

The Eastern District region is the smallest in SA at 22,240 km2 and contains the most southern pastoral leases administered by the Board forming the northern half of the Murrylands and Riverland Landscape Region. The pastoral properties of the region encompass both sheep and cattle production along with individual conservation leases and adjoining large conservation parks on the eastern boundary. The landscape is diverse ranging from alluvial and gentle plains with black oak and chenopod shrublands, sand plains and dune fields of extensive mallee occupying half of the district, through to chenopod shrublands and grasslands.

Key words: bush encroachment, stocking rate

Abstract

Kalahari Savanah rangeland of Southern Africa is known for well-balanced herbaceous and woody layers. Historic use of conventional grazing, with long grazing periods and insufficient rest periods, caused bush encroachment. High density grazing might prevent bush encroachment. Two grazing approaches were compared to quantify their impact on tree density. The conventional grazing (CG) approach consisted of four camps. Cattle grazed each camp for 14 days, at a grazing pressure of 0.5 large stock units (LSU) per hectare (ha), followed by 42 days of rest. This equates to a stocking rate of 8 ha per LSU. For the high-density (HD) approach, camps were grazed one to two days, at 27.5 LSU/ha, with rest periods of 120 days. Which equates to a stocking rate of 4 ha per LSU. Surveys were done along a 100m x 2.5m belt transect (four replicates, three distances from watering point), using the Biomass Estimates from Canopy Volume model (BECVOL). This method measures woody species richness, total tree density (plants ha^{-1}), total dry matter production estimates (kg DM ha^{-1}) and Total Evapotranspiration Tree Equivalents (ETTE ha^{-1}). Tree density was lower at HD (780 plants ha^{-1}) compared to CG (1 077 plants ha^{-1}), ($P > 0.05$). Evapotranspiration tree equivalents was significantly ($P < 0.05$) lower at HD (1 605 ETTE ha^{-1}) than at CG (2 295 ETTE ha^{-1}). Total woody biomass production was almost similar for CG (2 730 kg DM ha^{-1}) and HD (2 790 kg DM ha^{-1}). Seedling density was significantly ($P < 0.05$) higher at CG (1 303 plants ha^{-1}) than at HD (684 plants ha^{-1}). High-density grazing generally had a far less negative impact on tree density than conventional grazing. It can therefore be concluded that a HD grazing approach could contribute positively towards ecosystem health in the Kalahari Savannah of South Africa.

Introduction

Pristine Kalahari Savanah rangeland of Southern Africa is known for well-balanced herbaceous (grass) and woody (tree and shrub) layers (Mucina and Rutherford, 2006). Historic application of continuous grazing and later conventional rotational grazing systems, with long grazing periods and insufficient rest periods, has caused bush encroachment (Smit 2004, Ward 2005, Bond & Midgley 2012, Belayneh and Tessema 2017). High density grazing, which entails higher densities of grazing livestock for shorter periods, followed by longer resting periods, proofed to enhance general ecosystem health (Chaplot et al. 2016; Malan 2022; Malan and Paulse 2023). This method of grazing forms part of regenerative grazing which has the benefit, amongst others, of preventing bush encroachment (Teague and Barnes 2017; Franke and Kotze 2022, Gebremedhn et al 2023). The objective of this study was to compare the tree densities of two adjacent farms, one under conventional grazing and the other under high density grazing.

Methods

The study area is situated within the Kalahari bushveld bioregion (SVk 1, Mafikeng bushveld), (Mucina and Rutherford, 2006), with a long-term grazing capacity of 8 ha LSU^{-1} (hectare per Large Stock Unit) as indicated in the Long term Grazing Capacity Provincial Maps (2018). This region is characterized by a well-developed grass layer consisting of species such as *Stipagrotis uniplumis, Eragrostis lehmanniana, Schmidtia pappophoroides* and *Schmidtia kalihariensis* (Mucina and Rutherford, 2006; Sandhage-Hofmann et al. 2015). The dominating trees and shrubs are: *Dichrostachys cinerea, Grewia flava, Grewia retinervis, Tarchonanthus camphoratus, Vachellia erioloba, Vachellia hebeclada,* and *Ziziphus mucronata* (Mucina and Rutherford, 2006). The aim was to compare the vegetation dynamics of two adjacent, commercial cattle farms, who were grazed at different grazing approaches over a 20-year period. Two grazing approaches were compared to quantify their impact on the density of woody vegetation. The conventional grazing (CG) approach (normal stocking rate of 8 ha/LSU per year) consisted of four camps, 62 ha each. Cattle (Brahman cross breeds, mean cow weight 550kg, weaning rate 95% at 260kg) grazed each camp for 14 days, at a low stocking density of 0.5 large stock units (LSU) per hectare (ha), followed by 42 days rest. For the high-density (HD) approach (double the stocking rate at 4 ha/LSU per year) camps (10 ha each) were grazed (with Bovelder cross breed cattle, mean cow weight 470kg, weaning rate 98% at 230kg) one to two days at a high stocking density of 27.5 LSU/ha, with rest periods of 120 days.

Surveys were done along a 100m x 2.5m belt transect (four replicates at each of three distances from watering point), using the Biomass Estimates from Canopy Volume model (BECVOL) (Smit 1996; Smit 2014). This method measures woody species richness, total tree density (plants ha^{-1}), total dry matter production estimates (kg DM ha^{-1}) and Total Evapotranspiration Tree Equivalents (ETTE ha^{-1}). The ETTE is defined by Smit (2014) as the leaf volume equivalent of a 1.5m single-stemmed tree. The SPPS statistics for windows package was used for statistical analyses (IBM, 2017)

Results

Results are summarized in Table 1. Total woody biomass production was almost similar for CG (2 730 kg DM ha^{-1}) and HD (2 790 kg DM ha^{-1}), while the other characteristics had big differences. The reason for similar biomass is due to the presence of more big trees in relation to small trees on the HD farm. This phenomenon usually corelates with a healthier savanna ecosystem (Bond and Midgley 2012; Smit 2022). Tree density was lower at HD (780 plants ha^{-1}) compared to CG (1 077 plants ha^{-1}), ($P > 0.05$). Evapotranspiration tree equivalents was significantly ($P < 0.05$) lower at HD (1 605 ETTE ha^{-1}) than at CG (2 295 ETTE ha^{-1}). The higher number of ETTE's on the CG farm is an indication of more, but smaller trees, an indication of a bush encroached area (Belayneh and Tessema 2017; Smit 2022). Similar results were found with seedling density, which was significantly ($P < 0.05$) higher at CG (1 303 plants ha^{-1}) than at HD (684 plants ha^{-1}). The majority of the seedlings present on the CG farm was that of unwanted species like *Dichrostachys cinerea* and *Gymnosporia buxifolia*.

Table 1: Mean tree density, ETTE, total biomass production and seedling density of woody plants for two grazing approaches. (mean ± SE).

Woody layer	**CG**	**HD**
Tree density (Plants ha^{-1})	1 077 ± 42	780 ± 46
ETTE (ETTE ha^{-1})	2 295 ± 59	1 605 ± 55*
Total biomass (kg DM ha^{-1})	2 730 ± 74	2 790 ± 99
Seedling density (Plants ha^{-1})	1 303 ± 19	684 ± 15*

*P < 0.05. Total Evapotranspiration Tree Equivalents (**ETTE**), Grazing approaches [conventional grazing (**CG**), high-density grazing (**HDRa**).

Although this paper focusses on the woody layer, it is worth mentioning that CG had a lower veld condition score of 412 compared to 581 of HD, while the percentage of perennial grasses was also higher (64%) at HD than at CG (43%).

Discussion

Bush encroachment due to wrong grazing practices is a huge problem in the savanna areas of the world (Kgosikoma and Mogotsi 2023; Di Virgilio et al. 2019, Gebremedhn et al. 2023). Such grazing practices includes continuous grazing and approaches with long grazing periods and improper resting periods. High density grazing leads to a high grazing impact for a short period, followed by an extended rest (recovery) period (Chaplot et al. 2016, Franke and Kotzè 2022). This grazing approach is believed to hold many benefits by improving soil health, vegetation health and animal health (Hawkins et al. 2017; Malan 2022). In this study, high-density grazing generally had a far less negative impact on the density of woody vegetation than lower density (conventional) grazing. It can therefore be concluded that a HD grazing approach could contribute positively towards ecosystem health in the Kalahari Savannah of South Africa.

Key words: *Pennisetum ciliare*, Sonoran Desert, *Pyricularia*, seed quality.

Abstract

Buffelgrass (*Pennisetum ciliare*) leaf blight is a disease caused by the fungus (*Pyricularia grisea*), which may kill plants and reduce the quantity and quality of foliage and seeds. The study was conducted on three ranches during 2016-2017 in Sonora, Mexico, to determine the effect of leaf blight on seed production and the economic impact on ranchers. Pastures damaged by the pathogen were selected to evaluate the number of affected plants, plant density, raw and clean seed production, seed cost, net gain from seed sales, and economic loss. Data were analyzed using ANOVA ($P \leq 0.05$). Precipitation was 10 to 40% above the average at all sites and in all years of the study. From 46 to 59% of the buffel grass plants showed some damage. Null to very light plant damage was found in 31.5-36.6% of the plants, slight damage in 21.3-42.8%, and moderate damage in 25.7-42.1%. The production of raw seed was affected ($P \leq 0.05$) by the damage from the fungus and varied from 61.4-81.8 kg/ha for no damage, 46.2-53.8 kg/ha for light damage, and 28.6-36.9 kg/ha for moderate damage. The cost of clean seed for sale averaged $90.00 Mexican pesos during 2017 and 2018, and the clean buffelgrass seed produced differed ($P \leq 0.05$) among treatments. It averaged 41.27, 30.9, and 17.3 kg/ha for areas with no damage, light damage, and moderate damage, respectively, representing a net profit from seed sales of $3,714.3, $2,781.0, and $1,557.0 pesos/ha for areas with no damage, light damage, and moderate damage, respectively. Therefore, the loss caused by fungal damage was $933.0/ha in areas with light damage and $2,157.3/ha in areas with moderate damage. We concluded that leaf blight affects the seed production of buffelgrass, and necessary measures must be taken to reduce plant and seed damage.

Introduction
Buffelgrass leaf blight is a disease caused by the fungus (*Pyricularia grisea*), (*Magnaporthe oryzae*) or (*Magnaporthe grisea*) which reduces the quantity and quality of the foliage and the amount and quality of seed produced by the grass. The grass has been successfully established in more than 2 million hectares in Mexico and in more than 30 million hectares in different regions of the world (Ibarra et al., 1989; Cox et al., 1988). In Northeast Mexico and Southeast United States reductions between 10 and 50% in grass production are reported (Rodriguez et al., 1999; Diaz et al., 2007). More recently, under the climatic conditions of Northwestern Mexico, leaf blight damage has been also reported with severe foliage and seed damage (Ibarra et al., 2022). Perrott and Chakraborty (1999), report similar results in foliage and seed damage by the fungus in buffelgrass in rangelands at Queensland Australia.

The buffel blight fungus is very small and cannot be seen with the naked eye, it lives in the ground and in the base of the plants, can last several years there and it is moved by wind, water, livestock and man (Ibarra *et al*, 2022). Severe damage can reduce the amount of dry forage by 25 and 62% and between 20 and 55% the nutritional quality of the grass. During severe attacks total buffelgrass seed production may be reduced by 45 and 60% and in years even with less humidity, less severe attacks may appear, and they can kill from 20 and 35% of the grass seed. Several million ha of desert brushland has been planted with buffelgrass to restore productivity. Forage production and cattle numbers in these areas have five to ten-fold (Martin *et al*., 1995) and a decline in forage production by fungus damage will reduce meet production and ranchers' income. Information that shows how *Pyricularia* will affect buffelgrass forage production as well as seed quantity and quality does not exist. The objective of this study was to measure how much buffelgrass forage and seed will be affected by the fungus at different ranches in central Sonora Mexico.

Methods
The study was conducted on three ranches during 2016-2017 in Sonora, Mexico, to determine the effect of leaf blight on seed production and the economic impact on ranchers. Ranches selected were la Loma, located 15 km west of Santa Ana; El Águila ranch, located 20 km south of Santa Ana, Sonora; and Pozo Crisanto ranch, located 86 km north of Hermosillo. Pastures damaged by the pathogen were selected to evaluate the number of affected plants. Evaluated variables were number of young and adult plants affected, plant density, gross seed production, clean seed production, percentage of loss in harvested seed, seed cost, net profit from seed sales and economic loss due to fungus damage. The number of damaged and undamaged adult and young plants was determined by quantifying the total number of plants present in 10 quadrats of 10 x 20 m in each ranch. In each plot, the degree of damage was quantified in three categories. The scale used was created using the three categories: (1) No damage or very slight damage, when the plants showed green foliage and no chlorotic or spotted symptoms typical of the pathogen were present and less than 10% damage was shown in the total of foliage, (2) Light damage, when the plants showed between 11 and 30% of the leaf material damaged, and (3) Moderate damage, when the plants showed between 31 and 50% of foliage with damage. Data were analyzed using ANOVA ($P \leq 0.05$ (Steel and Torrie, 1980)). To estimate the cost of clean buffel grass seed, three of the main harvesters and seed producers in the state were interviewed in order to ask the cost of selling it during the production periods of 2017 and 2018, which resulted in $90.00 per kilogram for sale, with an average germination that varied from 27.9 to 37.8% and a viable seed percentage from 79.5 to 92.0%, the same information was compared with the Department of Machinery Division of the Cattlemen Union of Sonora, (UGRS, 2017). The net profit from the sale of seed in each farm was estimated by multiplying the kg of clean seed/hectare harvested in each farm, by the cost of the clean seed assigned previously. The economic loss in seed production associated with *Pyricularia*

damage was determined by difference, comparing its production in areas with light and moderate damage against the production achieved in areas without damage.

Results

Precipitation was 10 to 40% above the average at all sites and in all years of the study. From 46 to 59% of the buffel grass plants showed some damage. Leaf blight caused significant damage ($P \leq 0.05$) to buffelgrass plants at all evaluation sites (Table 1). Null to very light plant damage was found in 31.5-36.6% of the plants, slight damage in 21.3-42.8%, and moderate damage in 25.7-42.1%. More importantly, even new buffelgrass seedlings 5 to 10 cm tall show severe fungus damage.

Although on average 38.9% of the total plants in the grasslands showed no to very light damage, 61.1% showed light to moderate damage. Adult plants, which generally represent the largest volume of coverage of the occupied land, showed a varied intensity of damage. Lightly damaged plants represented between 31.5 and 48.7% of the plants in all farms, with moderate damage between 19.8 and 42.8% of the plants were detected and with intense damage between 25.7 and 42.1% of the plants.

The production of raw seed was affected ($P \leq 0.05$) by the damage from the fungus (Table 2) and varied from 61.4-81.8 kg/ha for no damage, 46.2-53.8 kg/ha for light damage, and 28.6-36.9 kg/ha for moderate damage. Clean seed was also affected by the pathogen. The cost of clean seed for sale averaged $90.00 Mexican pesos during 2017 and 2018, and the clean buffelgrass seed produced was different ($P \leq 0.05$) among treatments. Clean seed averaged 41.27, 30.9, and 17.3 kg/ha for areas with no damage, light damage, and moderate damage, respectively, representing a net profit from seed sales of $3,714.3, $2,781.0, and $1,557.0 pesos/ha for areas with no damage, light damage, and moderate damage, respectively. Therefore, the loss caused by fungal damage was $933.0/ha in areas with light damage and $2,157.3/ha in areas with moderate damage.

Table 1. Degree of leaf blight damage in adult buffelgrass plants in three locations during the summers of 2016 and 2017 in the central region of Sonora, Mexico.

Degree of Damage	Ranches			Average
	La Loma	El Águila	El Pozo	
None to very Light	31.5 b*	36.6 b	48.7 a	38.9
Light	42.8 a	21.3 c	19.8 c	28.0
Moderate	25.7 c	42.1 a	31.5 b	33.1
Total	100	100	100	100

* Means between treatments with different lowercase letters are different ($P \leq 0.05$).

Table 2. Production of raw seed of buffelgrass (kg/ha) affected in various intensities by leaf blight during the summers of 2016 and 2017 in three cattle ranches in the central region of Sonora, Mexico.

Degree of Damage	Ranches			Average
	La Loma	El Águila	Pozo Crisanto	
None to very Light	81.8 a*	71.9 a	61.4 a	71.7
Light	53.8 b	46.2 b	48.4 b	49.5
Moderate	36.9 c	28.6 c	34.6 c	33.4
Average	57.5	48.9	48.1	

* Means between treatments with different lowercase letters are different ($P \leq 0.05$). The average is the result of two years of harvest.

Discussion

The results of this study agree with those reported by FAOSTAT (2010); Baker et al. (1997), Yoon et al., (2011) and Shirasawa et al. (2012), on the susceptibility of the grass family such as corn and rice, reporting that the plants are not equally damaged by *Pyricularia,* varying from 10 to 15% of the annual yield losses. In the case of common American buffelgrass, the results in this study show a reduction in foliage of 61% in plants that present light to moderate damage. In Tamilnadu, India, in rice cultivation this is one of the most devastating diseases in susceptible cultivars, causing a yield loss of up to 90% (Mehrotra, 1998; Jaiganesh et al., 2007).

Blight affects the foliage of plants, directly interrupting the synthesis of chlorophyll production, which influences the seed production capacity and quality of the affected plants (Díaz et al., 2007), Consequently, the spikes do not develop completely, since the florets do not have complete caryopses or are empty. On the other hand, it has been shown that the quality of the seed is affected due to the physiological disorders suffered by the plant, reporting losses of up to 11% of chlorophyll, 20 to 26% in biomes, 13% in protein and 30% in the digestibility (González, 2002). This is very important, especially for producers who sow or use the seed for the rehabilitation of buffel pastures, since, in the grass seed, the pathogen is found that can be transmitted and transported to other areas where it does not exist and runs the risk of contaminating

Conclusions and implications

Common buffelgrass plants were damaged by leaf blight, but not all plants in the prairie were similarly affected, seedlings from 5 to 10 cm tall were also severely attacked by the pathogen. We concluded that leaf blight affects the seed production of buffelgrass, and necessary measures must be taken to reduce plant and seed damage. Ranchers with buffelgrass pastures under similar conditions can expect a 25.1 to 58.0% decrease in annual seed production, representing approximate losses of $933.00 to $2,157.00 pesos per hectare per year.

Larger trees facilitate understory herbaceous biomass but not diversity in a South African savanna

Monegi, P [1, 2]; Samuels, I [2, 3]

Keywords: Grass biomass; grass cover; invasive species; species richness; tree architecture; woody plant encroachment

Abstract
Large single-standing trees contribute to the structural diversity of savannas as they strongly influence their immediate surroundings such as soils and understory plant communities. The influence of woody vegetation at a stand level on the understory vegetation has been extensively studied; however, the understanding of the role of single large trees is limited. The objectives of the study were to 1) evaluate the impact of large trees on understory plant species diversity and composition, herbaceous cover and grass standing biomass, and 2) to establish if plant size and functional qualities such as N-fixing ability modulate understory vegetation responses to overstory trees over two growing seasons (January 2022 and 2023). *Vachellia tortilis* (a leguminous tree) and non-leguminous woody species (*Searsia l*ancea and *Ziziphus mucronata*) were studied. We systematically selected 30 trees for each woody species and divided them into two size classes (i.e. small and large trees). Understory plant vegetation was assessed using quadrats under and outside the tree canopies. Plant species diversity and abundance were highest under small tree canopies and outside tree canopies compared to under large trees. Panicum maximum was the dominant grass species under large trees regardless of N-fixing ability. Nonetheless, grass cover was enhanced under large *V. tortilis* and *Z. mucronata*. Standing grass biomass was higher under the canopies of large trees compared to small trees and outside canopies, with N-fixing ability having no significant effect ($p > 0.05$). The current findings imply that in agrosilvopastoral systems and game farming, where ecological conservation is a priority for farmers, it is essential to have an overstorey composed of both small and large trees to sustain understory diversity and biomass.

Introduction

Our understanding of the role of trees of varying sizes and functional qualities is limited (Pillay and Ward, 2012). There is a considerable variance on the impact of large trees on the understory vegetation. For instance, studies conducted in a semi-arid savanna of Ethiopia have found that large trees enhance herbaceous understory richness and biomass, with significant increases recorded under N-fixing leguminous trees (Tessema and Belay, 2017). Other studies conducted in South African savannas have found non-significant effects, particularly on standing herbaceous biomass, regardless of N-fixing ability (Treydte et al., 2007).

Nonetheless, certain nitrophilous grasses, particularly *Panicum maximum* (Jacq) have been documented to colonise and flourish under trees (Smit, 2005). *P. maximum* is a shade-tolerant and highly competitive grass species (Smith et al., 2013). Consequently, *P. maximum* may threaten species richness and diversity under tree canopies. Nevertheless, effects of woody plants to understory may vary by encroaching species, and understory herbaceous species (Kahi et al., 2009), thus, site-specific assessment of herbaceous plant responses to overstory trees is crucial.

Methods and Study Site

The study was conducted at Roodeplaat experimental farm (25°56′S, 28°35′E) of the Agricultural Research Council (ARC) in Gauteng Province of South Africa. Three dominant woody species representing one leguminous (*Vachellia tortilis*) and two non-leguminous tree species (*Searsia lancea* and *Ziziphus mucronata*), found in isolation, were selected for this study. These woody species are representative of the dominant trees in the study area. We systematically selected 30 trees for each woody species and divided them into two size classes (i.e. small and large trees). Small trees had a similar canopy area (≈ 10 m^2) and height (≈ 3 m). Large trees also had a similar canopy area (≈ 40 m^2) and tree height (≈ 6 m) (Ludwig et al., 2004). In total 90 trees (three species × 30 trees) were selected for this study in a permanently fenced area where grazing was excluded.

We recorded the species composition of understory vegetation including herbaceous species as well as seedlings of woody species under and outside individual tree canopies over two growing seasons (January 2022 and 2023). Four quadrats (0.5 m × 0.5 m) in four directions (north, south, east and west) were used for herbaceous assessments under the inside and outside canopy (i.e. the area surrounding the canopy within a 2 m range) of each individual tree. Outside canopy sampling points functioned as a control for possible changes in microclimate or plant cover in the understory. To ascertain the relative contributions of each functional group, the species were further divided into grasses, forbs and woody species. All individual plant species were counted and identified to species level in each 0.5 m × 0.5 m quadrat. Herbaceous cover (grass and forb) was visually assessed within the quadrat by two individuals, and their estimates were subsequently averaged to produce a single representative measurement. Standing grass biomass regardless of species was harvested in each 0.5 m × 0.5 m quadrat. The grass samples were oven dried at 70ºC for 72 h and weighed to determine dry-matter yield.

A two-way ANOVA was conducted using general linear models (GLMs) to determine the main effects of tree species and microsites on mean total species richness and diversity, herbaceous cover and standing grass biomass.

Results

A total of 26 plant species were recorded with perennial species being the most abundant, with grasses recording the highest contribution (n = 14). Poaceae was the most dominant family with predominantly native species, whilst forbs were mostly invasive species.

Plant species diversity was substantially affected by microsites ($F = 26.429$; $p < 0.001$), tree species ($F = 11.818$; $p < 0.001$) and their interactions ($F = 5.723$; $p < 0.001$). A Bonferroni post hoc test indicated that small *S. lancea*, *Z. mucronata* and *V. tortilis*, and outside of the canopies recorded a greater species diversity compared to large *S. lancea* and *Z. mucronata*. Plant species richness was significantly greater under small trees and outside canopies than under large trees ($p < 0.05$), particularly under large *S. lancea* and *Z. mucronata*.

Grass cover was substantially low under large *S. lancea* trees compared to outside canopies, and under large V. tortilis and Z. mucronate ($p < 0.05$). Large trees of *S. lancea*, *V. tortilis* and *Z. mucronata* significantly increased understory standing grass biomass ($p < 0.05$). In addition, large *S. lancea*, *V. tortilis* and *Z. mucronata* trees were associated with a higher abundance the highly nutritious *P. maximum* than other understory grass species.

Discussion

Effects of mediated microsites on plant species diversity and richness

Reduced species diversity under large trees could be attributed to the dominance of *P. maximum* under large trees, which significantly reduced understory diversity and richness. In support, Mlambo et al., (2005) demonstrated that *P. maximum* increases in abundance under large *Colophospermum* mopane trees. The findings from the current study suggest that an increase in abundance of *P. maximum* under tree canopies result in a significant reduction in understory species diversity. Nonetheless, the results from the current study indicated that the facilitative effects of smaller trees on the diversity and richness of understory vegetation out-weighed the competitive effects of trees on understory species. Thus, our result confirmed that the facilitative effects would lead to more number of species and plant abundance under canopies of smaller trees compared to large trees. However, this relationship shifts as tree size increases.

The effects of tree-meditated microsites on herbaceous cover and standing grass biomass

The substantial reduction in grass cover under large *S. lancea* trees was attributed to that herbaceous cover under woody plants with evergreen leaf phenology significantly decline (Belay and Moe, 2015). The study findings suggest that the traits of specific woody plants are more useful for predicting the effects of woody plant encroachment on grass herbaceous cover than increased tree densities. Although grass cover declined under large *S. lancea* trees, grass biomass was substantially enhanced under large trees of all the study species. we attributed the increased standing grass biomass under large trees to the enhanced soil fertility through N-fixing ability (i.e. *V. tortilis*) and greater litter biomass that returns to the soils (i.e. *S. lancea* and *Z. mucronata*). Nonetheless, our study shows that the impact of small trees on standing grass biomass may operate independently of diversity and richness because small trees had a similar number of species compared with outside canopies but distinct standing grass biomass, particularly *V. tortilis* and *Z. mucronata*.

Responses of plant species composition to mediated microsites

Large *S. lancea*, *V. tortilis* and *Z. mucronata* were associated with a high abundance of *P. maximum*, which was not surprising result because of the possible elevated micro-climate under the canopies of these species. The study findings demonstrate that the increased abundances of *P. maximum* plants under canopies of large trees is more important for grazers because of the high nutritional value of this species (Hare et al., 2021). Although *P. maximum* was the dominant plant species under large trees, the invasive Lantana camara was also associated with large trees, particularly *V. tortilis*. These results concur with McMahon and Ward (2021) who reported a higher abundance of *L. camara* under large trees, particularly of leguminous species.

Conclusions

Overall, the findings showed that understory plant vegetation, particularly of the herbaceous layer, responses regarding grass cover and biomass, diversity and composition depend on the tree sizes and microsites (i.e. under or outside the canopies). The increased standing grass biomass under large trees indicate that it may be beneficial to maintain large trees in savannas, particularly where pastoralism and game farming are the main objectives, although herbaceous diversity may decline. Additionally, the dominance by *P. maximum* under large trees have the greatest potential for providing forage for herbivores its high production and nutritive value (Hare et al., 2021).

You Can Lead a Horse to Water: Mapping Seasonal Water Resources to Predict Wild Horse Movements on Utah Rangelands

Nelson, M[1]; Stoner, D[2]; Thacker, E[3]; Greenhalgh, E[1]

[1]Utah State University Extension; [2]Utah State University Department of Wildland Resources; [3]Utah State University Extension and Department of Wildland Resources;

Key words: Wild Horses; Rangelands; Water Resources.

Abstract
Livestock producers in Utah can be adversely impacted by competition from wild horses whose seasonal distribution is strongly influenced by the availability of temporary surface water. We used a simple analysis of Landsat imagery acquired over an 18-year period to determine the distribution and duration of surface water in Utah rangelands. The resulting maps can be used to identify conflict hotspots and prioritize management activities. Improved prediction would result from future mapping of water sources not resolved at the 30-m scale of our analysis.

Introduction
Deserts are defined not only by the lack of water, but also by tremendous year-to-year variation in the timing and amount of precipitation. Water distribution strongly influences animal movements and habitat use in these systems. A major problem on western ranges in the United States is that areas managed for wild horses overlap those managed for livestock.

Seasonal movements of wild horses (*Equus caballus*) are determined by water availability (Schoenecker et al., 2022), which varies with elevation, latitude, and from year to year. In summer, herds with access to permanent springs or stock ponds may remain relatively sedentary, whereas those without these resources may become nomadic, searching for temporary water resulting from rainfall or snowmelt. Field studies in Utah and Arizona have shown that surface water availability is the strongest determinant of habitat use for horses and livestock (Miller, 1983; Schoenecker et al., 2022). Migrating horses traverse cattle grazing allotments (areas of public land managed by federal agencies like the Bureau of Land Management – BLM - and the U.S. Forest Service -USFS - where livestock grazing is permitted), croplands, and highways, resulting in conflict with other land uses.

Wild horses and burros in Utah are managed by the BLM within congressionally designated wild horse herd management areas (HMA), all of which overlap BLM grazing allotments. In dry periods or droughts, to which the region is prone, wildlife and livestock concentrate in mesic areas, which can become problematic for farmers and livestock producers.

We aimed to map the annual distribution of temporary surface water across Utah as an aid in predicting the likely impact of wild horses on livestock grazing operations.

Methods

To estimate the extent and duration of surface water (perennial and ephemeral, combined), we employed the methods described in Feng et al. (2016). This procedure involved compiling images from the Landsat archive from May through October, 2000-2018. These months were selected as they encompass the growing season when temperatures and therefore evapotranspiration are highest, and water is most limiting to animals. This is also the driest time of year as all snow cover has melted and the only ephemeral surface water available is the result of highly sporadic summer thunderstorms. Based on these criteria, we selected all available images for the study area across this interval. This amounted to approximately 2-4 images per month at 30-m pixel resolution. We then used the Normalized Difference Water Index (NDWI) to detect areas of water cover. This index uses near-infared (NIR) to distinguish water from soil or vegetation, as water strongly absorbs NIR, whereas vegetated surfaces reflect this wavelength. The NDWI is defined as [NIR-Red]/ [NIR+Red]. Index values range from -1 to 1, with negative values indicating water cover (McFeeters 1996).

To estimate the duration of surface inundation, we overlaid all images compiled between 1 May and 31 October and calculated the proportion of time each pixel displayed evidence of surface water using NDWI < 0 as our threshold. Thus, a pixel with NDWI values < 0 for the entire 6-month duration would be indicative of perennial water, and proportions less than 100% would be indicative of corresponding degrees of ephemeral water cover. Some localized water sources could not be detected at 30-m resolution, so our estimates are biased low.

To estimate the number and areal extent of public-lands grazing allotments potentially affected by wild horses, we used spatial data from the Utah Automated Geographic Reference Center (AGRC: https://gis.utah.gov/). This dataset delineates all allotments designated for grazing on USFS or BLM land. Attributes include the area (in acres) and the species of livestock that are permitted. We then overlaid HMA polygons, to determine the identity and size of all grazing allotments that fell within any HMA. Lastly, we overlaid this new data layer on the water rasters described above to calculate the amount and duration of water on each allotment.

Results

Within the state of Utah, there are approximately 9,709 grazing allotments, covering 57,566 square miles of federal and state rangelands (BLM, USFS and State Institutional Trust Lands Administration). Of these, 1,651 (17%) fall within 6 miles (9.7 km) of a HMA, representing 27% of all grazing lands by area. The number of allotments and total grazing area are inversely related to the seasonal duration of surface water (Table 1). Allotments on which water is only available for approximately 10% of the growing season account for 24% of rangelands within the 6-mile buffer while those with perennial surface water (available for > 90% of the growing season) account for only ~ 5%. Figure 1 illustrates this relationship.

Table. 1. The proportion of the growing season during which the ground is covered by water (1 May to 31 October). This does not include manmade sources, such as guzzlers, stock ponds, or leaking pipes. The number of allotments is determined by a six-mile buffer around each HMA.

Water present (days)	Proportion growing season	No. allotments	Total area of grazing allotments (mi^2)
18	10%	940	13,472
37	20%	495	9,163
55	30%	326	7,811
73	40%	240	6,479
92	50%	199	5,162
110	60%	170	4,507
128	70%	141	3,501
146	80%	122	3,115
165	90%	88	2,671

The distribution of water, grazing allotments, and vulnerability to competition with wild horses were not distributed evenly across the study area (Table 2).

Discussion

Horses in the American West typically travel > 6 miles per day in search of forage and water. Approximately 17% of public lands grazing allotments fall within this distance of a HMA, representing 27% of all grazing lands, by area. Since this figure does include some allotments potentially affected, or account for horses moving on and off tribal, military, or national park lands, it probably underestimates the number of allotments affected. Competition between wild horses and free-ranging livestock thus has the potential to affect many Utah producers, especially when consumption of forage by horses prevents ranchers from returning their livestock to grazing allotments in the spring after the traditional winter rest.

Areas in which water is reliably available are likely to experience a disproportionate amount of crop depredation and competition for water from wild horses. We found that only about 5% of the area grazed within the HMA buffers had water available for 90 % of growing season (although water can also be permanently available from other natural and anthropogenic sources). Conversely, the 24% of the grazing area that has water available for only 10% of the growing season is likely to experience a much lower level of conflict.

Our approach provided a quick assessment of the locations and times when ranchers may be impacted by wild horses. Managers can use these maps to identify conflict hotspots, provide proactive deterrents during droughts, prioritize fence constructions and maintenance, and establish range monitoring stations to evaluate grazing impacts. Future mapping of water sources that were not resolved at the 30-m scale would further refine our predictions.

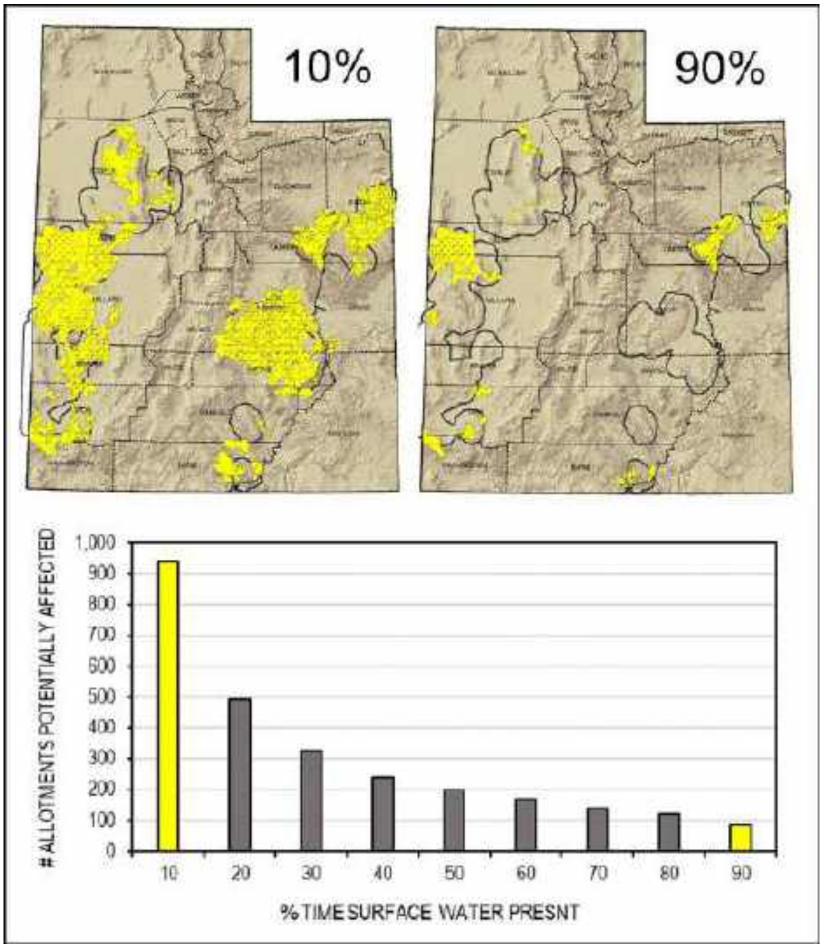

Figure 1. Relationship between the number of grazing allotments within a 6-mile buffer of HMAs and duration of surface water. Yellow bars represent the driest (10%) and wettest (90%) conditions (i.e. only ~ 100 allotments have surface water present for 90% of the growing season). Maps illustrate the distribution of grazing allotments that could be affected by wild horses for corresponding periods.

Table. 2. The number, proportion of total, and area of grazing allotments potentially affected by wild horses. All figures are for allotments within 6 miles of a HMA.

	GRAZING ALLOTMENTS

What can herbaceous forbs tell us about sustainably managing mesic grasslands in South Africa?

Nkuna, SC[1]; Morris, CD[1,2]

[1] School of Life Sciences, University of KwaZulu-Natal, Private Bag X01, Scottsville 3209, Pietermaritzburg, South Africa; [2] Agricultural Research Council – Animal Production (ARC-AP), Pietermaritzburg, South Africa

Key words: Forbs; diversity; grazing; mesic grassland

Abstract

High plant diversity maintains ecosystem functioning and delivery of services in response to disturbance through the insurance of functional redundancy. Forbs (herbaceous dicots and non-graminoid monocots), rather than grasses, comprise most of the species in South African mesic grasslands, which receive more than 600 mm of annual rainfall. Research in South Africa's mesic grasslands has shed light on the critical role of forbs in maintaining ecosystem health. Grazing significantly impacts forbs, with overgrazing drastically reducing diversity and replacing native species with hardy, often exotic ones, underscoring the importance of light stocking and judicious grazing management. Certain forb species serve as indicators of grazing intensity, with their relative abundance informing a forb condition score for monitoring and adjusting grazing practices accordingly. High-density, short-duration grazing (HDG) may not immediately affect forb diversity but can damage individual plants, promote unpalatable grasses, and alter forb composition, potentially harming soil health. Forbs exhibit individualistic responses to grazing and competition, highlighting the need for nuanced management strategies. Although forbs regrow after defoliation, their underground storage organs are depleted, affecting future growth and potentially reducing diversity in the long run, emphasizing the importance of lenient grazing pressure. While HDG can increase litter accumulation, it might not effectively replace fire's role in stimulating growth and reducing competition, underlining the significance of fire in maintaining forb diversity. Beyond grazing, certain forbs provide valuable food for herbivores, support pollinator communities, and offer essential resources for human livelihoods, necessitating a deeper understanding of their role in the ecosystem. Managing for forb diversity involves maintaining forb-rich habitats through responsible fire and grazing management practices to sustain biodiversity and the various services these grasslands provide. In conclusion, forbs are an indispensable component of healthy mesic grasslands in South Africa, and understanding their responses to disturbances informs effective land management practices for ensuring long-term ecosystem health.

Introduction

Mesic grasslands, which receive more than 600 mm of annual rainfall, are fire-dependent and consist of a diverse herbaceous plant community (Uys 2006). Forbs, including herbaceous dicots and non-graminoid monocots, contribute more to species richness than grasses in these grasslands (Siebert et al. 2024). High plant diversity ensures functional redundancy and maintains ecosystem functioning and stability when faced with intense disturbance (Hallett et al. 2017), such as by high-density, short-duration grazing. This grazing system, known as high-density grazing (HDG) or regenerative grazing, concentrates livestock in small areas for short periods to create a 'herd effect' that breaks soil crusts, accelerates the recycling of litter and dung, stimulates microbial communities, and boosts rangeland productivity—all while discouraging fire use (Savory and Parsons 1980). The contended benefits of HDG include increased livestock production by increasing the production of key foraging species and improved biodiversity (Savory and Butterfield 2016). Historical research focused on grasses and less was known about the response of forbs to different grazing management systems. This paper reviews the relevant literature to summarize the effects of HDG and heavy continuous grazing on the forb component of mesic grasslands.

Short and long-term effects of HDG and continuous heavy grazing

Long-term studies (over 10 years) in South African mesic grasslands have shown that high grazing pressure and the prolonged exclusion of fire results in the loss of most mesic grassland forbs with a community shift (Chamane et al. 2017a; Morris and Scott-Shaw 2019). Increased grazing pressure leads to changes in forb dynamics, shifts in species composition, life history strategies and growth forms (Nkuna and Morris 2024). Forbs play a critical role in rangeland ecosystems and can serve as indicators of habitat health as studies have shown that heavy grazing shifts perennial forb composition from erect decreaser species to prostrate increaser species (Table 1) (Chamane et al. 2017a; Morris and Scott-Shaw 2019; Morris 2021a). Additionally, annual ruderal and alien invasive forbs are favoured over perennials under intense grazing (Table 1, Table 2). Morris and Scott-Shaw (2019) identified a subset of indigenous mesic grassland forbs that showed a clear negative response to increased grazing pressure (Decreaser species) and other Increaser species that appear to be favoured by heavy grazing (Figure 1).

Contrary to HDG claims, intense trampling under high stocking density led to more compacted soils, with no significant difference in nitrogen and carbon levels compared to low-density grazing (Table 1). Litter mass was higher under HDG compared to an adjacent ranch that employed a lower stocking density (Table 1). A similar pattern was observed over a shorter time period where HDG resulted in a four-fold increase in (and deeper) litter accumulation (Chamane et al. 2017b). Dense litter can reduce evaporation and increase water availability but soil moisture is not limiting in these mesic grasslands and excessive litter can reduce irradiance received by plants, thereby limiting their growth (Chamane et al. 2017a).

More than 90% of forb species were defoliated by grazing or mechanically damaged by the ripping, shredding and tearing of hooves under HDG over the short-term (<10 years) period (Chamane et al. 2017b). Even low-abundance species do not always escape damage. These impacts may be reversible provided it is over a short period or less frequent with adequate recovery time because several mesic forbs have underground storage organs (USOs) that they can resprout from.

Table 1: Schematic presentation of the long-term effects of high-density grazing (HDG) compared to low-density grazing (LDG) on vegetation and soils (data from Chamane et al. 2017a).

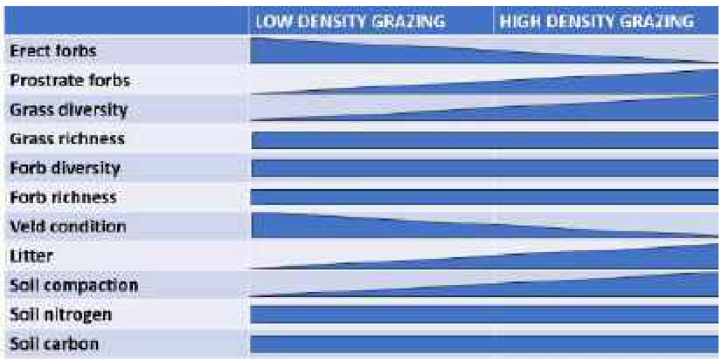

Table 2: The life-history strategy and growth form of mesic forbs under different types of grazing pressure. Data are from Chamane et al. (2017a; Morris and Scott-Shaw 2019).

LIGHT GRAZING	HEAVY GRAZING
Perennials	Ruderal annuals & perennials
Native	Mostly non-native

Leaves on stems	Leaves at base

Response of forbs to repeated defoliation

Recurrent leaf damage due to heavy grazing in the growing season reduced the vigour (Morris and Nkuna 2024) and regrowth in the following spring (Morris 2021b) of *Hypoxis hemerocallidea* and *Thungergia atriplicifolia*. Regrowth and USOs declined progressively under recurrent leaf damage. For both species, the USOs were more vulnerable to herbivory than the aerial organs; in *H. hemerocallidea*, corms were nearly halved in mass, accompanied by reduced inflorescence production (Morris 2021b; Morris and Nkuna 2024). This indicates that persistent defoliation reduces the USOs under chronic disturbance by overgrazing or frequent mowing which may weaken and eventually kill the plant. That would reduce the overall forb species richness and in turn reduce the resilience of forbs, diminishing their competitiveness against grasses and threatening their long-term survival (Siebert et al. 2024). Interestingly in another study of *Merwilla plumbea,* spring defoliation did not result in lasting impacts on carbohydrate reserves or macronutrients, suggesting that *M. plumbea* may be resilient to infrequent, intense defoliation, including in spring (Morris and Nkuna, unpublished data). Further research is needed on defoliation effects across different seasons.

Ecosystem services provided by forbs

Forbs provide essential services such as forage for livestock, food for humans and habitat for wildlife (Morris 2024; Siebert et al. 2024). The common cultural uses of forbs include spiritual uses and medicine for humans and animals (Siebert et al. 2021). Forbs also play a role to regulatory and support services by contributing more to diversity which ensures ecosystem resilience and stability (Morris and Nkuna 2024).

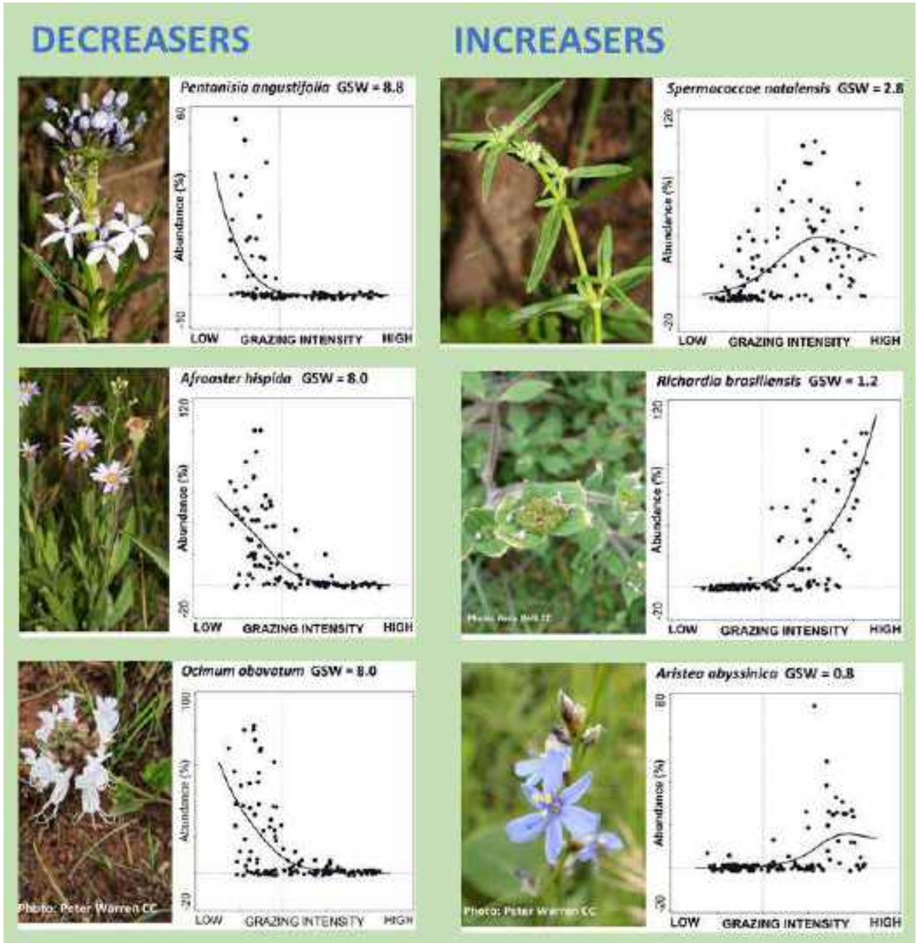

Figure 1: Examples of Decreaser and Increaser mesic grassland forbs that respond negatively or positively, respectively, to increased grazing pressure (Morris and Scott-Shaw 2019). GSW is a grazing score weight indicating a higher sensitivity to grazing. Reproduced from Morris (2019).

Managing for forb diversity in mesic grasslands

Grazing management tools for livestock production can be adapted to maintain forbs in mesic grasslands (Morris and Nkuna 2024). Strategies include adjusting stocking rates, selecting livestock types and managing movements (Kirkman et al. 2023). The combinations of management actions which include the frequency, intensity, duration and timing of grazing and trampling will affect the defoliation regime experienced by forbs and thereby, should influence their vigour and long-term survival (Morris and Nkuna 2024). The response of forbs can be explained by the intermediate disturbance hypothesis, which suggests that moderate disturbance is important while too little or excessive disturbance can reduce their abundance (Fynn et al. 2004). Complete protection from defoliation may favour shade-tolerant forbs and alter community structure (Fynn et al. 2005). Although it is known that forbs require some disturbance, the optimal frequency and intensity for maintaining forbs as well as the effects of disturbance timing are not well known (Morris and Nkuna 2024). Given the insufficient empirical data for managing perennial forbs, a precautionary approach is recommended. To help forbs recover from intense grazing and trampling or cumulative defoliation, it is important to provide periodic, year-long rest from grazing. Such extended rests will allow forbs to regain their vigour, develop bud banks, replenish underground storage reserves, and reproduce vegetatively or by flowering. Controlled burning is also important for removing excess litter and for stimulating the growth of some mesic forbs. Regularly assessing the abundance of key indicator forb species and monitoring reduced flowering or stem growth can help managers to adjust grazing practices to prevent long-term degradation and maintain species-rich grasslands (Morris and Nkuna 2024).

Conclusions

Studies in mesic grasslands have shown that forbs are sensitive to chronic disturbances from HDG or heavy continuous grazing. While the importance of grassland forbs is increasingly recognized (Siebert et al. 2024), the optimal timing and intensity of management practices for forbs are still not well understood. Therefore, to support diverse forb populations, a precautionary approach is recommended: avoid intense and frequent grazing, provide year-long rest periods for grazed areas, use controlled burning, and implement adaptive management through regular monitoring of forb vigour and abundance.

Alluvial gully erosion: evolution, processes and management

Pelgay, P[1]; Koci, J[2]; Smithers, S[1]; Jarihani, B[1]
[1]College of Science and Engineering, James Cook University, QLD, Australia;
[2] TropWATER, James Cook University, QLD, Australia

Key words: Great Barrier Reef, Land degradation; Remediation; Water Quality

Abstract
Gully erosion is a globally significant form of land degradation, adversely affecting agricultural and rangeland productivity as well as downstream ecosystems. In northeast Queensland, Australia, substantial investments in alluvial gully remediation are being made to improve water quality within catchments draining to the Great Barrier Reef World Heritage Area. However, understanding of alluvial gully evolution, processes, and management strategies remains limited. This PhD project aims to investigate the long-term evolution of alluvial gullies, contemporary erosion processes, and the effectiveness of remediation strategies, focusing on the Upper Burdekin catchment. The research findings will inform alluvial gully management and contribute to reducing sediment runoff into the Great Barrier Reef's lagoon.

Introduction
Gully erosion is a significant land degradation process that leads to loss in land productivity, damages infrastructure, and degrades downstream ecosystems (Poesen et al. 2003). In northeast Queensland Australia, gully erosion accounts for approximately 40% of the total suspended sediment (<63µm) load delivered to the Great Barrier Reef (GBR) lagoon, posing a significant threat to the reef's health (Waterhouse et al. 2024). Growing concern about the deteriorating health of the GBR has prompted millions of dollars of investment over the past decade to improve catchment-scale water quality through gully remediation and other land management practices (State of Queensland 2018).

In this region, gullies are typically classified as either hillslope gullies or alluvial gullies. Hillslope gullies are typically linear and more isolated incisional features eroding into colluvium and are primarily driven by concentrated overland flow processes (Poesen et al. 2002). In contrast, alluvial gullies are erosional features entrenched into vast alluvial landscapes not previously incised since initial deposition (Brooks et al. 2009). In the GBR catchment, early sediment budget models assumed hillslope gullies were the dominant sediment source to downstream waterways (McKergow et al. 2005), and as a result, remained the primary focus of gully erosion studies and management practices (Wilkinson et al. 2018). More recent studies, however, recognise alluvial gullies as a dominant source of fine sediment delivered to the GBR lagoon (Brooks et al. 2021).

Despite this recognition, there remains a limited understanding of long-term alluvial gully evolution, contemporary erosion processes and rates, as well as the effectiveness of common remediation strategies. A comprehension of long-term dynamics is key to address issues concerning whether the contemporary rates of gully erosion are within the normal range or are accelerated due to land use, climate change or other anthropogenic factors. This PhD project will contribute to addressing each of these key knowledge gaps.

Methods

The research is focussed in the Upper Burdekin, a sub-catchment of the Burdekin Basin, identified as a major source of fine sediment delivered to the GBR lagoons (Bainbridge et al. 2024) (Figure 1). On-ground field studies will focus on a group of alluvial gully systems deeply incised into the Quaternary alluvium within 1km of the Burdekin River (Figure 2). The predominant soil types are Brown Chromosols and Brown Sodosols, characterised by highly dispersive subsoil horizons. The region experiences a dry tropical climate with annual average rainfall of 628mm, 80% of which falls during the wet season (October to March).

To achieve project aims, a range of methods will be applied (Figure 3). To obtain the minimum age of gully initiation, sediment stratigraphy and Optically Stimulated Dating (OSL) will be conducted following the method described by Lee et al. (2011). Historical gully expansion and lifetime volumetric loss will be quantified using the method described by Daley et al. (2021). Past land-use and climate proxies of the area will be analysed to investigate the factors driving gully development (Lewis et al., 2021). Temporal variation of gully development will be assessed to examine the growth model (Nachtergaele et al., 2002). An empirical approach will be adopted to assess the dominant factors and processes driving contemporary gully development, incorporating hydrological and water quality monitoring, terrain analysis, and erosion pin measurements. The effectiveness of alluvial gully remediation will be determined through a Before-After-Control-Impact (BACI) approach as described by Brooks et al. (2024).

Results

The project is in the preliminary stage and results are not yet available.

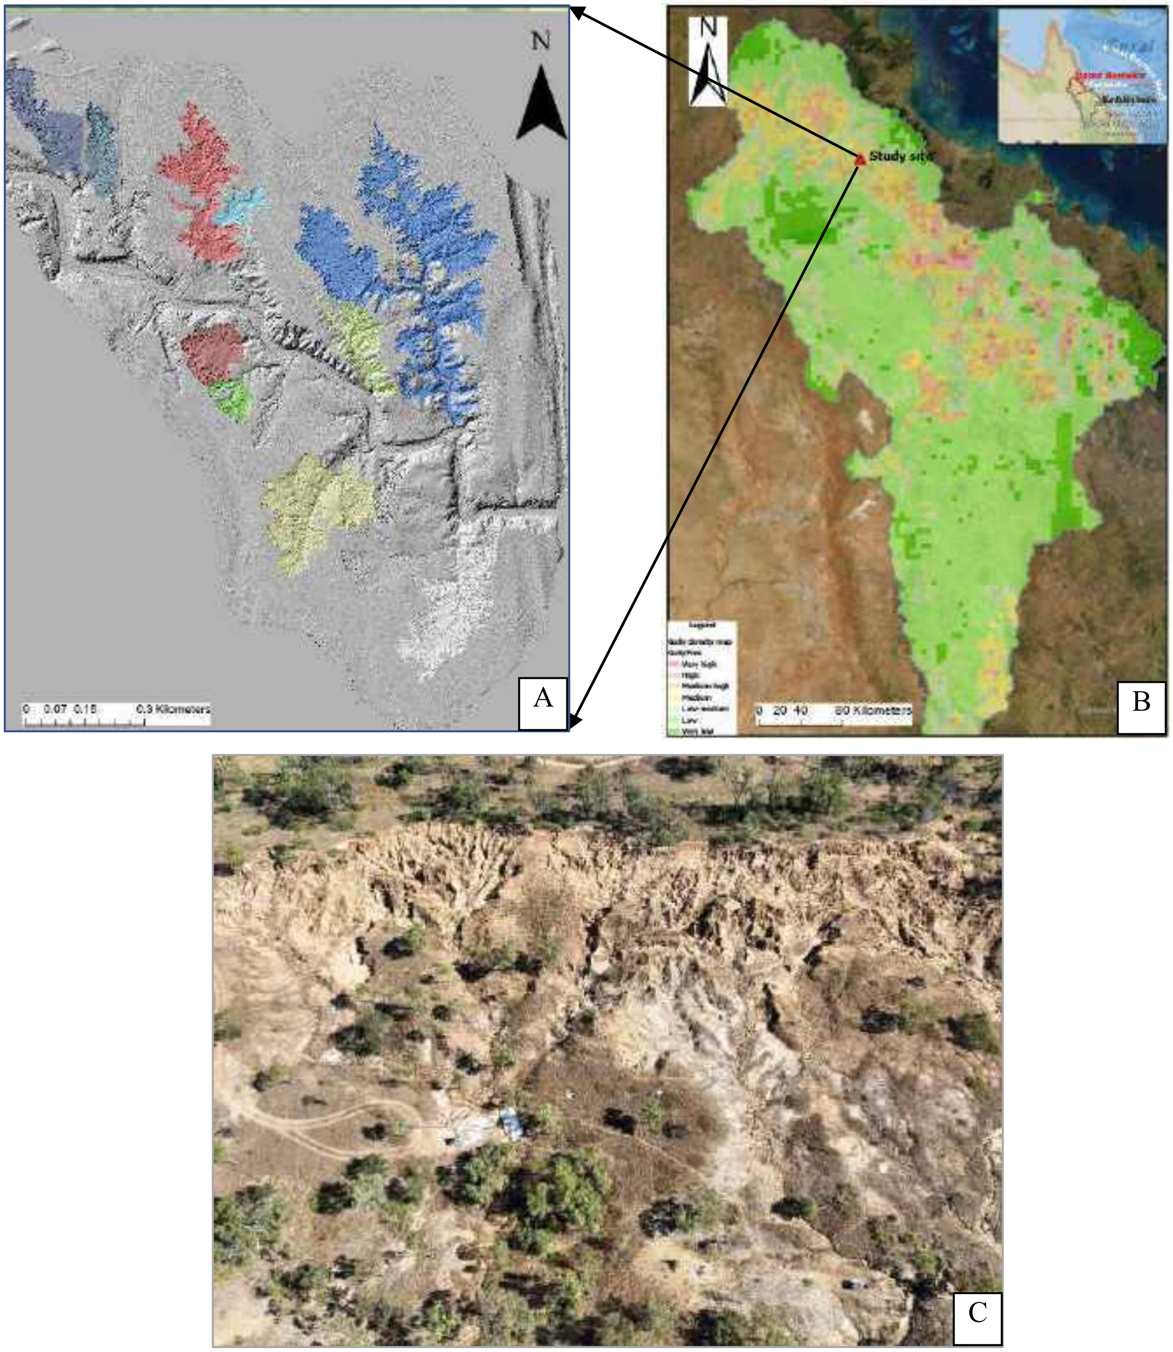

Figure 1 (A) Location map showing gullies in the study area. (B). Gully density map of the Burdekin catchment, modified from Tindall et al., (2014). (C) Picture showing an example of alluvial gully in the study area.

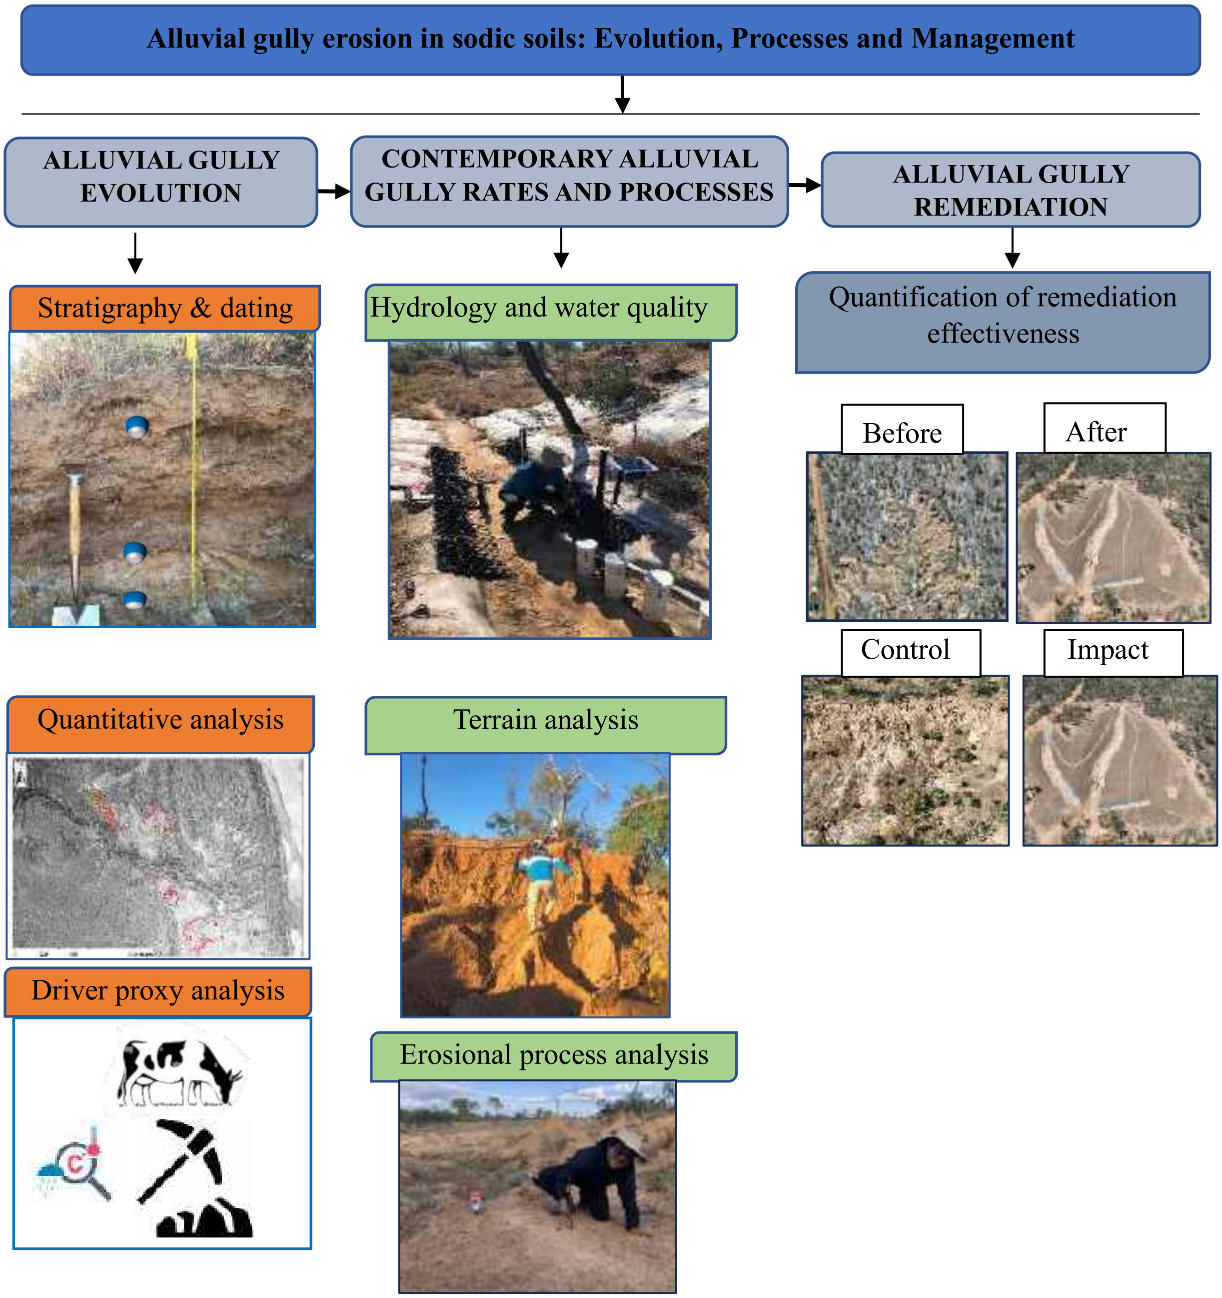

Figure 2. Schematic diagram showing different methods to be used for the study. Detail description in the text.

Discussion

The proposed research will enhance fundamental scientific understanding of alluvial evolution, contemporary processes, and remediation effectiveness. The study on long-term gully evolution will enhance understanding of key factors and processes influencing alluvial gully formation, long-term sediment yields, and potential future trajectories. The study on contemporary process and rates will enhance understanding into the current dynamics of alluvial gullies occurring in sodic soils, including an assessment of the quantitative relationship between different erosional processes and the sediment yield. The study on gully remediation will provide new insights into the effectiveness of various remediation approaches implemented within the alluvial gully system. The new data, knowledge and understanding generated through this research will be of great value to a range of stakeholders involved in gully monitoring, modelling and management, both in Australia, and internationally.

FIREGRAZE: Using strategic patch burning to influence cattle grazing behaviour and improve land condition.

Pettit, CL[1]; Wirf, B[1]; Bailey-Preston, G[2]

[1] Northern Territory Department of Agriculture and Fisheries, Darwin; [2] Northern Territory Department of Agriculture and Fisheries, Katherine

Key words: fire; grazing distribution; land condition

Abstract

Managing grazing distribution in large, diverse paddocks is a key challenge in the tropical rangelands of northern Australia. These landscapes consist of varying land types, ranging from fertile alluvial clays to rugged, skeletal red earths, leading to uneven grazing patterns as cattle favour areas with higher-quality forage. Overgrazing of preferred land types can degrade soil health and pasture composition, while underutilized areas contribute less to overall paddock productivity.

This study investigated whether burning underutilized areas could attract cattle and redistribute grazing pressure. Conducted at Victoria River Research Station, Northern Territory, two areas of 2.3 km² and 3.3 km² were burned. Global Navigation Satellite System (GNSS) collars tracked cattle movements across burnt and unburnt land types. There was increased cattle activity in burnt areas during the wet season following burning, with reduced grazing pressure on productive grey clays and vulnerable red earths.

The findings suggest that targeted burning can effectively redirect grazing pressure, enhancing the use of underutilized areas and promoting more sustainable land management in heterogeneous rangelands.

Introduction

The average size of a cattle station in the Victoria River District in the northwest of the Northern Territory is 3,377km² with a median paddock size of 120km² (Cowley 2014). These vast grazing lands are a mosaic of land types with unique topography, soil characteristics and pasture composition. Within paddocks, productive alluvial clay soils may sit juxtaposed with skeletal red earths, creating stark contrasts in grazing value and preference. This patchiness is both an opportunity and a challenge; while it provides diverse resources for cattle, it also leads to uneven grazing patterns as cattle instinctively favour areas with higher-quality forage (Tomkins and O'Reagain 2007).

Overuse of productive land types can lead to a decline in desirable palatable perennial pastures and soil health. At the same time, less fertile or areas further from a water source are often underutilised, reducing their contribution to overall paddock productivity. One strategic management tool to address this imbalance and improve grazing distribution across a paddock is the use of fire to stimulate regrowth in less-used areas.

Cattle are strongly attracted to post-fire regrowth, which is high in protein and digestible energy (Reid, 2022, Andrew 1986) offering a natural and low input method to redirect grazing pressure and promote more even utilisation of the land.

This study aimed to investigate if burning less preferred, underutilised areas within a paddock can attract cattle to these areas, thereby reducing grazing pressure on more preferred areas to improve overall paddock productivity.

Methods

The study was conducted at Victoria River Research Station (VRRS), 220 km south-west of Katherine in the Victoria River District of the Northern Territory. The climate is tropical with a median rainfall of 793mm, with the majority of rain falling between October and April. The study sites were in Conkerberry paddock (17km^2) and Box paddock (21km^2). The study sites were broadly a mix of alluvial grey clays dominated by ribbon grass (*Chrysopogon fallax*) and Flemings bush (*Flemingia pauciflora*) and calcareous red earths dominated by black spear grass (*Heteropogon contortus*) and white grass (*Sehima nervosum*). Land unit mapping at 1:30,000 scale of Kidman Springs (Forster 1972) defines 5 land units consistent across both paddocks: 4a and 4b (gently undulating to flat plains with grey, brown and red clays), 5a (Gently undulating to flat plains with a mix of calcareous red earths and grey, brown and red clays), 3a, 3b and 3c (undulating plains with calcareous red earths) and 7b (creeklines). Land unit 2a (Rugged undulating terrain on limestone with shallow skeletal soils) only occurred in Box paddock and 6d (severly eroded red earths) only occurred in Conkerberry paddock.

An underutilised area in each paddock was selected for burning. In October 2022, a 2.3km^2 area of Conkerberry was burnt (12% of paddock). In October 2023 a 3.3km^2 area of Box paddock was burnt (15% of the padddock). The burnt areas were predominately 2a and 3b land unit in Box paddock and a mix of 3a, 5a and 4b in Conkerberry paddock. Land units were combined into broad land types for analysis. 4a and 4b were combined into grey clays. 5a, 2a, 3a, 3b, 3c and 6d were combined into red earths.

The paddocks were stocked to long-term carrying capacity. All cattle were fed a standard supplement of urea in the dry season and phosphorus in the wet season. Twenty GNSS collars were deployed randomly in a mob of 76 pregnant Brahman cows in Conkerberry paddock in September 2022, and 24 GNSS collars were deployed randomly in a mob of 75 pregnant Brahman cows in Box paddock in May 2023.

The collars comprised a 61mm x 89mm x 89mm IP68 rated plastic shell, with a metal, wide “U” shaped bracket bolted to the top and PVC webbing used as straps to attach around the neck of the animal. A GNSS logger inside the shell from IGotU (GT600) recorded GNSS location every 10 minutes.

GNSS loggers were downloaded at each muster (May and September). GNSS data was analysed using QGIS plug ins to calculate total GNSS pings across the paddock and within different land types. GNSS pings were converted to relative time spent to allow for comparison between land types of different sizes. A selection index for time spent per land type was calculated as the proportion of time spent in a land type / the proportion of the paddock of that land type. GNSS pings around water points were omitted where cattle were known to rest for long periods.

Repeat photo monitoring sites marked with metal pickets were established in burnt areas prior to burning. Photos were taken at the picket before and after burning and through the study period facing north, east, south and west.

Results

There was a significant increase in animal presence within the burnt areas in both paddocks following fire once wet season rainfall occurred. The preference for the burnt areas in the wet season immediately after burning was higher in Conkerberry paddock (Fig. 1) than in Box paddock (Fig. 2). A preference for burnt areas continued throughout the wet season (November to April) in both paddocks.

The time spent on grey clays decreased during the wet season in both paddocks in both burn and no burn years, however in Conkerberry paddock cattle spent less time on the grey clays in the year burning occurred (0.7 relative time spent) compared with the following year without burning (0.9 relative time spent).

The relative time cattle spent on erodible red earths (6d) in Conkerberry paddock between November and April was significantly higher in the non-burn year (3.4 relative time spent) compared to the burn year (Fig. 3, 1.9 relative time spent).

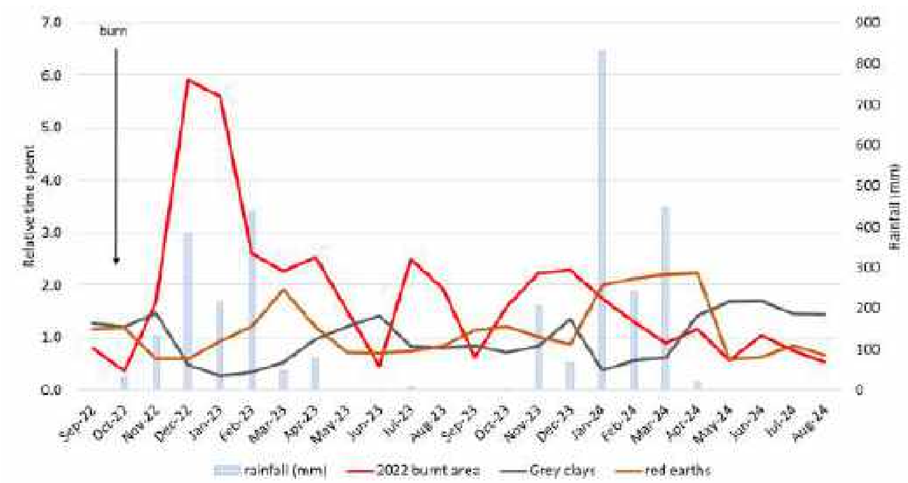

Figure 1. Relative time spent (averaged monthly) following fire on different land types and burnt areas in Conkerberry paddock

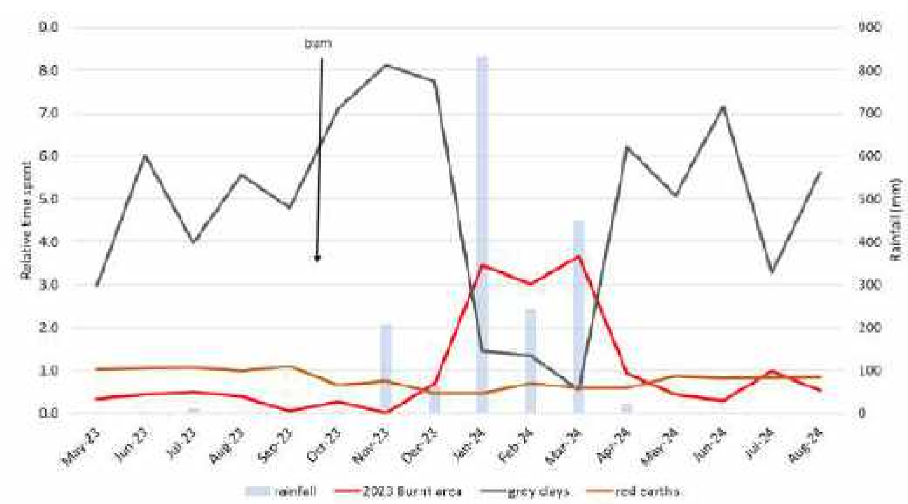

Figure 2. Relative time spent (averaged monthly) before and after fire on different land types and burnt areas in Box paddock

Figure 3. Relative time spent (averaged monthly) following fire on erodible red earths (6d) compared to burnt area in Conkerberry paddock.

Discussion

Cattle are known to prefer red soil areas during the wet season to avoid boggy conditions on the black and grey clays (Hunt et al. 2007), so it is unclear if the preference for red soil areas in the second wet season after fire in Conkerberry paddock was what occurs naturally, or if there was still some lagging effect of the previous years burn on cattle preference. Further monitoring of landscape preference in both paddocks over time will help to distinguish background versus burn driven landscape preferences.

The significant increase in cattle presence within the burnt areas during the wet season suggests that fire-stimulated regrowth attracts cattle, aligning with previous studies highlighting the nutritional appeal of post-fire vegetation (Reid 2022). Similarly, Fuhlendorf and Engle (2004) found that integrating fire and grazing can create a dynamic forage mosaic that redirects grazing activity and balances land use across heterogeneous landscapes.

Burning also reduced grazing pressure on more productive grey clays, particularly in the year there was fire introduced to the paddock. This outcome supports the hypothesis that pyric herbivory can mitigate overgrazing in high-value areas, increasing the potential for recovery. Moreover, the reduced time spent on erodible red earths (6d) during the burn year highlights the potential of fire to divert grazing pressure from ecologically vulnerable areas. Grazing in these areas during non-burn years likely exacerbates soil erosion and pasture degradation, a concern corroborated by Mott (1986), who linked uneven grazing patterns to environmental decline.

The strong preference for burnt country by cattle highlights the potential for overgrazing. It is important that the patch burn area is large enough to not be too heavily grazed but small enough to ensure some parts of the paddock are rested. Stocking rates should also be adjusted to match the carrying capacity of the paddock.

It is difficult to assess changes in land condition over short periods of time however photo monitoring points and regular pasture monitoring will continue to measure the effects of patch burning within the burn area and surrounding land types.

The findings of this study suggest pyric herbivory can be effective in redistributing grazing pressure and enhancing the utilisation of underused areas in tropical rangelands.

Rehabilitation planning at the landscape scale. The Martin Fire as a case study

Phipps, LA[1]; Stringham TK[1]; Gibson, Y[1]

[1] The University of Nevada Reno

Key words: Restoration planning; Wildfire rehabilitation, Spatial mapping

Abstract:
The Martin Fire, which ignited on July 5, 2018, in Nevada's Great Basin, burned over 177,750 hectares of shrubland, profoundly impacting rangeland ecosystems and wildlife habitats. This case study examines the methods and spatial datasets used to inform post-fire rehabilitation efforts, providing a framework for large-scale landscape restoration. Legacy grazing practices, compounded by an Aroga moth infestation, had degraded the herbaceous understory and increased fuel loads, further challenging recovery. Within the Bureau of Land Management's (BLM) 30-day Emergency Stabilization and Rehabilitation (ESR) planning window, tools were employed to evaluate pre-fire conditions, assess resilience, and prioritize rehabilitation needs.

Key methods included the use of Disturbance Response Groups (DRGs) to classify plant communities by their response to disturbances and the integration of remote sensing and ground-based vegetation data to map plant functional group cover. Near-real-time annual grass mapping, validated against ground measurements, highlighted areas prone to invasive species dominance, while soil texture and precipitation data-informed microclimate resilience assessments. Historical wildfire data provided context for evaluating past rehabilitation outcomes, and guiding strategies for the current fire rehabilitation effort.

Results revealed substantial variability in vegetation recovery, influenced by pre-disturbance conditions and environmental factors. Areas with resilient soils and adequate herbaceous cover recovered well, while those dominated by invasive annual grasses or dry fuels exhibited poor recovery. Herbicide treatments showed a notable reduction in bare ground and a temporary increase in annual vegetation, emphasizing the role of targeted interventions.

This study demonstrates the utility of spatial datasets and collaborative planning in addressing large-scale disturbances. While implementation remains complex, the lessons learned from the Martin Fire provide valuable insights for improving future wildfire rehabilitation strategies, emphasizing the importance of integrating ecological data to support decision-making at the landscape scale.

Introduction

On July 5, 2018, the Martin Fire ignited near Paradise Valley, Nevada, and over the course of several days, it consumed approximately 177,750 hectares of shrubland in the Great Basin, USA. Driven by strong winds, the fire devastated iconic landscapes and wildlife habitats. The affected area included the Owyhee High Plateau, a historically productive ranching region where plant communities had become dominated by woody vegetation. Legacy grazing practices had diminished the herbaceous understory, reducing its resilience to fire. Compounding the issue, a recent Aroga moth (*Aroga websteri*) infestation had defoliated and killed large portions of sagebrush across the region, leaving abundant dry fuel and a depleted seedbed for post-fire recovery.

This paper discusses the strategies and tools used to advise and support post-fire rehabilitation efforts in the wake of this disaster. Effective rehabilitation at this scale requires tools to assess pre-disturbance conditions, map plant communities, group areas by their disturbance response, evaluate the likelihood of natural recovery without intervention, and identify the most effective rehabilitation techniques. Within the 30-day window mandated by the Bureau of Land Management (BLM) for developing a rehabilitation plan and applying for Emergency Stabilization and Rehabilitation (ESR) funding, we aimed to provide a straightforward and effective framework for addressing this challenge.

The BLM's rehabilitation planning process was highly collaborative, incorporating input from local landowners, stakeholders, ranchers, wildlife managers, and rangeland professionals. The Stringham Rangeland Ecology Laboratory contributed resources to this effort, and this paper shares the datasets and visualization techniques employed during the planning process. While the efficacy of some rehabilitation measures is evaluated, the primary focus is on demonstrating how existing datasets can be integrated to enable rapid assessment and planning at such a large scale.

The tools developed by the Stringham Rangeland Ecology Laboratory, including Disturbance Response Groups (DRGs) as described in Stringham et al. (2016) and later works (Phipps and Stringham, 2024), were instrumental in assessing rangeland response to disturbances of this magnitude. These tools provided a framework for prioritizing resources and efforts in a triage-like manner, given the limited resources available for rehabilitating the entire burn area.

While numerous physical and political challenges influenced the implementation of the rehabilitation plan, this case study demonstrates the value of collaborative efforts and the practical application of these tools in addressing large-scale disturbances. As wildfires of this scale become increasingly common, the lessons learned from the Martin Fire rehabilitation process can inform future disaster response and landscape restoration efforts.

Methods

Once the Martin Fire was extinguished by regional wildland firefighters, the Bureau of Land Management (BLM) fire management teams provided final fire extent mapping (Personal communication, Phipps, 2018). To evaluate fire intensity, the BLM collected additional imagery and produced Burned Area Reflectance Classification (BARC) data. Using ArcGIS, the fire boundary was overlaid onto spatial datasets to guide response planning and assess pre-fire conditions. Relevant base data, including political boundaries and geographic information, were compiled to support subsequent analyses.

Disturbance Response Groups

Disturbance Response Groups (DRGs), as described by Stringham (2016), were clipped to the fire boundary to identify plant communities likely to exhibit similar post-fire responses. DRGs are based on Ecological

Sites, which are defined as "a distinctive kind of land with specific characteristics that differs from other kinds of land in its ability to produce a distinctive kind and amount of vegetation" (NRCS, 2024). These groups cluster Ecological Sites by their resilience and response to disturbances such as wildfire. For example, areas dominated by plants capable of resprouting after fire are grouped together, while areas prone to invasive annual grass proliferation are classified separately. This analysis helped prioritize areas within the burn perimeter requiring stronger intervention and areas that may recover well without intervention.

Vegetation Monitoring Data

Pre-existing vegetation monitoring data were compiled across the burn area, including data from State-and-Transition Modeling, annual ranch monitoring, and national-scale efforts like the BLM's Assessment, Inventory, and Monitoring (AIM) dataset and the NRCS National Resource Inventory (NRI). These datasets were normalized to display plant functional group and ground cover percentages, including categories such as annual grass, perennial grass, annual forbs, perennial forbs, shrubs, rock, litter, and bare ground. The point-based data were visualized in GIS, mapped to soil types and plant communities, and scaled using color ramps to highlight the relative dominance of functional groups.

Annual Grass Monitoring

Annual grass, a serious concern in the Great Basin, was of particular focus. Its presence increases wildfire spread and hinders post-fire recovery due to localized seedbeds that expand after disturbances. Near-real-time annual grass cover data (Boyte & Wylie, 2016) were used to map current grass cover across the burn area. Ground-based measurements collected using the Line-Point-Intercept method were assessed alongside remote sensing data to examine trends, revealing that remote sensing often underestimated annual grass cover. These comparisons informed adjustments and validated the data's utility for large-scale assessments.

Multi-Source Remote Sensing Integration

The Multi-Resolution Land Cover Consortium (MRLC) Rangeland Condition Monitoring Assessment and Projection (RCMAP) products (Shi et al., 2022) were used to map plant functional group cover across the burn area. Ground-based data were compared to remote sensing values, and discrepancies were noted to interpret patterns across the larger landscape. Color-ramped visualizations of plant functional group cover allowed for efficient spatial assessments.

Precipitation and Soil Analysis

Annual precipitation strongly influences rangeland resilience (Chambers et al. 2013). However, the study area's remoteness limited access to on-site weather station data. Instead, precipitation data from PRISM (Daly et al., 2013) were modeled and categorized into zones familiar to resource managers. Recognizing PRISM's limitations in capturing microclimates within the Basin and Range topography, the raster data were vectorized to better inform planning.

Soil characteristics, including texture and chemical properties, were analyzed using remotely sensed datasets (Chaney et al., 2016; Nauman et al. 2024). These datasets highlighted areas with high clay content, which retain water and support specific vegetation types, and regions with high pH levels, which may affect the efficacy of post-fire herbicide treatments like Imazapic.

Historical Wildfire Data

Historical wildfire perimeters from the U.S. National Interagency Fire Center were mapped and compared with annual grass cover data to evaluate past fire responses and rehabilitation outcomes. This overlay provided insights into the effectiveness of previous restoration efforts and informed current strategies.

Application to State-and-Transition Models

Plant functional group cover data were integrated with State-and-Transition models (Stringham and Snyder, 2017) to assess the likely post-fire trajectories of different areas. Areas with intact perennial bunchgrass understories were identified as more likely to recover without additional intervention due to a generally positive response to fire from perennial grasses, while shrub-dominated areas with limited herbaceous cover were flagged as at risk of transitioning to annual grass dominance.

This comprehensive, multi-scale analysis informed targeted rehabilitation strategies to optimize resource allocation and address post-fire challenges effectively.

Results

Variation in vegetation response was observed across the study area. Areas with poor pre-disturbance conditions, characterized by low perennial herbaceous biomass and abundant dry fuels such as Aroga moth (*Aroga websteri*)-killed stands of Wyoming Big Sagebrush (*Artemisia tridentata var. wyomingensis*), have visibly shown limited recovery. In contrast, areas with more resilient soils and favorable pre-disturbance conditions exhibited visibly better plant community recovery, often independent of rehabilitation efforts.

Visual observation of the remotely sensed cover data by plant functional groups appears to show evidence of the application of pre-emergent herbicides. Approximately three years after herbicide treatment, corresponding to the duration the chemical remains active in the soil, a clear pattern emerged: bare ground appears to have decreased while annual vegetation increased. These trends are visibly apparent in the data, and were not remeasured due to lack of funding, but are consistent with measurements acquired by other groups and local knowledge of the area.

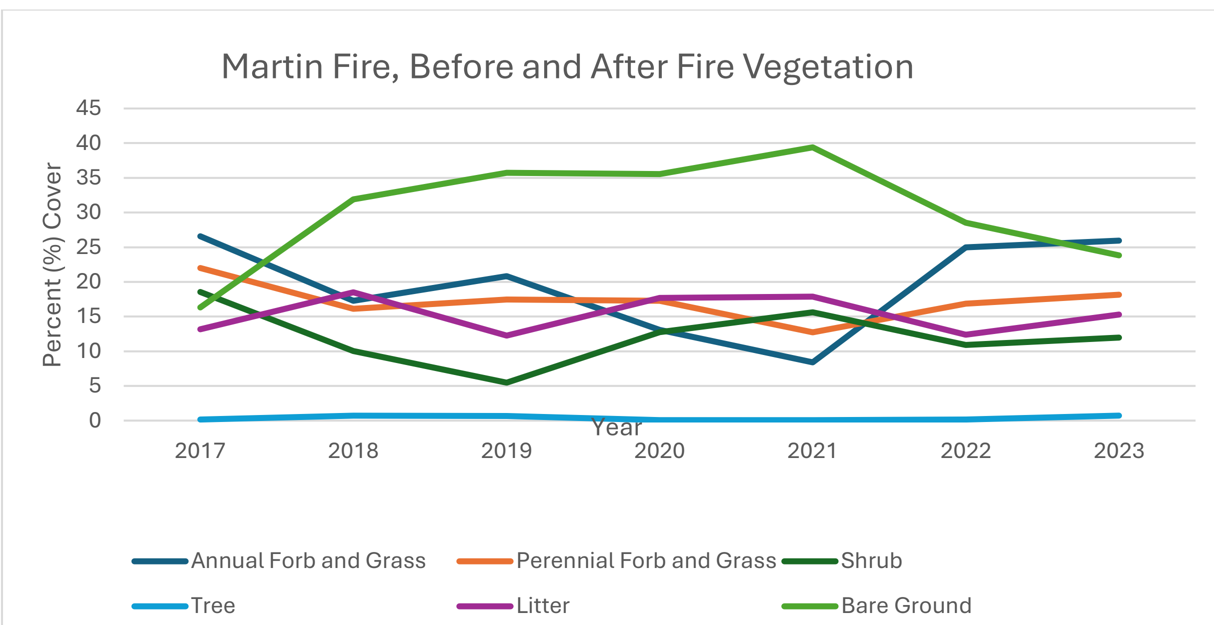

Figure 1: Data from the Rangeland Analysis Platform (RAP) summarizes vegetation response across the entire Martin Fire perimeter. These results average diverse plant community responses before and after the fire, capturing the variability across the landscape.

During site tours following the fire, it was visibly evident that perennial bunchgrass establishment was particularly evident in the southern portion of the study area, where aggressive cultivars like crested wheatgrass (*Agropyron cristatum*) performed well. Areas receiving additional soil moisture, such as drainages or slopes with reduced evaporation and solar gain (north- and northeast-facing aspects), also demonstrated stronger recovery of native vegetation which is dramatically visible on the landscape due to increased resilience in these microclimates.

Maps generated during the study, included in Appendix A, supported the development of a restoration plan by the BLM's Elko District Emergency Stabilization and Rehabilitation (ESR) Coordinator, Marissa Murphy. Her collaborative approach incorporated input from diverse stakeholders, which not only enhanced the plan's quality but also facilitated broader stakeholder support.

These findings highlight the importance of integrating vegetation, herbicide, and soil data to understand post-fire recovery dynamics and inform future rehabilitation efforts.

Discussion [Conclusions/Implications]

This case study highlights the use of spatial datasets and methods for post-wildfire rehabilitation assessment and planning, with a focus on their application across large spatial scales. The purpose of this discussion is to provide illustrative examples of these tools and techniques rather than to test specific hypotheses. Additional maps and spatial analyses will be included in the accompanying poster to be presented at IRC 2025.

While the implementation and success of post-wildfire rehabilitation involve a complex interplay of variables, many of which are beyond control, this study emphasizes the potential of emerging datasets and spatial methods to support effective planning. By demonstrating how these tools can be applied to large-scale rehabilitation efforts, we aim to contribute to the development of more efficient and informed decision-making processes in post-fire recovery.

The authors are actively engaged in further advancing this field and are working on additional tools to enhance rehabilitation planning at landscape scales. We welcome continued dialogue on this topic and encourage interested readers to contact us using the provided email addresses for further discussion.

Acknowledgements

A very special thank you to Marissa Muphy with the BLM for allowing such a collaborative effort in rehabilitation planning on the Elko District portion of the wildfire. Thank you to everyone who contributed, including all the datasets provided to help in the generation of this mapping effort.

Moderate defoliation improves Mitchell Grass leaf, tiller and inflorescence production

Phelps, DG[1]; Phelps, WJ[2]

[1] James Cook University (TNQ Drought Hub), Townsville & Longreach; [2] no affiliation

Key words: drought recovery; drought resilience; perennial tussock grass; Astrebla

Abstract
The Mitchell grasslands are unique to Australia and make important contributions to grazing, conservation, cultural heritage, and rural socioeconomics.

Previous studies suggest there is an optimal range of 15-20cm defoliation height to promote Mitchell grass (*Astrebla* spp.) leaf, tiller and inflorescence production during average to above average rainfall periods. However, there is evidence that a different defoliation height and frequency is needed to increase the responsiveness of Mitchell grass leading into, during, and exiting drought.

A long-term drought resilience experiment commenced in December 2021 at Longreach, Queensland to determine the interaction between defoliation height and frequency and water stress on Mitchell grass response to rainfall.

Treatments commenced in October 2022 once establishing plants reached maturity. The main effect of water stress is induced through rainfall received or alleviated through supplementary irrigation. Treatment interaction is applied through defoliation height (15cm or 0cm) and frequency (never, annually or biennially) at the end of the dry season (early October). Soil moisture and key plant parameters are monitored monthly and quarterly respectively.

Preliminary findings of plant recovery from the initial two defoliations indicate that cutting: increased end-of-wet-season photosynthetic area at both heights; increased tiller and inflorescence production and canopy area at 15cm height; but reduced tiller and inflorescence production at 0cm.

These early results support previous studies that Mitchell grass responds positively to ‘moderate’—but negatively to severe—defoliation. The current study has been during average to above-average rainfall. Further papers will report longer-term results that will begin to reflect drought conditions.

Investment into long-term research is needed to continuously improve our understanding of perennial grass species management as a changing climate brings new challenges through increased temperature and

rainfall variability. The ultra long-lived (>20 years) *Astrebla* spp. are an excellent model species for this purpose.

Introduction

Astrebla spp (Mitchell grasses) are tropical tussock grasses which are endemic to Australia. They are very long-lived perennials (>20 year life span, Orr and Phelps 2013), and produce relatively high levels of palatable forage. They grow predominantly on clay soils in arid to semi-arid regions, on naturally tree-less rolling downs and plains. These grasslands make important contributions to pastoralism, conservation, cultural heritage, and rural socioeconomics. Previous studies suggest there is an optimal range of defoliation height and frequency which can increase the responsiveness and resilience of Mitchell grass leading into, during, and exiting drought. Globally, defoliation frequency and height is recorded as impacting photosynthetic capacity (Cullen et al. 2006), tiller dynamics and dry matter yield (Kaufononga et al. 2017), and interacts with drought to increase mortality (Hacker et al. 2006) in perennial grasses. Studies of Astrebla spp can therefore contribute to the international understanding of perennial grass management.

Methods

A long-term drought resilience experiment commenced in Longreach in December 2021 to determine the role of defoliation and water stress on *Astrebla lappaecea* (Curley Mitchell grass) response to rain. The main treatment is a) exposure or b) non-exposure to drought water stress, achieved by a) relying on rainfall received or b) supplementary irrigation to match monthly average rainfall. Sub-treatments are annual or biennial clipping to remove a) all tiller nodes (1-2 cm height) b) all but 3-4 tiller nodes (15 cm height) and c) an unclipped control. Clipping occurs at the end of the dry season (October). Plots and plants were allocated randomly with a split-plot design with four replicates. Five plants are arranged in the corners and centre of each of eight 0.7m x 0.7 m sized plots, with a 0.3m access path between each plot.

Forty plants were established over December 2021-March 2022, and irrigated until all plants had reached maturity in October 2022. During this time, heatwaves and insect incursions killed many young seedlings which were replaced with newly germinated seedlings, and set-back the growth of others. Emergent tillers were tagged in control plants during the establishment phase to track survival.

Soil moisture is recorded monthly through a DeltaT PR2 probe, with two access tubes installed per plot and 10 access tubes within walkways to monitor for the possibility of lateral flow from irrigated to non-irrigated plots. Plants are recorded daily, weekly, monthly, quarterly, or biannually depending on the parameter (Table 1). No statistical analysis is reported for these preliminary results.

Results

The Longreach region was drought declared from December 2021 to May 2023 (LongPaddock 2024). Heatwaves, high evapotranspiration, and insect incursions killed many of the young seedlings and set-back the growth of others during the establishment phase (Dec. 2021 to Jan. 2022; days 0-90; Fig. 1a). Nevertheless, soil moisture levels were relatively consistent at depth (600-1000mm) and more dynamic in response to rainfall events within the soil cracking zone (0-400mm, Fig. 1b).

The preliminary trends for plant recovery from a single defoliation indicate that clipping: increased end-of-wet-season photosynthetic area at both heights; increased tiller production, basal area and canopy area at 15cm height but; reduced tiller production and basal area at 0cm. In contrast with other studies, defoliation did not increase inflorescence production. Drought exposed plants tended towards reduced photosynthetic area compared with non-exposed (irrigated) plants within every clipping sub-treatment (Fig. 2).

Table 1. Frequency of plant parameter measurements.

Frequency	Parameter	Method
Daily-weekly	Visual overview	Photographic record
Weekly-monthly	Plant height	Direct measurement (cm)
Monthly-quarterly	Photosynthetic area	Number of green leaves, direct measurement of representative leaf length and width (mm)
	Tiller number (primary and axillary)	Direct count
	Inflorescence number (primary and axillary)	Direct count
	Rhizome emergence	Direct count
	Canopy area	Direct measurement of perpendicular widths (leaf tip to leaf tip, cm)
Quarterly-biannually	Basal area	Direct measurement of perpendicular widths (mm)
	Node number per tiller	Direct count of 10 random tillers
	Tiller lifecycle	Direct estimate of live, senescent and dead tillers; counts of tagged tillers emerged in first year
	Leaf lifecycle	Direct estimate of live, senescent and decaying leaves
Annual- biennial	Biomass	Weight of harvested material (dry matter, g)

One of the 1-2 cm height clipped plants has died, and all have greatly reduced basal area (data not presented). One of the unclipped control plants is dominated by dead tillers and leaves, with very little new growth. Other control plants are starting to show similar signs of reduced vigour. Tagged tiller mortality reached 46% after 11 months, and 93% by 29 months after emergence. By April 2024, the majority (60%) of control plants' total primary tillers were dead.

Discussion

High mortality of seedlings during the summer establishment phase suggests that mid-summer conditions may not be conducive to *Astrebla* seedling establishment. This potentially contradicts earlier findings that seedling recruitment occurs any time during the wet season (Orr and Phelps 2013) but may also reflect the drought and heatwave conditions experienced over the 2021-22 summer at Longreach.

The early results of clipping support previous studies that Mitchell grass responds positively to 'light'—but negatively to severe—defoliation. Despite challenging drought conditions during the establishment phase of this experiment, subsequent average to above-average rainfall conditions have led to relatively reliable soil moisture and a lack of exposure to drought since the initiation of clipping.

Further papers will report longer-term results that include drought and hence water stress conditions. The key question that remains to be answered is whether there is an optimal defoliation height and frequency which increases the responsiveness and resilience of Mitchell grass during and exiting drought.

The high mortality of the first years' tagged tillers in unclipped control plants, supported by high overall primary tiller mortality, suggests old tillers will dominate the demographics of clipped plants. This is likely to reduce the potential for recovery compared with tiller demography dominated by younger tillers. Clipping to 1-2cm height forced regrowth as primary tillers from the crown, as all nodes that could initiate growth are removed. Clipping to 15cm height retains 3-4 nodes where leaves and axillary tiller growth can initiate from. It remains to be seen if clipping to force consistently younger primary (annual or biennial 1-2cm clipping) or axillary (annual or biennial 15cm clipping) tillers will promote growth during drought recovery, or if reduced basal area and reduced overall tiller number will impede growth.

Investment into long-term research is needed to continuously improve our understanding of Mitchell grass as a changing climate brings new challenges through increased temperature and potentially more variable rainfall conditions.

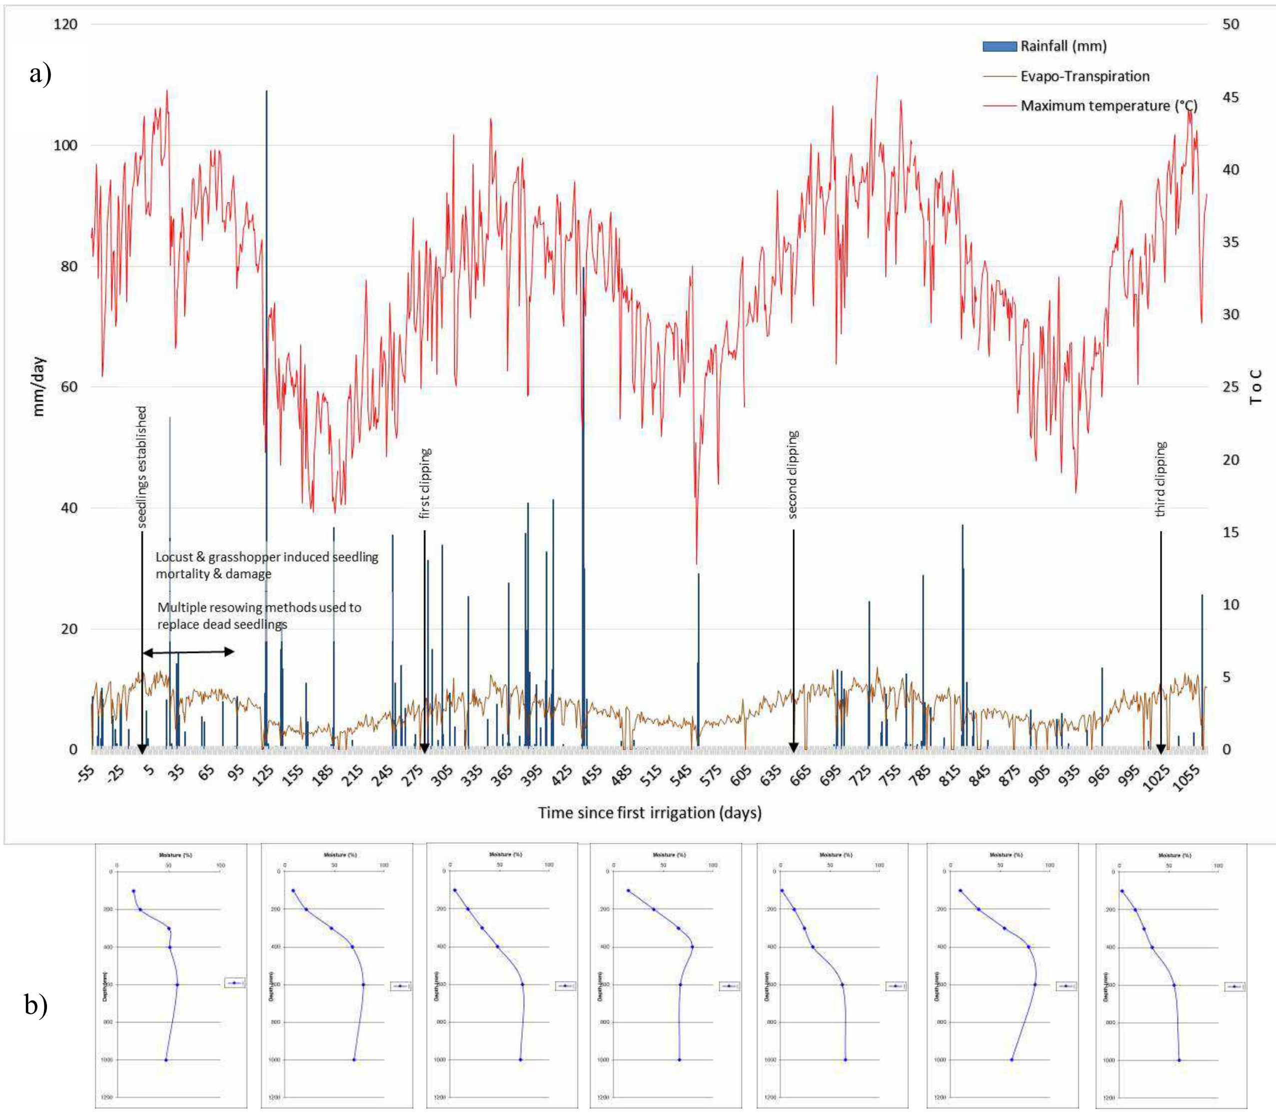

Fig. 1. a) Seedling establishment phase and clipping events in relation to maximum temperature, evapotranspiration and insect incursions throughout the experiment; b) plot level soil moisture levels at days 7, 140, 315, 444, 686, 825, and 1027.

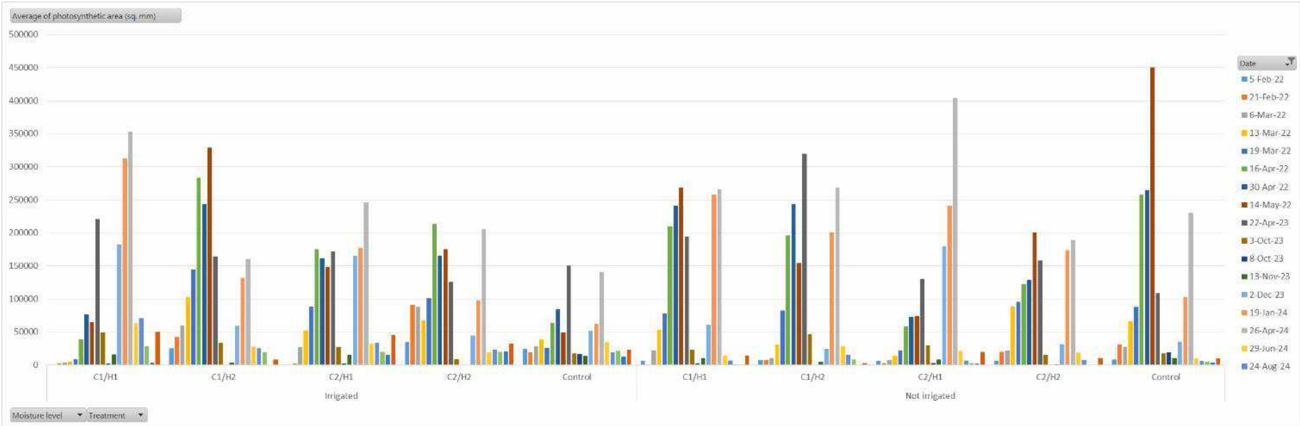

Fig. 2. Photosynthetic area (sq mm/plant) over time under drought and non-drought conditions and at five clipping intensities.

Trends in avian diversity and abundance in remnant vegetation in inland eastern Australian farmland between 2014 and 2023

Reid, NCH[1]; Reid, JRW[2]; Simpson, I[1]; Smith, R[1]

[1] Ecosystem Management, School of Environmental and Rural Science, University of New England, Armidale NSW Australia, 2351; [2] Fenner School of Environment and Society, Australian National University, Acton ACT Australia, 2601

Key words: climatically driven variability; Common Myna; declining woodland birds; floodplain vegetation; rainfall; threatened species

Abstract

Australian bird communities fluctuate greatly in composition and abundance in response to rainfall. At the same time, increasing numbers of threatened bird species are declining in abundance and range, due to various threatening processes. An opportunity to study the dynamics of avian communities in inland eastern Australia arose when birds were surveyed in remnant floodplain vegetation on cotton farms in spring (September–November) 2014 and again in spring 2023, mostly at the same sites (197 sites in 2014, 195 in 2023 and 167 in common). Sites were censused twice on different mornings by separate observers in both years, with 133 diurnal landbird species and 4384 individuals recorded in 2014, and 151 species and 8227 individuals in 2023. Mean (± SE) species richness and total abundance of landbirds were 10.9 ± 0.03 and 22.3 ± 0.08 per 2-ha site, respectively, in 2014, and 17.8 ± 0.04 and 42.4 ± 0.13 per site, respectively, in 2023. Birds were almost twice as abundant in 2023 as 2014, likely attributable to 3 years of above-average rainfall in 2020–22. By contrast, the 2014 surveys were preceded by 1.5 years of average or below-average rainfall. Most (104) of the 126 species recorded in both years were more frequent in 2023 than 2014. Of concern, however, were four sedentary and 'declining' woodland species in south-eastern Australia that were either not recorded in 2023 or were less widespread or abundant than in 2014: Speckled Warbler,* Varied Sittella, Crested Shriketit and Crested Bellbird. Introduced species were also more prevalent in 2023 than 2014, with Common Myna increasing greatly in the intervening 9 years. Our findings accord with the rainfall-driven variability of Australian bird communities, help prioritise the species most in need of recovery interventions, and focus attention on the impact of the rapid increase of the Common Myna in inland eastern Australia.

* Latin names in Table 1 at end of this paper.

Introduction

Australian inland woodland, shrubland and grassland bird communities fluctuate greatly in composition and abundance in response to variable rainfall, increasing in abundance and richness in wet periods (Pascoe et al. 2021; Recher and Davis 2014; Reid et al. 2024; Smith 2015). The recent unusual triple La Niña in 2020–2022 (Voiland 2023) presented an opportunity to compare the impact of this 3-year wet period on the bird community in remnant semiarid woodland and grassland floodplain vegetation in inland eastern Australia, with a similar survey conducted in 2014 after a 20-month dry period. At the same time, increasing numbers of bird species are being listed under state and Commonwealth legislation as threatened with extinction. In addition, many woodland bird species in south-eastern Australia have been identified as ‘declining’ (Reid 1999). Not only is the number of threatened bird species in Australia steadily increasing but, between 1985 and 2018, the relative abundance of threatened bird species decreased by an average of 60% (Cresswell et al. 2021). Of interest, therefore, is whether populations of threatened and declining bird species are able to recover during wet periods such as the recent triple La Niña. Also of interest is whether wet periods are similarly advantageous to introduced bird species, since invasive species are the principal threat to flora and fauna species listed as threatened under the Commonwealth *Environment Protection and Biodiversity Conservation Act 1999* (EPBC Act; Cresswell et al. 2021).

This paper reports the abundance and richness of birds in remnant floodplain vegetation in inland eastern Australia resulting from two surveys, one in 2014 and the second in 2023, with a particular focus on threatened and declining species, as well as introduced species.

Methods

Birds were surveyed in remnant vegetation (riparian forests, woodlands, tall shrublands and native and derived grasslands) and in native revegetation on floodplain cotton farms from central Queensland to southern New South Wales between 25 September and 29 November 2014, and between 22 September and 22 November 2023. Farms were clustered in four zones (from north to south): (1) central Queensland (Fitzroy River basin) in the Emerald district; (2) Border Rivers, comprising the Condamine–Culgoa River basin in southern Qld and the Macintyre, Gwydir and Namoi River catchments in north-western NSW, centred on Moree; (3) Macquarie River basin in central NSW around Trangie, and (4) southern NSW consisting of the Lachlan and Murrumbidgee catchments, centred around Griffith. A distance of approximately 1300 km separated the northern sites near Emerald in central Qld and the southern sites near Coleambally in southern NSW.

The climate of the three northern zones is humid subtropical (Cfa) grading into semiarid (BSh) in the Köppen–Geiger system, whereas the southern NSW zone is cold semiarid (BSk; Peel et al. 2007). Mean annual rainfall between 2000 and 2023 varied from 567 mm and 564 mm at Emerald and Moree, respectively, to 471 mm at Trangie and 289 mm in Griffith. By analysing Bureau of Meteorology rainfall data for weather stations in each zone in survey years and the 3 preceding years, we determined that both survey years were similarly dry (38–72% and 35–76% of mean annual rainfall falling in the 8 months prior to the September–November survey period in 2014 and 2023, respectively). However, seasonal conditions in the 3 years preceding the survey years differed. Annual rainfall across the region was 98–116% of mean annual rainfall in 2011–13 compared to 115–156% in 2020–22. The latter was an unusual 3-year ‘Triple-Dip La Niña’ wet period (Voiland 2023).

Land use in all four zones is predominantly irrigated and dryland cropping and extensive livestock grazing of native pastures and woodlands, although some remnant vegetation on irrigated farms in all zones is ungrazed by domestic livestock. In 2014, the 197 sites surveyed were all on cotton farms, whereas 22 of the 195 sites surveyed in 2023 were on public land (travelling stock routes, national parks, nature reserves). These and six other sites on cotton farms were substituted for sites that were unable to be surveyed in 2023 due to changes in ownership or vegetation clearance, and were selected to sample vegetation types more evenly; 167 sites were common to both surveys.

Sites were classified into nine types by vegetation structure, dominant plant species and as remnant native vegetation or native (planted) revegetation: (1) river red gum (*Eucalyptus camaldulensis*) forest and woodland; (2) coolibah (*E. coolabah*) woodland; (3) black box (*E. largiflorens*) woodland; (4) poplar box (*E. populnea*) woodland; (5) myall (*Acacia pendula*) tall open shrubland; (6) belah (*Casuarina cristata*) forest and low-forest; (7) brigalow (*A. harpopyhlla*) low-forest; (8) grassland; (9) native revegetation of trees or trees and shrubs (planted 2–35 years ago). The structure and composition of each vegetation type is described in more detail by Smith et al. (2019).

Sites consisted of a 2-ha (generally 200 × 100 m) quadrat in a target vegetation type, generally contiguous with similar vegetation on at least two sides and sometimes all four. Birds at each site were censused twice on different mornings for 20 mins between sunrise and 11:00 hrs by separate observers in 2014 (JR and S. Green) and 2023 (JR and NR). Weather conditions were generally fine and sunny or overcast and still or with a breeze or light wind during both survey periods. Very windy conditions and rain were avoided. All birds seen or heard in the 2-ha quadrat were recorded. Data were averaged over the two censuses per quadrat in each survey period. Avian nomenclature follows Christidis and Boles (2008), and threatened bird species categories were as per Commonwealth and NSW legislation in December 2024, and applied retrospectively to species recorded in the 2014 and 2023 surveys.

Results

Some 133 diurnal landbird species and 4384 individuals were recorded in 2014, and 151 species and 8227 individuals in 2023 (Table 1). Mean (± SE) species richness and total abundance of landbirds were 10.9 ± 0.03 and 22.3 ± 0.08 per site, respectively, in 2014, and 17.8 ± 0.04 and 42.4 ± 0.13 per site, respectively, in 2023. Birds were almost twice as abundant in 2023 as 2014, and mean species richness one and half times greater in 2023 than 2014. Seven species were recorded in 2014 but not 2023: Scaly-breasted Lorikeet, Budgerigar, Pallid Cuckoo, White-fronted Honeyeater, Varied Sittella, Rufous Fantail and Little Crow. By contrast, 25 species were recorded in 2023 but not 2014. Most (126) species were recorded in both years, and 82 of these species were recorded in at least three more sites in 2023 than in 2014. By contrast, only six species were recorded in at least three more sites in 2014 than in 2023.

Consistent with the results for native species, introduced bird species were more widespread and abundant in 2023 than 2014 (Table 1). Only three introduced species were recorded in 2014: Rock Dove ($n = 2$ sites), Common Starling (11) and Common Myna (1). These species were recorded in many more sites in 2023 (10, 26 and 24 sites, respectively), particularly Common Myna. Spotted Dove, Common Blackbird and House Sparrow were also recorded in one or two sites each in 2023.

Also consistent with avian diversity and abundance comparisons between the 2 years, most threatened and declining woodland bird species were more diverse, frequent and abundant in 2023 than 2014 (Table 1). Fourteen species listed as Vulnerable or Endangered under the *Biodiversity Conservation Act 2016* (NSW) or the EPBC Act (Cwth), or both, were recorded in 2023 compared to 13 in 2014. Two listed species were recorded in 2023 but not in 2014 (Little Lorikeet, White-fronted Chat), whereas only one listed species was recorded in 2014 but not 2023 (Varied Sittella). Ten of the 12 listed species recorded in both years were both more frequent and abundant in 2023 than 2014, and paired t-tests comparing both the frequency and abundance (log-transformed) of the 12 species in the 2 years were significant (P = 0.009 and P = 0.002, respectively).

Twenty-seven declining woodland bird species were recorded in the two surveys (including seven of the listed species mentioned above). Twenty-six declining woodland species were recorded in 2023 compared to only 23 species in 2014 (Table 1). Eighteen of the 22 declining species recorded in both years were both more frequent and more abundant in 2023 than 2014. Paired t-tests comparing both the frequency and abundance (log-transformed) of the 22 species between the two years were significant (P = 0.002 and P = 0.004, respectively).

Discussion

We attribute the large increase in local and subcontinental-scale species richness and abundance of birds in 2023 compared to 2014 to the three La Niña years of above-average rainfall in 2020–22. Rainfall was well above average in the three southern zones in all 3 years between 2020 and 2022 (115–219% of mean annual rainfall), with only the 2021 rainfall at Emerald falling below average (90% of mean annual rainfall). By contrast, and despite above-average rainfall in 2011 and 2012 throughout all four zones (110–149% and 105–143% of mean annual rainfall, respectively), rainfall was well below average in 2013 (69–88%) in the year preceding the 2014 survey. The dry conditions from January to August in 2014 preceding the survey, coupled with the dry 2013, were sufficient to suppress avian abundance and diversity, whereas the dry start to 2023 was insufficient to dampen the increased population sizes and habitat spill-overs evident in the 2023 surveys. The general increases in population abundances and habitat spill-overs in these semi-arid woodland and grassland habitats in 2023 were likely due to increased food abundance, breeding and breeding success in 2020–22 compared to 2013–14 (Recher and Davis 2014; Smith 2015; Stevens and Watson 2013).

Of interest are the seven species recorded in both years that were not more abundant and widely dispersed in 2023 than 2014: Australian Hobby, Nankeen Kestrel, Horsfield's Bronze-Cuckoo, Crested Bellbird, Little Crow, Zebra Finch and Australasian Pipit. Several of these are mobile species often found commonly in arid Australia in good seasons and prefer some non-vegetated ground for foraging; hence part or all of the kestrel, cuckoo, crow, finch and pipit populations might have relocated inland during the three La Niña years and continued to reside there during the 2023 survey.

The increase in avian abundance and local species richness in 2023 was generally evident among listed and declining woodland bird species, indicating that the excellent seasonal conditions in 2020–22 counteracted the various threatening processes responsible for these species' declines in historical times. However, eight threatened and/or declining species recorded in 2014 were either not recorded in 2023, or were less abundant or frequent in 2023 than 2014: Spotted Harrier, Superb Parrot, Horsfield's Bronze-Cuckoo, Speckled Warbler, Painted Honeyeater, Varied Sittella, Crested Shriketit and Crested Bellbird. While part of the populations of some of these species may have resided further inland in more arid habitats in 2023 for the reasons mentioned above (harrier, parrot, cuckoo), the reduced abundance or frequency of the more sedentary species (warbler, sittella, shriketit, bellbird) is a concern. It could indicate that the threatening processes contributing to their decline are having a greater influence than the positive effect of prolonged high rainfall. As the Painted Honeyeater is dependent on mistletoe fruit for food, part of its population, too, may have relocated to more arid habitats in 2023 if excellent seasonal conditions promoted an unusually large fruit resource further inland.

Although introduced bird species were more frequent or abundant in 2023 than 2014, in common with most other species, the increase in Common Mynas was startling. Only two birds were recorded in one site in

2014, whereas 102 birds were recorded across 26 sites in 2023. The Invasive Species Specialist Group, a specialist group of the Species Survival Commission of the World Conservation Union, declared this species to be one of the world's most invasive species, listing it with only two other bird species in '100 of the World's Worst Invasive Species' (Lowe et al. 2004). The species is spreading rapidly in inland eastern Australia.

Conclusions/Implications

Our findings support the notion that above-average rainfall is an important driver of breeding success and population increase in semi-arid Australian bird communities. The threatened and declining sedentary species that showed the reverse trend (Speckled Warbler, Varied Sittella, Crested Shriketit, Crested Bellbird) deserve special conservation attention. Research is also required to assess the environmental impact of the rapid expansion of the Common Myna in inland eastern Australia.

Abstract

Alpine ecosystems are characterized by extreme environmental conditions, including cold temperatures, low rainfall, poor soils, and high winds, which severely constrain plant growth and establishment. Despite these challenges, keystone plant species native to these habitats play a vital role in ecosystem restoration and conservation. One such species is *Festuca karatavica* (Bunge), a tussock grass native to alpine regions of northern Iran and Central Asia, found at elevations ranging from 1800 to 3100 m.a.s.l. This species is particularly valuable as a source of livestock fodder and for its contributions to soil and water conservation. In this study, we investigated the phenology, nutrient content, and ecological preferences of *F. karatavica* along an altitudinal gradient in its natural habitat on Shirbad Summit, northeast Iran. We also analyzed associated plant species diversity and richness, as well as soil physical and chemical properties. The phenological cycle of *F. karatavica* begins in early April and concludes with seed shedding by September, with seasonal variations influenced by annual rainfall. Crude protein content, acid detergent fiber (ADF), and neutral detergent fiber (NDF) were highest during early growth stages but declined over the growing season. Its seeds germinate easily without dormancy, suggesting strong regenerative potential. Soil conditions vary across the altitudinal gradient, with sandy loam textures and the highest pH (7.4) and electrical conductivity (EC) observed at the summit, decreasing at lower elevations. Species diversity peaked at mid-elevation (2831 m.a.s.l.), while species richness and evenness were highest at higher (3050 m.a.s.l.) and lower (2720 m.a.s.l.) elevations, respectively. The most favorable habitat for *F. karatavica* was identified at mid-elevation, where optimal soil nutrients (N, P, and organic C) and mycorrhizal associations supported its growth. Growth at higher altitudes is constrained by poor soil conditions and harsh climatic factors, whereas competition, intensive grazing, and erosion limit its success at lower altitudes.

Introduction

Festuca karatavica (Bunge), is a perennial native grass. It grows in alpine habitats and provides a reliable source of fodder for livestock and wildlife. It is also important for soil and water conservation in alpine ecosystems with harsh climates. Intense livestock grazing and possible climate change effects have led to the replacement of *F. karatavica* by *F.sclerophylla,* a closely related species whose distribution range extends through Alborz and central Zagros toward north-eastern Turkey and Caucasian mountains(Memariani and Arjmandi, 2013). According to the extent of its occurrence and its very peculiar habitats, which are highly sensitive to climate change, *F. karatavica* is evaluated as an endangered (EN, B1ab (ii, iii)) species in Iran (Memariani and Arjmandi, 2013). In this study, we investigated the ecological conditions and phenology of *F. karatavica* at Shirbad, the tallest summit of the Binalud Mountain range in northeast Iran.

F. karatavica(Bunge) B. Fedtsch. Turkest. (Fig1). It is densely tufted. Culms 50-100 (-140) cm, glabrous, at base tightly enveloped by brownish butt sheaths. Leaf sheaths glabrous on surface; ligule an eciliate membrane, truncate, 1.5-5 mm long (Memariani and Arjmandi, 2013).

Fig 1. *Festuca karatavica* in Flora of Khorasanica

Phytogeography and ecology

The general distribution of this Irano- Turanian species is from western Tian Shan, southwestern Pamir-Alay, to northeastern and northcentral parts of Afghanistan, and the newly recorded specimens from Binalood Mountains extend the distribution range of *F. karatavica* more westward to NE Iran. Ecologically, it grows in higher mountain and alpine areas on stony slopes, rocks, and screes. In the Binalood mountain ranges, its habitat is usually on metamorphic schistose rocks at high elevations between 1800 to 3000 m. From westward, in calcareous rocky slopes of the North Khorassan Province (Aladagh and Salook and Shah-Jahan Mts.) (Memariani and Arjmandi, 2013).

Methodology

The investigated area was determined by the priority of the presence of *F. karatavica*; in three altitudes, the first elevation was 3050 meters with the coordinates of 36º17"35' North and 59º05"40' East, the second is located at the height of 2831 meters of 36º17"27'N and 59º05"49.49' E. The third altitude was at 2720 meters of 36º17"20.6' N and 59 º 05"3.40' E.

In each elevation, three transects were established, in which 5 quadrats of one square meter were placed randomly. The abundance and canopy cover of *F. karatavica* and all other plant species were measured within quadrats.

Forage quality was monitored by measuring crude protein (nitrogen), ADF (Acid Detergent Fiber), NDF (Neutral Detergent Fiber) and DMD (Digestible Dry Matter). The formula provided by Oddy *et al*.,1983 was used: **DMD$^{\%10}$ = 83/56-0/824 ADF ٪+ 2/626 N٪**

Metabolic energy was calculated after calculating the digestibility percentage of dry matter from the equation provided by “Deutsches Institut für Normung” (DIN): **ME^{2} (MJ/Kg) = 0.17 DMD%– 2**

The SPSS software was used to analyze the data. The nutritive values of plant samples from different elevations were compared at different phenological stages using one-way analysis of variation.

To determine the phenological stages, 10 individuals *of F. karatavica* were selected from each elevation class. Phenological growth stages were recorded every 20 days from April to July in 2015 and 2016.

Results and discussion

Forage quality changes were compared according to NDF, ADF and protein (Fig 2). The amount of NDF increased (P=<0.00001) by increasing plant phenological stages from early emergence to seed shedding. Consistent with other studies on native grasses of Iran (Arzani et al., 2004), the highest amount of NDF was in the seed ripening stage and the lowest amount was in the early growth season, conversely protein content was reduced from the early growth towards the seed ripening stage. The critical limit of protein is shown as a line, which is defined as the critical level that is needed to keep the grazing livestock alive.

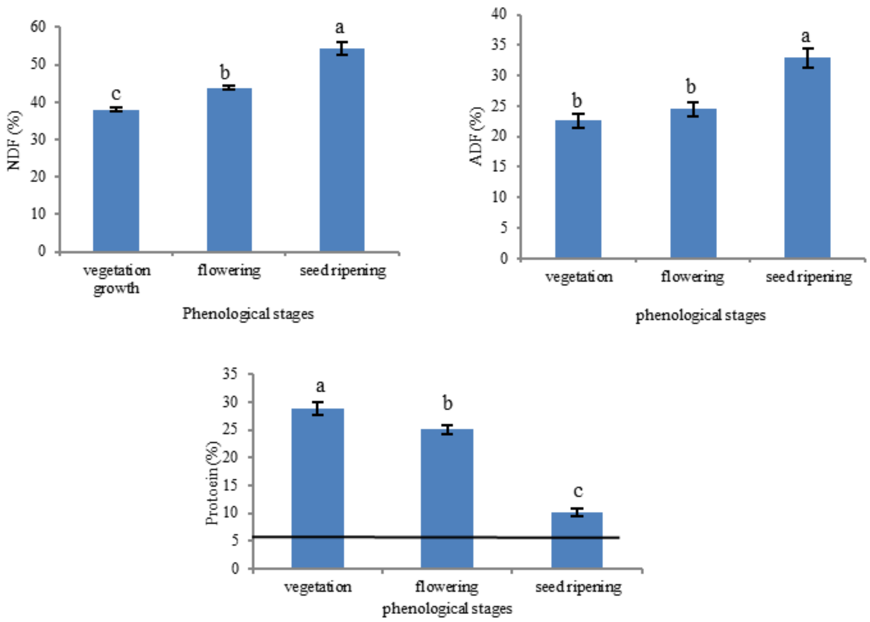

Fig 2. Effect of Phenologcal stages on Nutrition qualification factors

The results of the plant phenology in 2015 showed that growth initiation in high-altitude were from the end of April to the mid-May. Phenological stages commenced a week earlier in the mid and low elevations that the summit site. A dry spring in 2016 led to an earlier growth stages as compared the those we had recorded for 2015 as a normal year (Fig3).

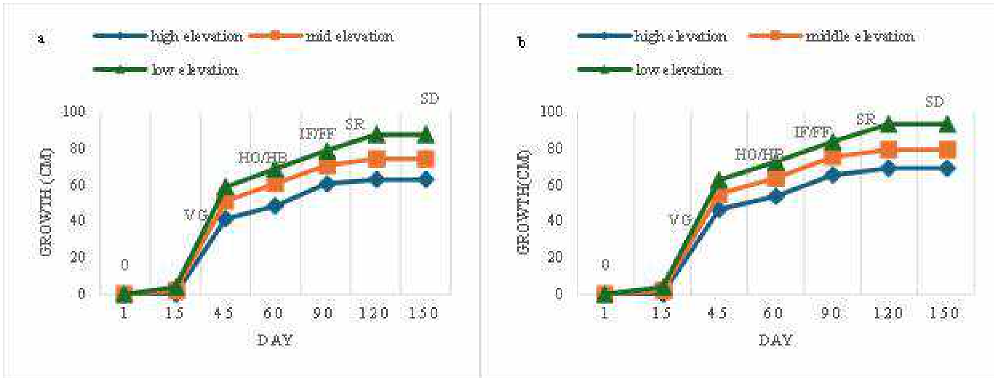

Fig 3. Phenological stages in different elevation in a normal (2015) and a dry (2016) year.

By increasing the elevation, mycorrhiza spore counts and the inoculation rate were reduced, similar to the changes observed for soil moisture (Fig4).

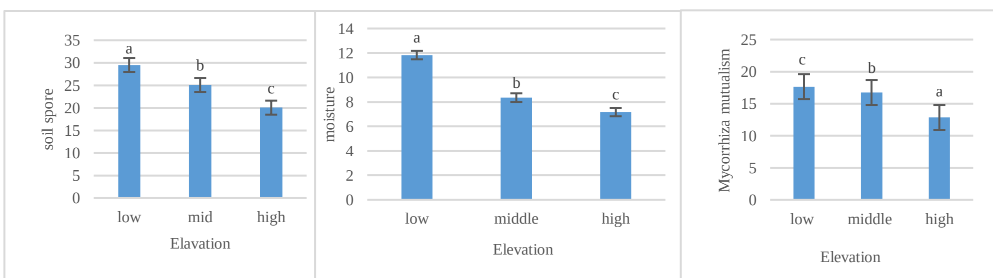

Fig 4. Changes in Spore, Moisture and Mycorrhiza in different states of study elevation.

The soil texture in each altitudinal habitat was loamy. Silt, nitrogen, and phosphorous levels were higher at lower altitudes, whereas clay and EC levels were higher at higher elevation. (Table1).

Table 1. Soil properties in three elevation

Index	Low Elevation	Mid Elevation	High Elevation
Sand (%)	43.75±0.79	57.5±2.62	46.75[a] ±1.75
Silt (%)	40.25±0.74	28.25±1.89	31.5±1.80
Clay (%)	16±0.35	14.25±1.35	20.75±1.43
Texture	loamy	loamy	loamy
EC (µs/cm)	1826±0.35	1824.50±1.35	1823.25±1.63
Ca (meq/lit)	140.5±0.55	124.5±1.01	108±1.25
N (ppm)	2129±0.93	2074.75±1.27	2021±1.75
pH	7.40±0.004	7.36±0.03	7.32±0.03
Organic matter (%)	2.82±.58	2.77±0.21	2.95±0.21
Phosphorus (ppm)	32.65±0.68	28.32±0.69	24.02±0.92

The habitats of *F. karatavica* differed in plant community indices, with mid-altitude habitats showing the highest species diversity and richness but the lowest evenness compared to high- and low-altitude habitats(Table2).

Table 2. Biodiversity indexes in different studied altitude

Elevation / Index	Index	Low	Middle	High
Diversity	Shannon-Wiener	2.490	2.695	2.518

Richness	Number of species	8	10	9
	Jack Knife	12.4	15.3	10.8

Conclusion

In this study, we provided detailed insights into the phenological growth stages, nutritive value, soil characteristics, mycorrhizal symbiosis, and plant community indices of *Festuca karatavika*, a keystone species native to the alpine ecosystems of northeast Iran. Our findings shed light on the environmental constraints limiting the distribution of this species and contributing to its classification as endangered. At lower elevations, higher soil organic matter and nutrient levels likely promote greater mycorrhizal symbiosis. However, more intense livestock grazing and competition from invasive species like *Eremurus olgae* may reduce its abundance in these areas. Conversely, harsh microhabitat conditions, such as low soil moisture, poor nutrient availability, and extreme climate, may account for its low abundance at higher elevations. Our results suggest that the mid-altitude zone of Shirbad Mountain provides the most suitable habitat for *Festuca karatavika*, offering a balance between protection from harsh upper-elevation conditions and reduced grazing pressure.

Key words: bird diversity; grassland conservation index (GCI); soil microorganism; active carbon; phosphatase activity

Abstract

This study investigated the relationship between soil health and biodiversity in grasslands, under the hypothesis that better livestock management practices result in a healthier balance between fungi and bacteria, greater carbon sequestration potential, higher bird diversity, and better coverage of forage species. Six farms were selected, and within each, variables were determined at farm and paddock level. At farm level, floristic variables related to pasture degradation as coverage of forage species, coverage of invasive exotic species, proportion and height of the upper stratum were assessed to form the Grassland Conservation Index (GCI) and Bird Monitoring Strategy. At paddock level, a representative pasture was chosen based on the dominant soil group. Two transects were established in these pastures along which soil was sampled for analyses of microbiologically, chemical and physical attributes. Fungal abundance, the fungi-to-bacteria ratio (F), enzymatic activities (beta-glucosidase and phosphatase), and active carbon (AC) were determined. These variables were used to construct the Microbiological Soil Health Index. Chemical analyses included nutrient content, micronutrients, pH, and bases. At the farm level, principal component analysis (PCA) revealed that the main and the second axis explained 39,4% and 24% respectively, of the variability, distinguishing two samples. AC and phosphatase, crucial for the soil health index, were determinant in this separation. These two samples showed higher total phosphorus (P total), AC, and phosphatase activity, suggesting that soils rich in total P can sustain a greater abundance of P-solubilizing microorganisms. Although the number is low and much more studies are needed to correlate the ecosystemic trophic chains and their relationships, this case study leaves lessons learned and trends of the relationships between ecosystemic services of rangelands.

Introduction

The Río de la Plata grasslands are among the largest, most diverse, and least transformed temperate subhumid to subtropical grasslands in the world, spanning central-eastern Argentina, Uruguay and southern Brazil (Soriano et al. 1991; Paruelo et al. 2022). These grasslands provide crucial ecosystem services, including food provisioning, biodiversity conservation (Bilenca and Miñarro 2004; Medan et al. 2011), and carbon sequestration (Modernel et al. 2016). Given climate change and increasing market demands, there is an urgent need to identify indicators that reconcile livestock production with environmental protection.

Evidence suggests that biological indicators, such as bird species richness and microbiological and biochemical indicators, offer a more precise assessment of soil health and functional potential than physicochemical indicators. Soil microorganisms perform essential functions for plants (Newsham et al. 1995; Smith and Read 2008; Mendes et al. 2013; Rillig et al. 2016) and serve as valuable bio-indicators. These include the abundance of beneficial organisms, the fungi-to-bacteria biomass ratio (H:B), enzyme activity crucial for nutrient cycling (Pérez Guzmán et al. 2021), and active carbon content, which reflects the carbon available to microorganisms and is sensitive to practices that sequester carbon in the soil (Hurisso et al. 2016).

Within Uruguay, El Paso Centurión and Sierra de Ríos is a protected landscape important for biodiversity. The main activity here is livestock farming on natural grasslands, which requires effective management based on scientific data. Our approach emphasizes that healthier soils promote better plant growth, that supports livestock production and plant diversity, which in turn sustains greater bird diversity and serves as bioindicators of environmental health.

Our main objective was to establish a baseline of environmental health indicators in the Paso Centurión and Sierra de Ríos Protected Landscape, generating information to propose management recommendations for biodiversity conservation. Specifically, we aimed to assess i) the health status of six livestock farms using soil, vegetation, and bird health indicators, and ii) the correlation between these health indicators at different spatial scales (farm and paddock).

Methods

This study was carried out in Paso Centurión and Sierra de Ríos, a protected landscape which is in the northeast of Uruguay. In November 2023 we selected 6 livestock establishments (named from A to F). At farm spatial scale we study percentage of natural pasture, vegetation cover index by satellite, bird abundance, bird richness species.

At the paddock spatial scale, two representative points within the dominant soil type were sampled in each establishment. For the study of chemical, physical and biological indicators of the soil, two composite soil samples from the first 15cm were taken, following two 60 m transects. We determined total P, micronutrients, total bases and organic matter according to MEHLICH - I; Sulfochromic Oxidation and soil physical analysis were performed with Bouyoucos Densimeter. In laboratorio Sosei we estimated biological variables such as Fungi and bacterial biomass to estimate the H:B ratio, and abundance of protozoa were determined by direct microscopy; phosphatase activity and betaglucosidase activity were measured by spectrophotometry and active carbon was determined by oxidation of potassium permanganate. To investigate the health of the vegetation, the cover of forage species, the cover of exotic species and the structural heterogeneity were assessed in these sample points. Using vegetation variables, we construct the Grassland Conservation Index at farm scale, which represents individual contribution of producers (at the level of rural establishments) to the conservation of natural grasslands. Integrating data of functional microbiological variables, the Microbiological soil health Index (MSHI) was constructed. To study the correlation between the different indicators at paddock scale, simple linear regression analyses were carried out between the different variables studied, as principal component analysis (PCA), standardizing different variables at paddock scales.

Results

Results at farm scale

Site C had the lowest ICP and, together with site F had a low number of birds compared to the other sites surveyed (Figure 1)

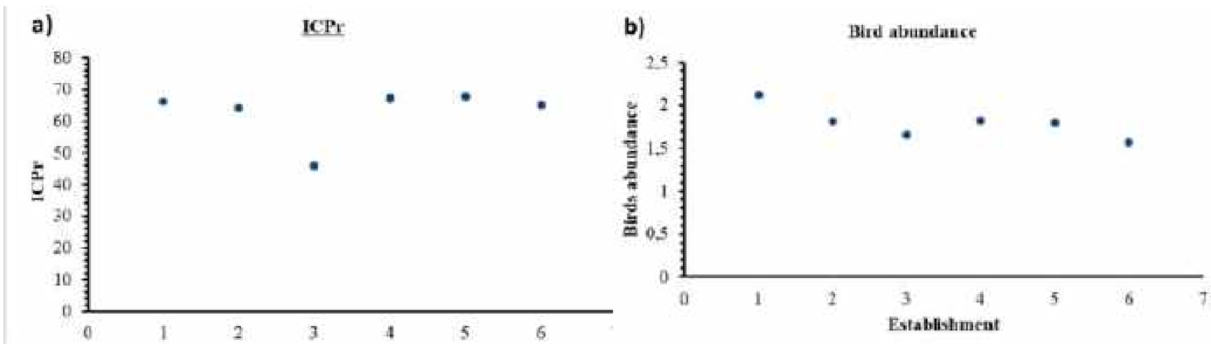

Figure 1. ICP value (a) and bird abundance (b) in the establishments studied.

Results at paddock scale

The abundance of the different microbial groups and as the H:B ratio, was relatively homogeneous among study sites (ranged 0.01-0.4). We found differences in soil microorganism functioning variables between sampled points. The principal component analysis separated samples A1 and C2 (samples with greatest MSHI) from the rest at paddock scale. The active carbon, phosphatase activity and total P in soil were important in explaining this grouping of sample points. (Figure 2).

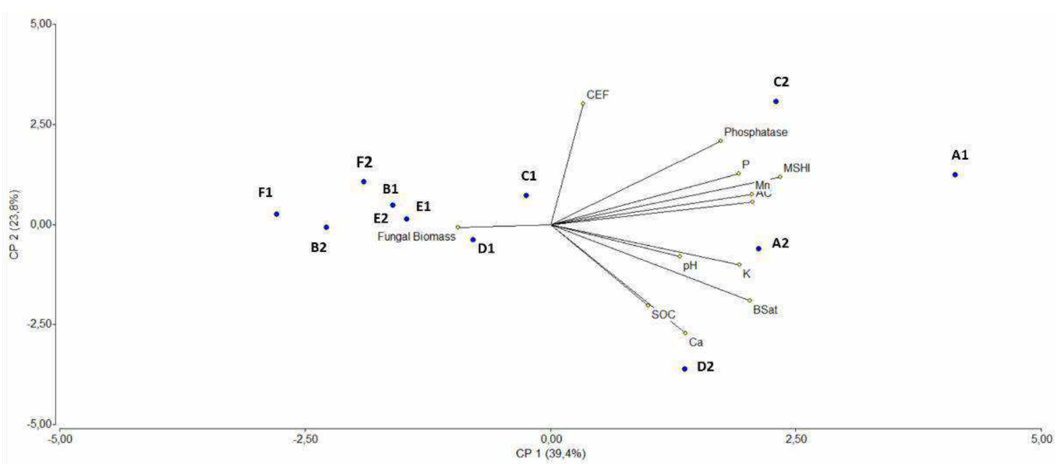

Figure 2. Principal component analysis performed with variables standardized at paddock scale. A1 and A to F1 and F2 are points 1 and respectively sampled and within paddock A to paddock F; MSHI: Microbiological soil health Index; AC: active carbon; Bsat: bases saturation; SOC: soil organic carbon; CEF: coverage of forage species.

In terms of grassland vegetation, all sites had a high total ground cover (70-98%), an índex of forage species cover between 1.6 -3.4 and no exotic species were recorded. Contrary we expected, the relationship between MSHI and forage species cover was weak (Fig 3).

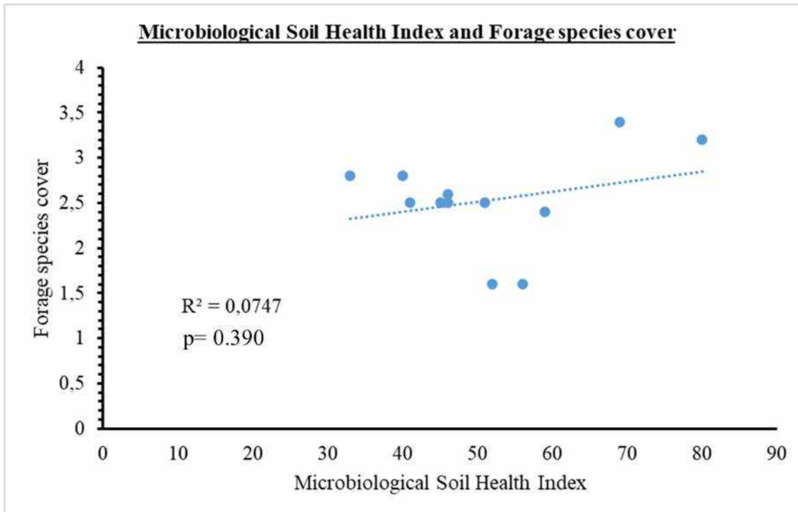

Figure 3. Relationship between the Microbiological soil health Index and coverage of forage species.

Discussion

Our research is the first to report values for soil microbial indicators in grasslands and shows that exist an association between soil and vegetation health in this ecosystem. The points with the highest MSHI were those with the highest levels of total P. This could be explained due to soils with more total P could support a greater abundance of P-solubilising microorganisms, as evidenced by a higher activity of the enzyme phosphatase. Contrary we expected we did not find a relationship between the MSHI and forage species cover, probably due to the small number of replications. Larger sampling efforts would be needed to explore this relationship further. A more comprehensive avian survey, including statistical modelling, is needed to establish a stronger, statistically significant link between bird diversity and ecological indicators. Identifying indicators that reflect the health of the different components of the natural field and how they relate to each other under different productive management is a fundamental step in creating incentives and promoting policies for the conservation of our most important ecosystem.

Acknowledgements

We thank the producers and the landscape authorities of El Paso Centurión.

Effect of soil and subhabitat differentiation on the growth of *Tarchonanthus camphoratus* seedlings from a semi-arid savanna of South Africa

Smit GN[1]; Jacobs IJ[1]

[1]Department of Animal Science, University of the Free State, P.O. Box 339, Bloemfontein, 9300, Republic of South Africa.

Key words: allelopathic effect; seedling growth rate; canopied zone, uncanopied zone; nutrient status

Abstract

Large areas in the savanna of the Northern Cape Province of South Africa suffer from bush thickening, especially by species such as *Tarchonathus camphoratus*. Effective management of these areas requires an understanding of the factors such as allelopathy that can affect the establishment, survival and growth of *T. camphoratus* seedlings. The objectives of this study were to investigate whether soil originating from different subhabitats would differ in soil nutrient status and whether *T. camphoratus* exhibit allelopathic effects by affecting the survival and growth of seedlings grown in soil originating from these different subhabitats. Soil and ripe seeds were collected in the Northern Cape Province of South Africa on two sites of different soil types (deep sandy and shallow rocky) and within three subhabitats (close to the stems of mature *T. camphoratus* plants; in the middle of the canopy; and away from tree canopies in the uncanopied zone). The trial was conducted under controlled conditions in a greenhouse over a period of 18 months and consisted of six treatments with ten replications. Soil analyses, including Na, Mg, K, Ca, P and N were performed on the soil from the different subhabitats. Seeds germinated abundantly in all the soil samples, confirming that there are no allelopathic effects preventing their germination. Significantly higher ($P<0.05$) plant heights, leaf numbers and growth rates were measured in seedlings grown in the soil originating from the canopied zone compared to those grown in soil from the uncanopied zone, while no significant differences ($P>0.05$) existed between the seedlings grown in soil from the same subhabitat but different soil types. The better growth of *T. camphoratus* seedlings in soil from the canopied subhabitats can be attributed to the higher soil nutrient status in these subhabitats. This has important implications for tree thinning operations as areas where mature trees are removed, will present ideal areas for seedling establishment, survival and growth.

Introduction

Southern African savannas are water-limited ecosystems and bush thickening is considered a major factor contributing towards the low occurrence or even total absence of herbaceous plants, due to severe competition from the woody plants for available soil water (Smit et al. 1999). Large areas in the savanna of the Northern Cape Province of South Africa suffer from bush thickening, especially by species such as *Tarchonathus camphoratus*. Many studies have shown a positive response of the herbaceous layer to the partial or complete removal of woody plants (Smit 2005; Harmse et al. 2016) and the success of bush-clearing or thinning operations is often measured on the basis of the recovery, productivity and stability of the herbaceous layer. However, the re-establishment of woody plants after thinning or clearing - either by resprouting or by seedling establishment from seeds - remains a serious threat and this phenomenon has been widely reported in southern African savannas (Smit 2004; Harmse et al. 2016). It is known that some plants release allelochemicals into the soil and these metabolic secretions, including long chain fatty acids, phenolic acids, terpenoides, organic cyanides and others are known to affect seed germination and seedling emergence, mortality and growth (Ghebrehiwot et al. 2014). The objectives of this study were to investigate whether soil originating from different *T. camphoratus* subhabitats (under- and between tree canopies) would differ in soil nutrient status and whether *T. camphoratus* exhibits allelopathic effects by affecting the survival and growth of seedlings grown in soil originating from these different subhabitats.

Methods

Soil and ripe seeds of *T. camphoratus* shrubs were collected from the Rooipoort Nature Reserve approximately 60 km west of the town of Kimberley in the Northern Cape Province of South Africa. The reserve is located within the savanna biome of southern Africa and Mucina and Rutherford (2006) described the area as the Eastern Kalahari Bushveld Bioregion. Twenty free-standing *T. camphoratus* shrubs of similar size (1.5 - 2.0 m height) were randomly selected on two sites of different soil potential (deep sandy soils and shallow rocky soils). Topsoil (0 - 20 cm) was excavated from three identified subhabitats (Smit & Swart 1994), namely: (1) close to the stem ; (2) in the middle of the canopy between the stem and the canopy edge; and (3) in the open uncanopied zone between the shrubs. The bulked samples were thoroughly mixed and a subsample was taken for laboratory analyses.

Large pots (18 700 cm^3) were filled with an equal volume of soil and placed in a greenhouse located at the facilities of the University of the Free State, Bloemfontein, South Africa. This amounted to 3 subhabitats x 2 sites x 10 replications = 60 pots. *T. camphoratus* seeds were planted in the pots during September 2018. Plots were regularly watered and germination of seeds recorded. Seedling height was measured weekly. Eighteen weeks later all plants were harvested. The number of leaves per seedling, number of daughter shoots, stem diameter at the base and seedling height was recorded. The stems, leaves and roots were separated and the soil washed from the roots with medium pressure water. Thereafter all biomass fractions were oven-dried at 70°C to constant mass and then weighed. The Shapiro-Wilk test ($p > 0.05$) was used to test all variables for normal data distribution. Analysis of variance using the randomized complete block design (RCBD) was used to test the influence of subhabitat and soil on the different plant growth parameters.

Results and Discussion

Soil nutrient status

Marked differences in soil nutrient status between the uncanopied subhabitat and the two canopied subhabitats were found (Table 1). However, the extent to which each soil nutrient was affected, differed. Subhabitat differentiation significantly ($p < 0.05$) influenced soil potassium and calcium concentrations as well as total nitrogen and organic carbon percentages on both soil types and followed a clear spatial gradient with increasing distance from the stem to the open grassland subhabitat. Magnesium concentrations differed between subhabitats on the rocky soil only, while plant available phosphorus only differed between subhabitats on sandy soil. Soil pH, calcium concentration, nitrogen and organic carbon percentage were significantly ($p < 0.05$) influenced by soil potential.

Table 1 Mean ± 1 SE of all tested soil variables for two soil potentials (sandy and rocky) in three subhabitats

Site Subhabitat	Rocky stem	Rocky canopy middle	Rocky open	Sandy stem	Sandy canopy middle	Sandy open

Seed germination and growth of seedlings

Germination of the seeds commenced very slowly and only by 15 January 2019 had the majority of seeds germinated, indicating that fresh *T. camphoratus* seeds undergo some form of seed dormancy (seed rest period) for approximately three to four months. Seedlings grown in the soil originating from the sandy site differed significantly ($p < 0.05$) in height between subhabitats. Seedlings grown in the soil from the two canopied subhabitats grew significantly ($p < 0.05$) higher than the seedlings grown in the soil from the uncanopied subhabitat. In the case of the soil originating from the rocky site, only seedlings grown in the soil from the stem subhabitat grew significantly higher ($p < 0.05$) than those grown in soil from the uncanopied subhabitat (Table 2).

Seedlings grown in the soil from the two canopied subhabitats of both the sandy and the rocky site grew significantly ($P < 0.05$) thicker (stem base diameter) compared to those grown in soil from the uncanopied subhabitat. However, the stem diameters of plants grown in soil of the canopied subhabitats of both soil types did not differ significantly ($p > 0.05$) (Table 2).

The number of leaves per seedling was 138% and 88% higher for plants grown in the soil originating from the stem and canopy middle subhabitats respectively, compared to plants grown in soil from the uncanopied subhabitat of the sandy site. Similarly, plants grown in the soil from the stem and canopy middle subhabitat, had 114% and 106% more leaves respectively, than plants grown in soil from the uncanopied subhabitat of the rocky site (Table 2).

The dry mass of the seedling leaves and shoots as well as total dry mass (leaves, shoots and roots combined) yielded very similar results. Significantly ($p < 0.01$) heavier leaf dry mass, shoot dry mass and total dry mass were recorded in plants grown in the soil from the canopied subhabitats compared to plants grown in the soil from the uncanopied subhabitat. The plants grown in the soil of the two canopied subhabitats were statistically non-significant ($p > 0.05$) in leaf, shoot and total dry mass in both soils.

Table 2 Soil effect on seedling height, stem diameter, number of leaves and number of daughter shoots (mean ± SE) as per subhabitat (n=10). The same letter for each subhabitat represents statistical non-significance ($p > 0.05$).

Subhabitat	Site	Seedling height (mm)	Stem diameter (mm)	Number of leaves	Number of daughter shoots.
Stem	Sandy	683.8 ± 71.5[a]	8.2 ± 0.5[a]	243.7 ± 31.8[a]	28.3 ±4.2[a]
	Rocky	664.6 ± 84.3[a]	8.7 ± 0.5[a]	206.3 ± 25.6[a]	28.2 ± 5.3[a]
Canopy middle	Sandy	655.9 ± 49.8[a]	8.6 ± 0.4[a]	192.0 ± 13.8[a]	24.4 ± 2.8[a]
	Rocky	570.0 ± 68.2[a]	8.1 ±0.8[a]	198.4 ± 27.0[a]	21.6 ± 3.2[a]
Uncanopied	Sandy	405.7 ± 46.1[a]	5.7 ± 0.3[a]	102.3 ± 11.5[a]	8.7 ± 2.0[a]
	Rocky	418.9 ± 29.8[a]	5.8 ± 0.2[a]	96.4 ± 8.6[a]	8.0 ± 2.1[a]

The only significant ($p < 0.05$) difference in root dry mass was found between plants grown in the soil from the canopy middle and uncanopied subhabitat of the rocky site (Table 3).

Table 3 Soil effect on leaf dry mass, shoot dry mass, root length and root dry mass (mean ± SE) as per subhabitat (n=10). The same letter for each subhabitat represents statistical non-significance ($p > 0.05$).

Subhabitat	Site	Leaf dry mass (g)	Shoot dry mass (g)	Root length (mm)	Root dry mass (mm)	Total dry mass (mm)
Stem	Sandy	15.6 ± 1.8[a]	9.9 ± 1.9[a]	486.8 ± 18.3[a]	9.6 ± 1.4[a]	35.1±5.04[a]
	Rocky	13.0 ± 1.6[a]	7.8 ± 1.6[a]	454.4 ± 32.9[a]	8.3 ± 1.0[a]	29.2±3.9[a]
Canopy middle	Sandy	14.4 ± 1.2[a]	7.9 ± 0.7[a]	480.0 ± 26.3[a]	8.7 ± 0.9[a]	31.0±2.8[a]

Uncanopied	Sandy	6.8 ± 0.6[a]	2.9 ± 0.5[a]	484.0 ± 37.1[a]	7.2 ± 0.6[a]	16.9±1.5[a]
	Rocky	6.3 ± 0.3[a]	2.3 ± 0.2[a]	417.1 ± 25.0[a]	5.9 ± 0.4[a]	14.5±0.8[a]

Conclusions

This study demonstrated the importance of *T. camphoratus* in soil enrichment and confirms the well documented development of "nutrient hotspots" under woody plant canopies. The delayed germination of ripe seed of T. *camphoratus* confirmed the existence of a dormancy period of three to four months. This is possibly an adaptation to prevent the seeds from germinating too early in the rainy season when the risk of desiccation is high.

No allelopathic effects that limit seed germination and the survival of *T. camphoratus* were observed in the soil collected from underneath their canopies. While above-ground seedling growth was generally higher in the soil from close to the stem compared to those in soil from the middle of the canopy, the differences between the two canopied subhabitats were statistically non-significant ($p > 0.05$). In contrast to the above-ground growth parameters, no statistically significant ($p < 0.05$) difference could be established between the root dry masses of seedlings grown in the soil of all three subhabitats.

Higher nutrient availability under the shrub canopy compared to the uncanopied zone is considered to be the primary cause for the observed increased above-ground growth of the *T. camphoratus* seedlings that were grown in the soil from the two canopy subhabitats. No statistically significant ($p < 0.05$) differences in any of the measured growth parameters could be identified between soil originating from the sandy or the rocky sites, clearly demonstrating the importance of *T. camphoratus* as a biological agent that is able to create islands of enhanced soil nutrients (soil enrichment), regardless of soil type. From this, it can be concluded that subhabitat differentiation has more definite effects on seedling growth than differences related to soil type. This has important implications for tree thinning operations as areas where mature trees are removed, will present ideal areas for seedling establishment, survival and growth.

Exterminating Bohemian knotweed (*Reynoutria* × *bohemica*) propagules using thermal treatment

Soames, A[1]; Gardner, W[2]

[1] Master of Environmental Science Student at Thompson Rivers University, Kamloops, BC, Canada; [2] Professor at Thompson Rivers University, Kamloops, BC, Canada

Key words: knotweed; reynoutria; fallopia; polygonum; invasive

Abstract

Invasive knotweeds in North America, including Japanese knotweed (*Reynoutria japonica*), Giant knotweed (*Reynoutria sachalinensis*), and Bohemian knotweed (*Reynoutria* × *bohemica*), cause significant environmental, structural, and economic damage worldwide. These impacts have placed knotweeds among just 37 plants on the International Union for the Conservation of Nature's list of the 100 worst invasive species. Despite their profound effects, most research has focused on specific treatment methods rather than exploring the plants' physiological vulnerabilities. Our study seeks to address this gap by investigating the thermal limitations of *Reynoutria* species. Specifically, we aim to identify the temperatures and exposure durations needed to achieve 100% mortality in knotweed rhizomes and seeds. Preliminary results show that temperatures of 150°C or higher can result in complete seed mortality within 60 minutes. These findings can inform various treatment methods, including incineration, composting, microwave radiation, thermal desorption, and other novel thermal approaches.

Introduction

Knotweeds, including Japanese knotweed (*Reynoutria japonica*), Giant knotweed (*Reynoutria sachalinensis*), and their hybrid, Bohemian knotweed (*Reynoutria* × *bohemica*), have caused significant economic and ecological damage worldwide. Lowe et al. (2000) identified Japanese knotweed as one of the world's 100 "worst" invasive species on a list encompassing plants, animals, fungi, and microbes.

These challenges underscore the need for effective prevention and management strategies for invasive knotweeds. Conventional methods, such as herbicide application and mechanical treatments, have shown limited success, with only herbicide treatments consistently achieving results (Hocking et al. 2023). However, even herbicide treatments require multiple applications over several years to ensure eradication. In construction projects where knotweeds are prevalent, excavation is often necessary to prevent long-term damage to foundations or paving. Disposal of excavated material remains a challenge; while deep burial is commonly used (McHugh 2006), it is not a reliable long-term solution since knotweed propagules can remain dormant in soil for up to 20 years (Parkinson and Mangold 2010).

Excavating contaminated soils presents an opportunity to apply off-site treatments. This study aims to establish a foundational understanding of the effectiveness of heat treatments on knotweed propagules. Specifically, the objective is to determine the temperature and duration combinations required to achieve complete mortality of Bohemian knotweed seeds and rhizomes. Bohemian knotweed, the most prolific and widely distributed of the three species (Grimsby and Kesseli 2010; Gaskin et al. 2014), is the focus of this study. Rhizomes, which account for most of the plant's establishment potential (Gowton et al. 2016), are a primary concern, but seeds are also included due to their emerging role in natural establishment, driven by the substantial seed production observed annually (Beerling et al. 1994; Bram and McNair 2004).

Methods

Bohemian knotweed rhizomes and seeds were collected on October 23, 2023, from a site near the municipal library in Mission, BC, Canada. Rhizomes were excavated and cut to 10 cm lengths before being sealed in plastic bags placed in a cooler for transport. Seeds were collected by severing dead seed heads, which were then stored in brown paper bags and later cold stratified.

Rhizomes were culled to exclude any that were obviously dead or excessively damaged. Samples lighter than 10 g were also removed. An average weight was calculated for the remaining rhizomes, and those that varied by the greatest degree were removed. To further limit the effect of third variables on treatment efficacy and analysis, samples were separated into four weight classes. Samples were then block randomized by weight class to assign treatment using formulas in Microsoft excel. Each treatment contained an even number from each weight class to ensure a weight distribution reflecting that of the overall population in each treatment.

Rhizomes were treated at three different temperatures for three different time periods. Temperatures of 100, 125 and 150°C over periods of 10, 20 and 60 minutes were used for this trial. Each treatment had nine replicates of four rhizomes for a total of 36 rhizomes per treatment. Each replicate of four rhizomes was fed through the oven separately in all cases. After treatment, rhizomes were planted in well-draining 4" pots with 600 ml of a 1:1 mixture of potting soil and sand. Rhizomes were left to grow for a period of 30 days and observed for signs of growth. As a control 36 untreated rhizomes were also planted before treatment (initial viability). After 30 days of growth, each rhizome was excavated and observed for growth. Presence of root or shoot material was determined as confirmation of survival. An ANOVA and Tukey test were conducted using R software, which looked to determine statistical significance of treatment as it related to mortality when compared to untreated samples.

Seed trials were similar to those of the rhizomes, but used time increments of 10, 20, 30, 40, 50, and 60 minutes, as more samples were available. Assignment of treatment was fully random, and seeds were placed in 15 mL centrifuge tubes filled with 10 mL of water, where they were allowed to grow over 30 days. Presence of a radicle was used as an indication of viability.

Results

Rhizomes had high initial viability at 97%. Viability by treatment can be seen in Fig. 1. Increases in treatment period and temperature resulted in a decrease in viability, with zero viability observed after 60 minutes at all temperature treatments, and at 20 minutes when treated at 150 degrees. All treatments, except treatment at 100 degrees Celsius for 10 minutes, had a significant effect when compared to controls.

Initial seed viability was 78%. Seed viability by treatment can be visualized in Fig. 2. Viability dropped with intensity of treatment, but there were some anomalous results – namely the 11.11% viability seen in treatments of 125 degrees Celsius for 60 minutes. There is also an unexpected 2.78% viability for samples treated at 125 degrees Celsius for 40 minutes. All treatments at 150 degrees Celsius resulted in seed mortality.

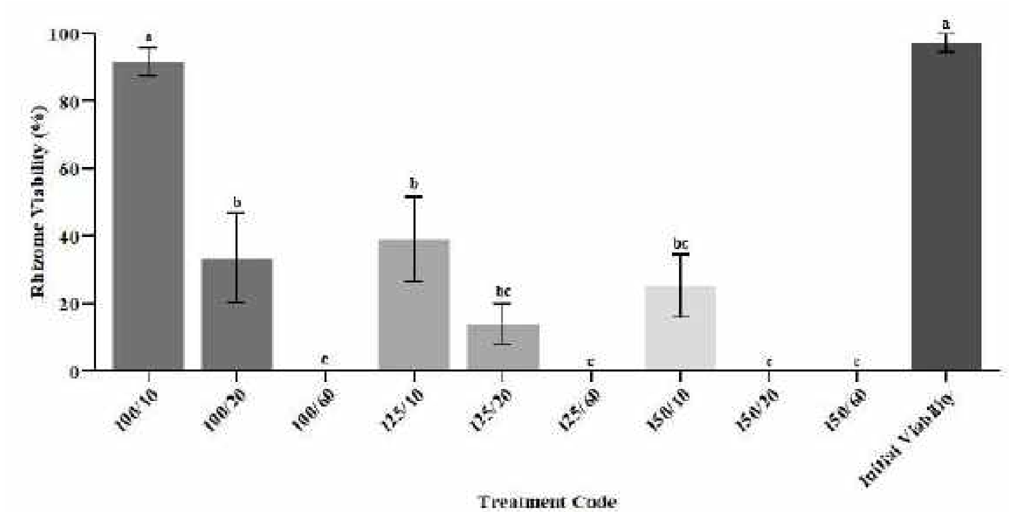

Fig.1: Viability of bohemian knotweed rhizomes based on thermal treatment with correlations. Treatment codes indicate temperature(°C)/time(minutes) except in case of Initial Viability (control), where no treatment took place. Columns are shaded based on temperature of treatment.

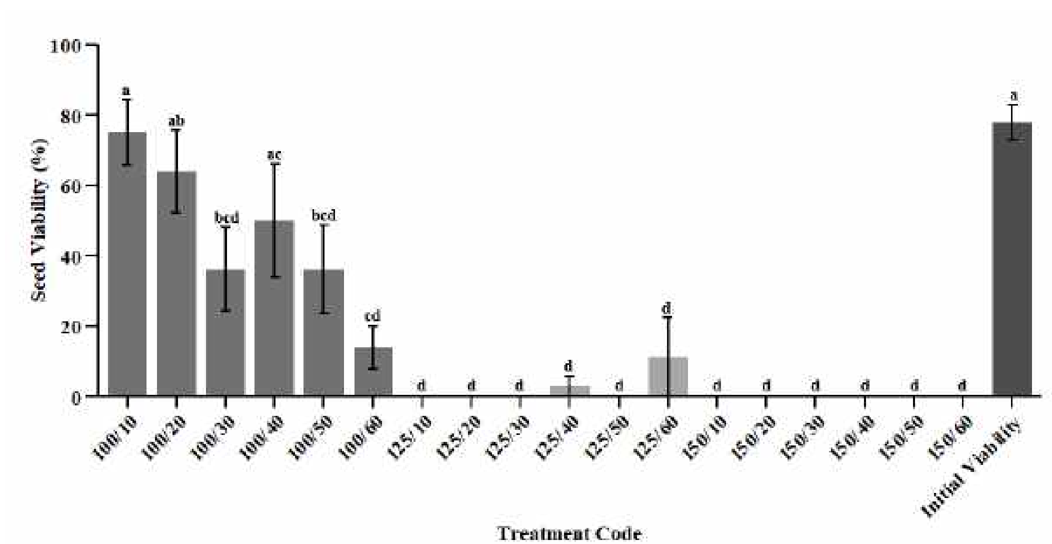

Fig.2: Viability of bohemian knotweed rhizomes based on thermal treatment with correlations. Treatment codes indicate temperature(°C)/time(minutes) except in case of Initial Viability (control), where no treatment took place. Columns are shaded based on temperature of treatment.

Discussion

Rhizome mortality under heat treatment exhibited a clear pattern of reduced viability with increasing temperature and application duration, suggesting that knotweed rhizome viability can be significantly diminished with relatively low energy input.

In contrast, results for seed viability under thermal treatment were less consistent. The expected decline in viability with increasing treatment intensity was not observed, with an unusual spike in viability at 125°C for 40 minutes. This anomaly is likely due to human or technical error, as all four surviving seeds came from the same experimental replicate, which showed 100% survival. Additionally, the inconsistency may stem from the lack of measures to ensure uniformity in the seed sample population, a step that was taken with rhizomes. Future trials could benefit from improved sample uniformity and increased sample sizes. Despite these challenges, initial seed viability fell within the 55–100% range reported in the literature (Forman and Kesseli 2003; Bram and McNair 2004), validating the novel viability assessment methodology used in this study, which also proved more cost-effective than conventional methods.

This research provides an initial understanding of the effects of thermal treatment on knotweed propagules but was limited by sampling location. Bohemian knotweed's high genetic diversity (Gaskin et al. 2014) suggests that the efficacy of thermal treatment may vary with location and seasonal factors. Additionally, knotweed propagules are often mixed with soil in practical applications, highlighting the need to study the impact of soil composition and moisture on treatment efficacy. Large rhizome and stem fragments could also limit treatment effectiveness.

Despite these limitations, results suggest that temperatures as low as 150°C, applied for as little as 60 minutes, can ensure the mortality of both seed and rhizome propagules. Although in-situ treatments using fire have been ineffective for killing vegetative propagules due to the plant's high water content (Child and Wade 2000), externally generated heat through incineration, composting, microwave radiation, or emerging technologies like thermal desorption may offer viable alternatives.

Passive vs active restoration to improve soil health of old potato production circles in the Leipoldtville Sand Fynbos, South Africa

Swanepoel, A[1]; Saayman, N[1]; Swart, R[2]; Rheeder, C[3]

[1] Western Cape Department of Agriculture, Elsenburg, South Africa, Annelene.Swanepoel@westerncape.gov.za; [2] Western Cape Department of Agriculture, Worcester, South Africa; [3] Western Cape Department of Agriculture, Lambert's Bay, South Africa

Key words: brush packing; soil phosphorous; soil organic carbon; indigenous plants

Abstract

Potato production is the main land use in the endangered Leipoldtville Sand Fynbos vegetation type on the west coast of South Africa. Many fields have been abandoned and their restoration is important to conserve this vegetation type. These abandoned fields are subject to wind erosion and have high soil phosphorous levels due to fertilisation. We addressed the question "Does active restoration enhance soil health faster than natural processes?" We selected three sites, all in sandy soils with high soil phosphorous levels (35–63 mg/kg) compared to the surrounding natural vegetation (7–11 mg/kg). Cultivation had ended 5–7 years previously and sites were in different states of recovery. Seven treatments were applied, including planting of indigenous species, an initial rye mix consisting of cereal rye, lupins and serradella, and brush packing using branches from invasive trees packed in a single layer at a density of 50–80% soil cover, in various combinations, as well as a control. Soil samples were collected to determine changes in phosphorous levels using citric acid analysis, organic carbon using the Walkley-Black method, and microbial diversity using Biolog EcoPlates. Due to drought from 2017–2020 the initial rye mix established poorly and had little impact on the soil-P levels. Phosphorous levels decreased over time at two of the sites but increased significantly at Site 3, adjacent to active croplands. Organic carbon increased over time at Site 2 and Site 3. At Site 1, with the least natural plant cover, organic carbon only increased in the treatments that included brush packing. At all sites there was a significant increase in soil microbial diversity, but at Site 1 it was better in treatments with brush packing.

There was an improvement in overall soil health over time. Abandoned fields with the least natural cover benefited most from restoration actions.

Introduction

The Fynbos biome is recognized as one of the global hotspots of diversity. It ranks among the world's 25 most threatened biodiversity hotspots (Mittermeier et al. 2011). Vast expanses of this once-pristine habitat have succumbed to permanent agriculture, with crops, potatoes, and rooibos tea plantations replacing natural vegetation. The biome's transformation is further exacerbated by inappropriate fire management practices, livestock grazing, invasion by alien plant species, and overexploitation of natural resources (Mucina and Rutherford 2006).

Leipoldtville Sand Fynbos is an arid, endangered ecosystem with a mediterranean climate and acidic, sandy soils (Mucina and Rutherford 2006). Less than 45% of its natural vegetation remains, the rest is cultivated lands of which 27% is under pivot irrigation and used for potato production. As input costs rise and soil diseases proliferate, many of the fields are being abandoned and left to recover through natural succession, which is a very slow process in drylands. The abandoned fields are prone to wind erosion and years of fertilisation has led to high soil phosphorous levels compared to the surrounding natural vegetation. These high phosphorous levels inhibit the establishment of Fynbos species (Hawkins et al. 2010), since Fynbos soils are acidic and nutrient-poor, especially in terms of nitrogen and phosphorous levels (Richards et al. 1997). Therefore, some form of active restoration is necessary to ameliorate the soil condition, reduce wind erosion, and initiate the establishment of natural vegetation. We addressed the question "Does active restoration enhance soil health faster than natural processes?"

Methods

The study was done at three sites in the Leipoldtville Sand Fynbos on the west coast of South Africa. This winter rainfall area receives an average annual rainfall of 263 mm. All sites are characterized by deep sandy soils with high phosphorous levels (29–62 mg/kg) and low organic carbon levels (0.07–0.20%) compared to soil phosphorous levels in the adjacent natural vegetation that are below 10 mg/kg. Cultivation ended 5–7 years previously and sites were in different states of recovery.

The same experimental design and layout were implemented at all three sites, following a randomised block design with four replicates and seven treatments, which consisted of a control and a mix of the following treatments:

1) To combat the high phosphorous levels an initial rye mix (R), consisting of cereal rye, lupins and serradella, was planted in 2017 and 2018. Minimum soil disturbance was done with a tine implement to prepare the soil, and after sowing, the soil was rolled to ensure good seed-soil contact. Due to a drought in 2017 the planting was repeated in 2018. The plants were cut down and removed before seed set to remove the phosphates from the trial.

2) To combat wind erosion, brush packing (B) was done with branches from local invasive trees in 2020, which also provided organic matter. The branches were packed in a single layer at a density of 50–80% soil cover. Wind speed reached 11 m/s at Redelinghuys and Eland's Bay sites, where signs of wind erosion was the most visible.

3) Lastly cuttings (P) from three species indigenous to the area were made and planted in the plots to increase the species diversity on the trial.

Composite soil samples were collected at the start (June 2017) and end (October 2023) of the study to determine changes in phosphorous levels using citric acid analysis, changes in organic carbon using the Walkley-Black method (The Non-affiliated Soil Analysis Work Committee 1990), and changes in microbial diversity using Biolog EcoPlates (Lee et al. 2020).

Data was analysed using ANOVA, Fischer's Least Significant Difference test and Principal Component Analysis.

Results

The study area experienced a drought from 2017 until 2020. This resulted in the poor establishment of the initial rye mix and it had no significant impact on the soil phosphorous levels (plant-available phosphorous). However, the phosphorous levels decreased significantly over time at two of the sites ($p < 0.01$) but increased significantly at Eland's Bay ($p = 0.0056$) (Fig. 1a). There were no significant differences between the treatments for each site over time.

The soil organic carbon (SOC) increased significantly over time at the Eland's Bay and Sandberg sites ($p < 0.001$) (Fig. 1b), with no significant difference between the treatments at both sites. At Redelinghuys, with the least natural vegetation cover on the abandoned land and the worst establishment of planted cuttings, the organic carbon only increased significantly (LSD = 0.0702) in the Brush packing treatment (Fig. 1b).

At all three sites there was a significant increase over time in soil microbial diversity ($p < 0.001$), as seen on the first axis of the PCA, indicating an improvement in the overall soil health (Fig. 2).

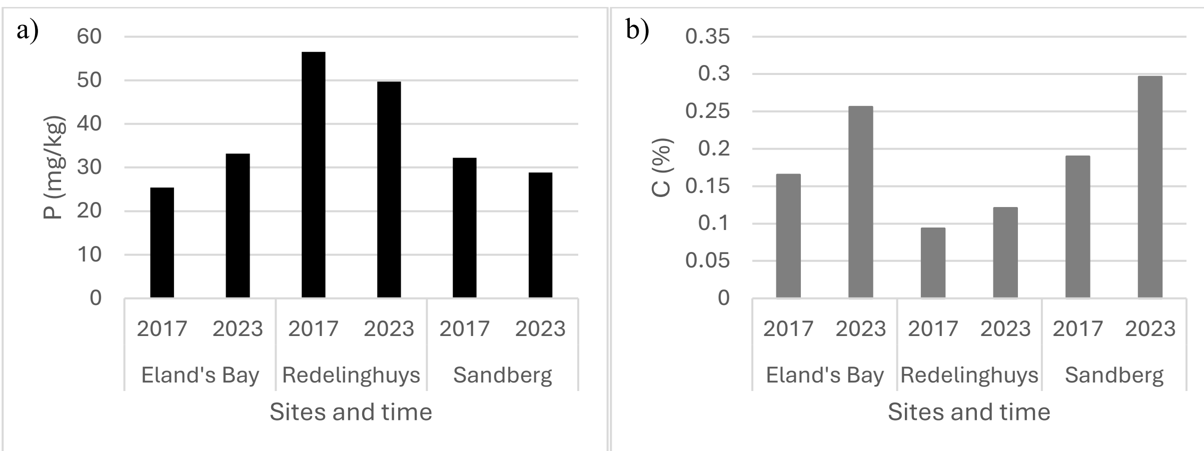

Fig. 1 Soil phosphorous levels (a) and organic carbon content (b) in 2017 and 2023 at Eland's Bay, Redelinghuys and Sandberg sites, South Africa.

Discussion

Hawkins et al. (2010) found that a cover crop mix of oats and lupins decreased the soil-P levels by 10–30% because of their fast growing rate. In the case of this study, the below average rainfall received in 2017 and 2018 resulted in no germination of the initial rye mix sown in 2017, and a poor growth rate of those plants that did establish in 2018. Therefore, the expected outcome was not achieved. According to Prasad and Chakraborty (2019), soil phosphorous is mostly lost through erosion and not leaching from the soil. At Sandberg soil-P was most probably removed from the soil by the plants established in each of the plots, as it had the best plant cover of all the study sites and no visible signs of wind erosion, with the maximum wind speed less than 9 $m.s^{-1}$. The wind at Redelinghuys and Eland's Bay sites reached a speed of up to 11 $m.s^{-1}$. At Redelinghuys, with visible signs of wind erosion, and the least plant cover, soil-P was lowered over time because of the wind erosion. At the Eland's Bay site, part of the trial area was covered by soil from an adjacent, actively used cropland caused by wind erosion.

This is most probably the reason for the increased soil-P over time. The other study sites did not have any active croplands in the surrounding area.

More plants established at Eland's Bay and Sandberg sites lead to an increase in the SOC in all the treatments over time supporting similar results reported by Qiu et al. (2018). At Redelinghuys the provisioning of branches on the soil assisted in the establishment of plants and an increase in SOC. The increase in SOC can lead to improved soil water retention and in dry areas, such as Leipoldtville Sand Fynbos, can result in improved vegetation growth (Li et al. 2024). This is likely to be beneficial during dry periods as the availability of soil water is a limiting factor in arid ecosystems (Qiu et al. 2018).

The improvement in the soil microbial diversity at all sites indicated an improvement in the soil health. Soil microbes are responsible for the decomposition of organic matter, nutrient transformation, plant health maintenance and the degradation of toxic compounds in the soil amongst others (Lee et al. 2020). This provides ecosystem services essential for humans, such as food production, climate regulation, and the provision of clean water (Adhikari & Hartemink 2016; Pulleman et al. 2012).

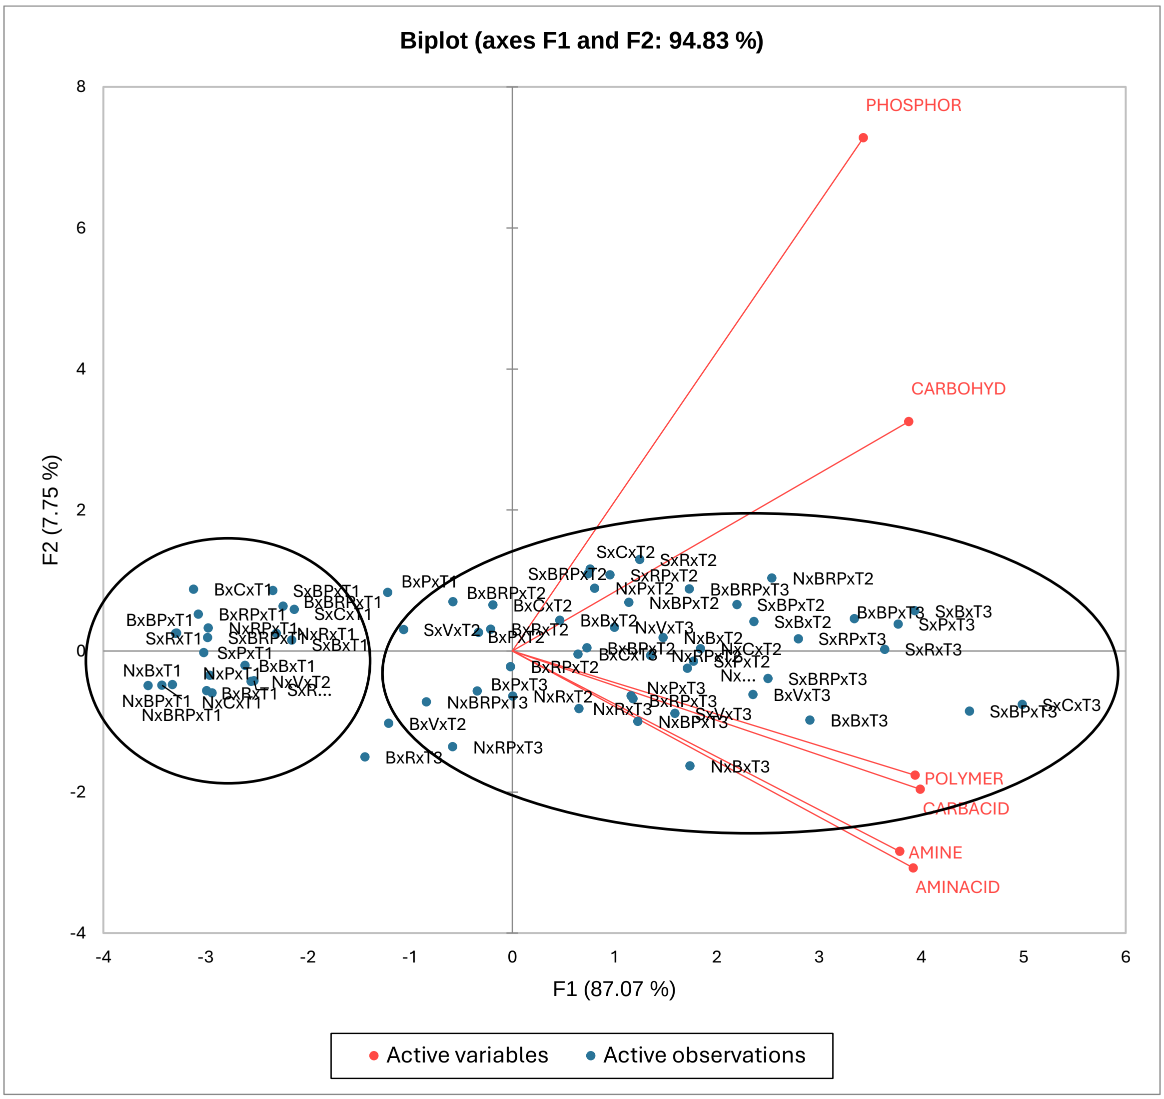

Fig. 2 Principal component analysis (PCA) of soil microbial diversity in 2017 (T1), 2021 (T2) and 2023 (T3) in the different treatments at Redelinghuys (B), Eland's Bay (N) and Sandberg (S). C = control; B = brush-packing; R = initial rye mix; P = planting indigenous species.

Conclusion/Implications

There was an improvement in overall soil health over time. Abandoned fields, such as the Redelinghuys site with the least natural cover benefited the most from the restoration actions.

Passive vs active restoration to improve soil health of old potato production circles in the Leipoldtville Sand Fynbos, South Africa

Swanepoel, A[1]; Saayman, N[1]; Swart, R[2]; Rheeder, C[3]

[1] Western Cape Department of Agriculture, Elsenburg, South Africa, Annelene.Swanepoel@westerncape.gov.za; [2] Western Cape Department of Agriculture, Worcester, South Africa; [3] Western Cape Department of Agriculture, Lambert's Bay, South Africa

Key words: brush packing; soil phosphorous; soil organic carbon; indigenous plants

Abstract

Potato production is the main land use in the endangered Leipoldtville Sand Fynbos vegetation type on the west coast of South Africa. Many fields have been abandoned and their restoration is important to conserve this vegetation type. These abandoned fields are subject to wind erosion and have high soil phosphorous levels due to fertilisation. We addressed the question "Does active restoration enhance soil health faster than natural processes?" We selected three sites, all in sandy soils with high soil phosphorous levels (35–63 mg/kg) compared to the surrounding natural vegetation (7–11 mg/kg). Cultivation had ended 5–7 years previously and sites were in different states of recovery. Seven treatments were applied, including planting of indigenous species, an initial rye mix consisting of cereal rye, lupins and serradella, and brush packing using branches from invasive trees packed in a single layer at a density of 50–80% soil cover, in various combinations, as well as a control. Soil samples were collected to determine changes in phosphorous levels using citric acid analysis, organic carbon using the Walkley-Black method, and microbial diversity using Biolog EcoPlates. Due to drought from 2017–2020 the initial rye mix established poorly and had little impact on the soil-P levels. Phosphorous levels decreased over time at two of the sites but increased significantly at Site 3, adjacent to active croplands. Organic carbon increased over time at Site 2 and Site 3. At Site 1, with the least natural plant cover, organic carbon only increased in the treatments that included brush packing. At all sites there was a significant increase in soil microbial diversity, but at Site 1 it was better in treatments with brush packing.

There was an improvement in overall soil health over time. Abandoned fields with the least natural cover benefited most from restoration actions.

Introduction

The Fynbos biome is recognized as one of the global hotspots of diversity. It ranks among the world's 25 most threatened biodiversity hotspots (Mittermeier et al. 2011). Vast expanses of this once-pristine habitat have succumbed to permanent agriculture, with crops, potatoes, and rooibos tea plantations replacing natural vegetation. The biome's transformation is further exacerbated by inappropriate fire management practices, livestock grazing, invasion by alien plant species, and overexploitation of natural resources (Mucina and Rutherford 2006).

Leipoldtville Sand Fynbos is an arid, endangered ecosystem with a mediterranean climate and acidic, sandy soils (Mucina and Rutherford 2006). Less than 45% of its natural vegetation remains, the rest is cultivated lands of which 27% is under pivot irrigation and used for potato production. As input costs rise and soil diseases proliferate, many of the fields are being abandoned and left to recover through natural succession, which is a very slow process in drylands. The abandoned fields are prone to wind erosion and years of fertilisation has led to high soil phosphorous levels compared to the surrounding natural vegetation. These high phosphorous levels inhibit the establishment of Fynbos species (Hawkins et al. 2010), since Fynbos soils are acidic and nutrient-poor, especially in terms of nitrogen and phosphorous levels (Richards et al. 1997). Therefore, some form of active restoration is necessary to ameliorate the soil condition, reduce wind erosion, and initiate the establishment of natural vegetation.

We addressed the question "Does active restoration enhance soil health faster than natural processes?"

Methods

The study was done at three sites in the Leipoldtville Sand Fynbos on the west coast of South Africa. This winter rainfall area receives an average annual rainfall of 263 mm. All sites are characterized by deep sandy soils with high phosphorous levels (29–62 mg/kg) and low organic carbon levels (0.07–0.20%) compared to soil phosphorous levels in the adjacent natural vegetation that are below 10 mg/kg. Cultivation ended 5–7 years previously and sites were in different states of recovery.

The same experimental design and layout were implemented at all three sites, following a randomised block design with four replicates and seven treatments, which consisted of a control and a mix of the following treatments:

1) To combat the high phosphorous levels an initial rye mix (R), consisting of cereal rye, lupins and serradella, was planted in 2017 and 2018. Minimum soil disturbance was done with a tine implement to prepare the soil, and after sowing, the soil was rolled to ensure good seed-soil contact. Due to a drought in 2017 the planting was repeated in 2018. The plants were cut down and removed before seed set to remove the phosphates from the trial.

2) To combat wind erosion, brush packing (B) was done with branches from local invasive trees in 2020, which also provided organic matter. The branches were packed in a single layer at a density of 50–80% soil cover. Wind speed reached 11 m/s at Redelinghuys and Eland's Bay sites, where signs of wind erosion was the most visible.

3) Lastly cuttings (P) from three species indigenous to the area were made and planted in the plots to increase the species diversity on the trial.

Composite soil samples were collected at the start (June 2017) and end (October 2023) of the study to determine changes in phosphorous levels using citric acid analysis, changes in organic carbon using the Walkley-Black method (The Non-affiliated Soil Analysis Work Committee 1990), and changes in microbial diversity using Biolog EcoPlates (Lee et al. 2020).

Data was analysed using ANOVA, Fischer's Least Significant Difference test and Principal Component Analysis.

Results

The study area experienced a drought from 2017 until 2020. This resulted in the poor establishment of the initial rye mix and it had no significant impact on the soil phosphorous levels (plant-available phosphorous). However, the phosphorous levels decreased significantly over time at two of the sites ($p < 0.01$) but increased significantly at Eland's Bay ($p = 0.0056$) (Fig. 1a). There were no significant differences between the treatments for each site over time.

The soil organic carbon (SOC) increased significantly over time at the Eland's Bay and Sandberg sites ($p < 0.001$) (Fig. 1b), with no significant difference between the treatments at both sites. At Redelinghuys, with the least natural vegetation cover on the abandoned land and the worst establishment of planted cuttings, the organic carbon only increased significantly (LSD = 0.0702) in the Brush packing treatment (Fig. 1b).

At all three sites there was a significant increase over time in soil microbial diversity ($p < 0.001$), as seen on the first axis of the PCA, indicating an improvement in the overall soil health (Fig. 2).

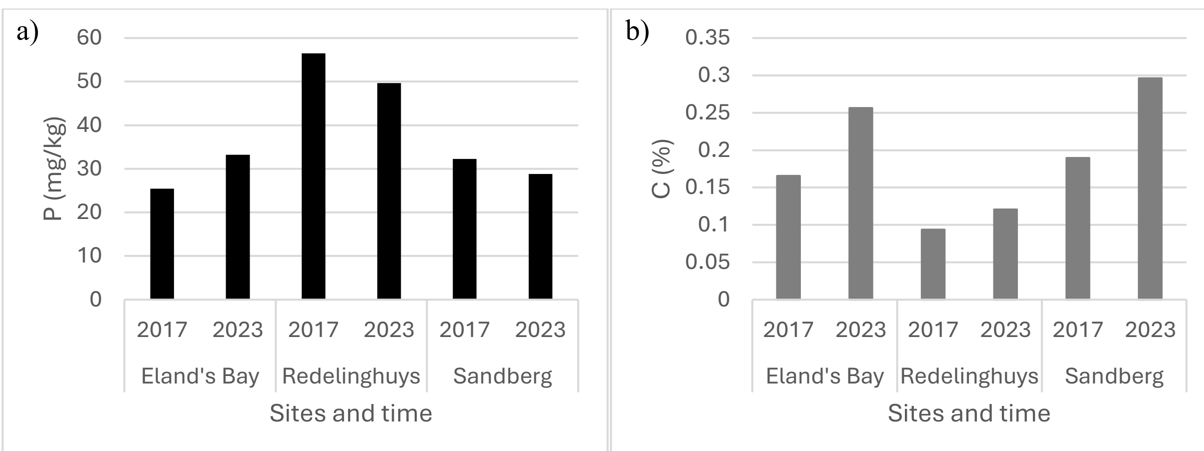

Fig. 1 Soil phosphorous levels (a) and organic carbon content (b) in 2017 and 2023 at Eland's Bay, Redelinghuys and Sandberg sites, South Africa.

Discussion

Hawkins et al. (2010) found that a cover crop mix of oats and lupins decreased the soil-P levels by 10–30% because of their fast growing rate. In the case of this study, the below average rainfall received in 2017 and 2018 resulted in no germination of the initial rye mix sown in 2017, and a poor growth rate of those plants that did establish in 2018. Therefore, the expected outcome was not achieved. According to Prasad and Chakraborty (2019), soil phosphorous is mostly lost through erosion and not leaching from the soil. At Sandberg soil-P was most probably removed from the soil by the plants established in each of the plots, as it had the best plant cover of all the study sites and no visible signs of wind erosion, with the maximum wind speed less than 9 $m.s^{-1}$. The wind at Redelinghuys and Eland's Bay sites reached a speed of up to 11 $m.s^{-1}$. At Redelinghuys, with visible signs of wind erosion, and the least plant cover, soil-P was lowered over time because of the wind erosion. At the Eland's Bay site, part of the trial area was covered by soil from an adjacent, actively used cropland caused by wind erosion. This is most probably the reason for the increased soil-P over time. The other study sites did not have any active croplands in the surrounding area.

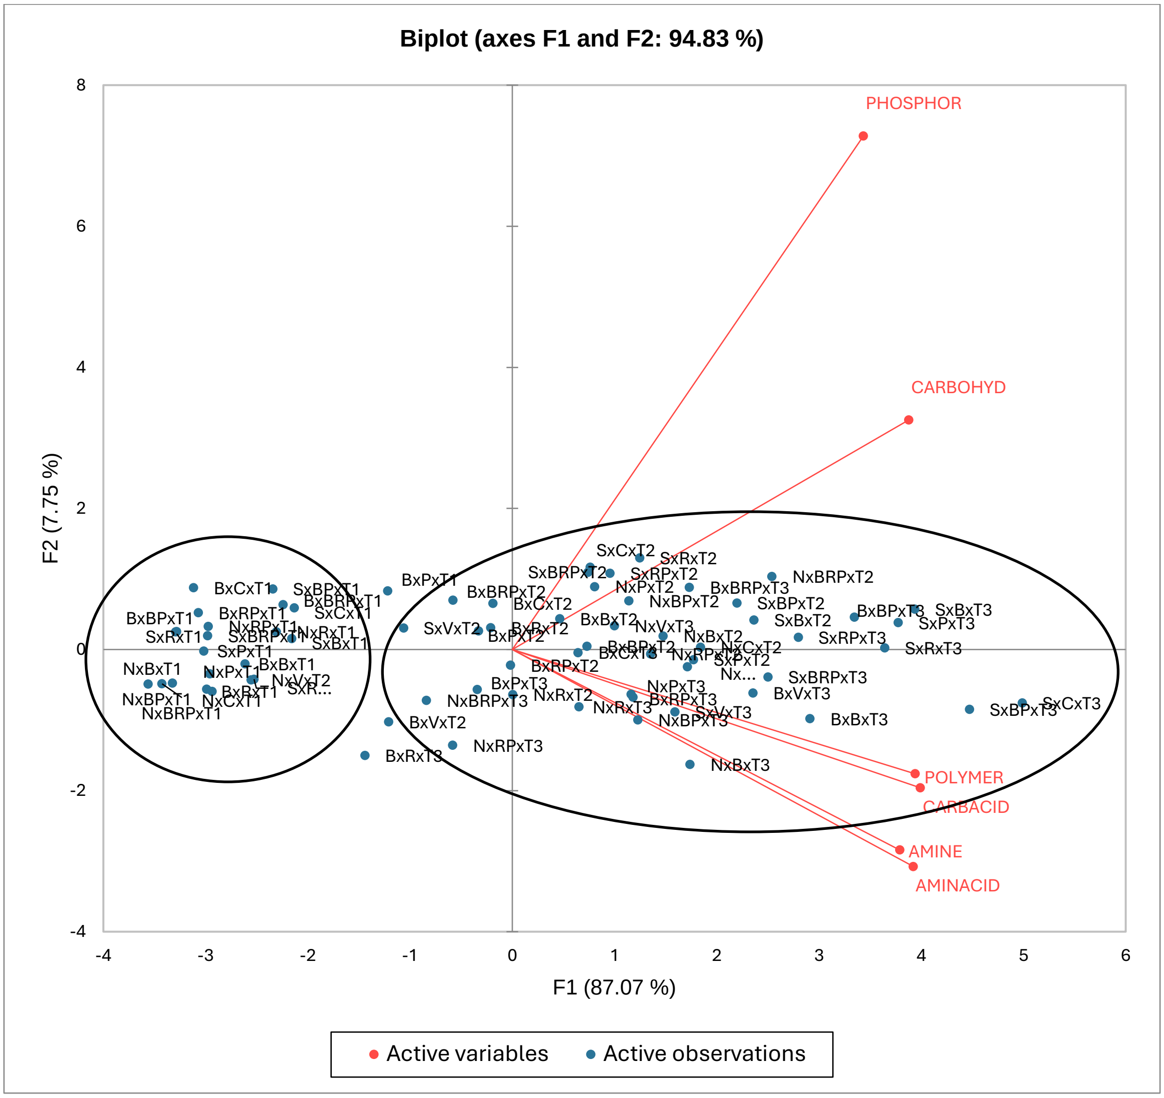

Fig. 2 Principal component analysis (PCA) of soil microbial diversity in 2017 (T1), 2021 (T2) and 2023 (T3) in the different treatments at Redelinghuys (B), Eland's Bay (N) and Sandberg (S). C = control; B = brush-packing; R = initial rye mix; P = planting indigenous species.

More plants established at Eland's Bay and Sandberg sites lead to an increase in the SOC in all the treatments over time supporting similar results reported by Qiu et al. (2018). At Redelinghuys the provisioning of branches on the soil assisted in the establishment of plants and an increase in SOC. The increase in SOC can lead to improved soil water retention and in dry areas, such as Leipoldtville Sand Fynbos, can result in improved vegetation growth (Li et al. 2024). This is likely to be beneficial during dry periods as the availability of soil water is a limiting factor in arid ecosystems (Qiu et al. 2018).

The improvement in the soil microbial diversity at all sites indicated an improvement in the soil health. Soil microbes are responsible for the decomposition of organic matter, nutrient transformation, plant health maintenance and the degradation of toxic compounds in the soil amongst others (Lee et al. 2020). This provides ecosystem services essential for humans, such as food production, climate regulation, and the provision of clean water (Adhikari & Hartemink 2016; Pulleman et al. 2012).

Conclusion/Implications

There was an improvement in overall soil health over time. Abandoned fields, such as the Redelinghuys site with the least natural cover benefited the most from the restoration actions.

Moderating soil surface temperature via restoration hollows and its implication for restoration strategies in arid rangelands

Swart, R[1]; Saayman S[2]; Milton SJ[3]

[1] Western Cape Department of Agriculture, Worcester, South Africa, rudi.swart@westerncape.gov.za; [2] Western Cape Department of Agriculture, Elsenburg, South Africa; [3] Renu-Karoo Veld Restoration, Prince Albert, South Africa

Key words: rangeland restoration; soil temperature; micro-climate

Abstract
Arid regions worldwide, including the drier areas of the Western Cape of South Africa, often suffer from rangeland degradation resulting from poor management, mining activities or other anthropogenic sources of disturbance. Without active restoration intervention, these areas may take a considerable amount of time to recover. Digging hollows as a form of active restoration has been successfully applied to restore vegetation to denuded areas in arid regions around the world. However, the effect of these hollows on soil surface temperature has yet to be determined.

To determine the role of restoration hollows in providing suitable micro-climates for plant growth, soil surface temperature measurements were compared between bare ground and hollows during both summer and winter at three sites in the arid region of the Western Cape. Soil temperatures within the hollows were lower than that of bare ground during the warmest part of the day, and higher than bare ground during the coolest part of the day. Hollows have a moderating effect on soil surface temperature, which creates a more suitable micro-climate for seed germination. Restoration hollows may offer a cost-effective alternative to other restoration methods, such as brush packing and tilling. This research contributes to the broader understanding of land restoration strategies in arid environments, potentially reducing restoration costs and improving ecosystem resilience in the face of environmental challenges, including climate change.

Introduction
Much of the arid rangelands of the world is degraded and denuded of vegetation, often due to disturbances such as overgrazing and mining activities, amongst others (Carrick 2022). Rangelands cover over 70% of the land surface of South Africa and most of these are degraded to some extent (Carrick 2022). Degraded rangelands have reduced plant productivity and are prone to soil erosion (Snyman 2003).

Restoration of degraded rangelands improves productivity by re-establishing plant cover to denuded areas and improves their capacity support grazing animals (Snyman 1999). Restoration can be expensive, time consuming, labour intensive and often prone to failure due to adverse weather conditions or inadequate rainfall (Saayman et al. 2017). Brush packing, digging soil hollows, and other forms of soil treatments have been promoted by many restoration practitioners to provide suitable seed germination sites (Coetzee 2005; Bothma and Van Rooyen 2006; Carrick et al. 2022). Soil hollows create a more favourable environment for seedling germination and establishment (Milton and Coetzee 2022). Soil hollows can be dug by hand or with the use of a specialized “dyker plough” that operates on a cam wheel and digs hollows at set distances and depths (Snyman, 2003).

The rationale being that these hollows will capture runoff rainwater, organic matter and seeds, and in addition, brush packing within the hollows will provide protection to seedlings (Bothma and Van Rooyen 2006).

There is a significant difference in temperature and in diurnal temperature fluctuations between bare ground, restored vegetation and intact vegetation, with bare ground reaching higher temperatures and temperature fluctuations (Drezner 2007; Hamberg et al. 2020). Snyman (2003) found that the soil temperature on bare ground in the grassland biome could reach temperatures as high as 65 °C. Large temperature fluctuations on bare ground are detrimental to seedling germination (Milton and Dean 1990; Saayman and Botha 2010). Nurse plants provide seeds with protection against severe temperature fluctuations (Esler et al. 2006). Brush packing is typically used in restoration of bare areas to simulate nurse plants (Ren et al. 2008).

The aim of this paper is to determine if the creation of hollows in bare patches may provide a moderating effect to soil temperature which creates a suitable microclimate for seeds to germinate and for seedlings to survive.

Methods

The trial was conducted at three sites in the Western Cape province of South Africa: the Worcester Veld Reserve, the Wolwekraal Nature Reserve at Prince Albert and at the Nortier Research Farm near Lambert’s Bay. All three sites have a Mediterranean climate. The Worcester and Prince Albert sites both have shallow, poorly developed soils with Mispah and Glenrosa soil forms prevailing. These soils are generally shallow and rocky with a high clay content. The soils of Nortier Research Farm consist of fine aeolian (regic) sands of the Namib soil form (Western Cape Department of Agriculture 2024).

January is the warmest month of the year for the Prince Albert site, with an average temperature of 22.2°C, while February is the warmest month for the Worcester and Nortier sites with average temperatures of 22.3°C and 19.7 °C respectively (Western Cape Department of Agriculture 2024). July is the coldest month for all three sites, with average temperatures of 10.8°C, 11°C and 12.9 °C for Prince Albert, Worcester and Nortier respectively (Western Cape Department of Agriculture 2024).

A row-column treatment design with two treatments and 20 replicates was followed at each study site. The two treatments are hollows dug and a control - an area of cleared ground adjacent to each hollow. At each study site the trial consisted of 20 hollows, placed 10 meters apart. The hollows were dug in a grid pattern of 5 columns and 4 rows. Each hollow is one meter in diameter with a concave bottom, 20 cm deep at the centre. The hollows were dug by hand and the removed soil was used to build a berm on the downslope side of the hollow, to retain runoff water (Coetzee 2005).

An Infrared thermometer was used to measure the soil surface temperatures within the centre of each hollow and in the centre of the control. These measurements were made at dawn and at 14:00, on one day during summer and winter. The timing of the measurements was intended to capture the temperature during the coldest and warmest time of day. Measurements were only taken on days with little or no cloud cover or strong wind.

Data were analysed separately by time and were subjected to analysis of variance (ANOVA) using the General Linear Models Procedure (PROC GLM) of SAS software (Version 9.4; SAS Institute Inc, Cary, USA). The Shapiro–Wilk test on the standardized residuals from the model verified normality (Shapiro and Wilk, 1965). Levene's test verified homogeneity of treatment variances (Levene, 1960). Fisher's Least Significant Difference (LSD) was calculated at the 5% significance level to compare interaction means (site*treatments, site*season, treatment*season, site*treatment*season) and main effects, treatment, site and season means (Ott and Longnecker, 2010). Box and whisker plots for temperature for site*treatment*season were constructed using XLSTAT (Addinsoft,2024).

Results

Temperatures within hollows were significantly higher at dawn compared to bare ground in each site (Figure1). Afternoon temperatures were lower within hollows compared to bare ground, though not all were significantly different. The winter afternoon temperatures at the Worcester site were the exception, with temperatures within the hollows being significantly higher than the control (Figure 2). It should be noted that there was a gentle wind present during this part of the data collection. The temperature difference between hollows and bare ground for each site, time and season is displayed in table1.

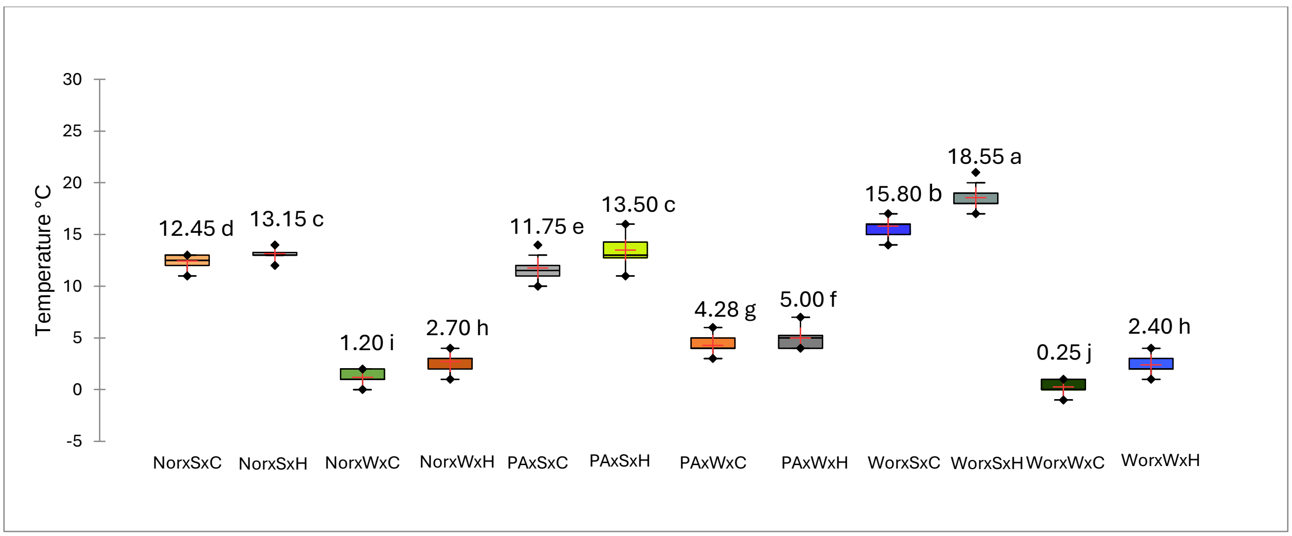

Figure 1. Soil surface temperatures within hollows and controls taken at dawn for three sites during summer and winter. Mean values with significant differences ($p<0.05$) are displayed with a different adjacent letter. Nor = Nortier, PA = Prince Albert, Wor = Worcester, S = Summer, W = Winter, C = Control, H = Hollow.

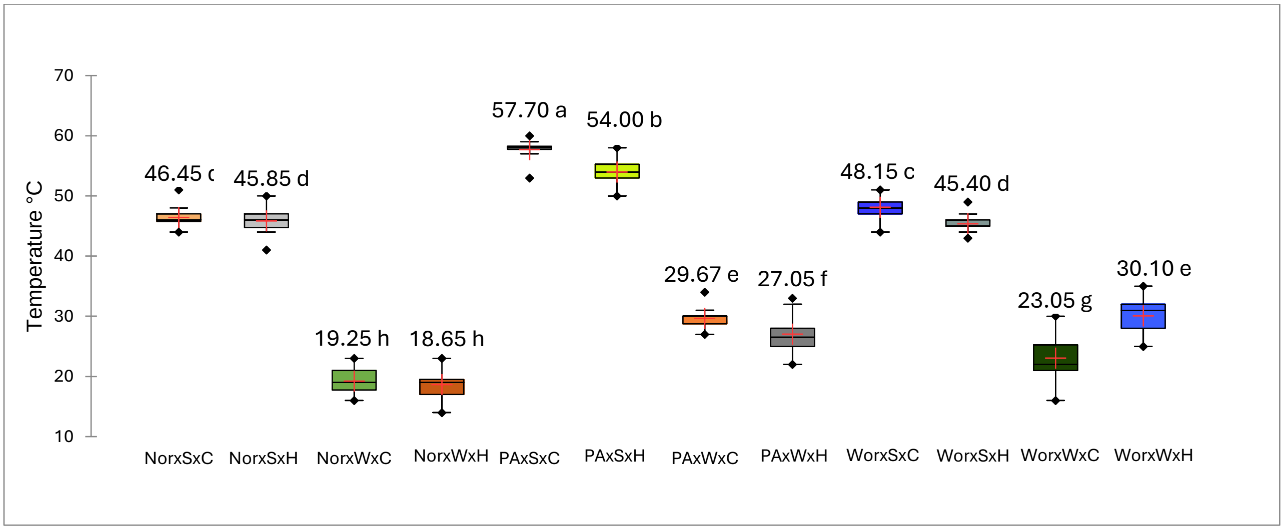

Figure 2. Soil surface temperatures within hollows and controls taken at 14:00 for three sites during summer and winter. Mean values with significant differences ($p<0.05$) are displayed with a different adjacent letter. Nor = Nortier, PA = Prince Albert, Wor = Worcester, S = Summer, W = Winter, C = Control, H = Hollow.

Table1: Effect of hollows on soil surface temperature compared to bare ground in °C. *=significantly different, $p<0.05$; ns= not significantly different.

	Worcester	Prince Albert	Nortier
Summer-Morning	+2,75*	+1,75*	+0,7 ns
Winter-Morning	+2,15*	+0,72 ns	+1,5*
Summer-Afternoon	-2,75*	-3,7*	-0,6 ns
Winter-Afternoon	+7,05*	-2,62*	-0,6 ns

Discussion

The soil surface temperature within the hollows were warmer during the coldest time of day, and cooler during the hottest time of day. This insulating effect protects seeds and seedlings from temperature extremes and contributes to creating the more stable micro-climate that seeds require to germinate and for seedlings to establish (Esler et al. 2006; Milton and Coetzee 2022).

Wind caused rapid soil surface temperature fluctuations, which impeded accurate measurements. These temperature fluctuations were especially evident at the Nortier site, which is adjacent to the coast and is particularly windy. It is likely that some of the temperature measurements taken during even slightly windy conditions, could have been affected by wind-chill (Ashcroft and Gollan 2013). Severe windy conditions may also decrease the efficacy of hollows, a problem that could be addressed by trapping air within the hollows with brush packing. Differences in soil composition and moisture content may also influence soil surface temperature in hollows (Ashcroft and Gollan 2013). Despite these confounding factors, it is clear that soil hollows provide a moderating effect on soil surface temperature.

Conclusions and Implications

Restoration hollows create a more favourable micro-climate for seed germination than bare ground. These hollows offer a simple way to improve the survival rate of seedlings and to allow revegetation of denuded arid rangelands.

Ranch economic aspects of Lesser Prairie Chicken habitat conservation efforts in central USA rangelands

Tanaka, JA[1]; Maczko, KA[2]; Windh, JL[3]

[1-3] Sustainable Rangelands Roundtable, University of Wyoming, Laramie, WY, USA

Key words: ranch economics; lesser prairie chicken; conservation practices

Abstract

The lesser prairie chicken has been listed as a threatened and endangered species by the U.S. Fish and Wildlife Service in distinct population segments. Approximately 95% of the species' habitat is in private land ownership. Conservation efforts focus on these lands, with funding potentially supplied through the Natural Resources Conservation Service (NRCS) Environmental Quality Incentives Program (EQIP). Under EQIP, practice payments are made to landowners to implement planned conservation practices. This project estimates the economic impact of implementing lesser prairie chicken conservation practices on small and large representative ranches in 4 Major Land Resource Areas (MLRA).

Economic models were developed in the General Algebraic Modelling System (GAMS) as recursive linear programs and run for 20 years. Random precipitation patterns and cattle price sets were used. Baseline models were first developed to balance forage with the average herd size. Models evaluated practices on all or half the rangeland area, with the ranch paying 100, 25, or 0% of the conservation cost and then compared to baseline models. The baseline models were based on a small and a large representative ranch for each MLRA with no conservation practices or payments. Results show that restoring lesser prairie chicken habitat on private rangeland may or may not be profitable, depending on ranch size, area treated, forage response, cattle prices, and how much of the conservation practice cost is paid by the rancher.

For all analysis scenarios and cattle prices, small and large ranches have higher household income (HI) when they pay 0% of the cost, regardless of treatment area. Small and large ranches show a decrease in HI when the ranch pays 25% of the conservation cost. These results may not be applicable to every ranch, so an individual ranch analysis should be conducted before participation in LPC conservation. Ranchers should also determine if profit, household income, or some combination is most important. The basic framework used in this study can guide individual ranch analysis.

Introduction

The US Fish and Wildlife Service has listed two Distinct Population Segments (DPS) of Lesser Prairie Chickens (LPC) under the Endangered Species Act. The Northern DPS is identified as threatened status and the Southern DPS is designated for endangered status. Elmore et al. (n.d.) noted that the current threats to the LPC include, but are not limited to, tree invasion and planting, long-term fire suppression, and improper cattle grazing management. Cattle grazing can reduce the height and density of grasses and allow for shrubs to become too dense (Van Pelt et al. 2013).

Approximately 95% of the land area of the species is in private land ownership. Conservation is thus focused on these lands with funding potentially supplied through Natural Resources Conservation Service (NRCS) conservation programs, most notably through the Environmental Quality Incentives Program (EQIP). Under EQIP, practice payments are made to landowners to implement planned conservation practices. The NRCS, through the Working Lands for Wildlife program, has taken the lead in encouraging private landowners to implement LPC conservation practices since 2010 with the Lesser Prairie Chicken Initiative (NRCS 2023a). Voluntary participation in the Working Lands for Wildlife can have significant long-term benefits to the landowner through protections for incidental take under the Endangered Species Act (NRCS 2023b).

Removing trees is a primary goal to improving habitat for LPC. Using prescribed fire is often described as the most efficient method, but it is not always an acceptable practice. In cases where it is not desired, using herbicides followed by skeleton removal mechanically is the option. Alternatively, prescribed grazing can be used to create habitat heterogeneity if properly applied.

This project seeks to understand the economic impact on small and large ranches in four Major Land Resource Areas (MLRA) covering most of the LPC habitat. As shown in Figure 1, we are focused on the southern portions of MLRAs 72 and 73 in Kansas, the northern portion MLRA 77D in New Mexico, and the eastern portion of MLRA 77E in Texas.

Methods

LPC conservation practices are derived from the Van Pelt et al. (2013) publication by the Western Association of Fish and Wildlife Agencies. LPC habitat occurs in the southern Great Plains, with a dry temperate climate that has a mean annual temperatures ranging from 45°F to 79°F. The annual precipitation in this area ranges from 10 to 30 inches.. Potential lesser prairie-chicken habitat was reduced by 56% from a potential of 43,258 km2 to the current 18,908 km2 in ~115 years (Portillo-Quintero et al. 2022). The MLRAs that were chosen correlate with the four vegetation types defined by Van Pelt et al. (2013) and each has different representative ranches and sizes and different practices that would be most likely. Ranch models were developed for each MLRA based on a small and large size. A baseline model used a representative ranch with no LPC conservation practices.

Counties in each MLRA were selected based on the algorithm used in Maczko et al. (2022). A rangeland county is defined as having more than 25% rangeland vegetation and fewer than 200 people per square mile. Only counties with more than 50% of their land area within an MLRA were included. The 2017 Census of Agriculture (NASS 2019) beef cattle and operation numbers were used to estimate a small and large size operation. Each counties numbers were weighted by the percentage of rangeland vegetation for a weighted average. Small ranches were considered to have 50-199 beef cows and large had greater than 200 beef cows.

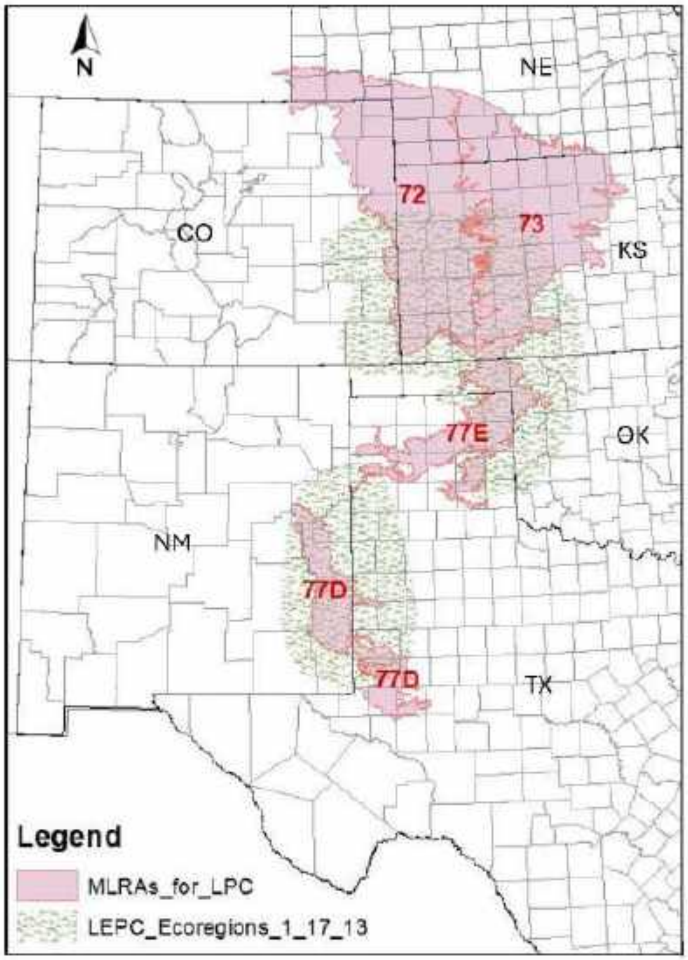

Fig 1a. Major Land Resource Areas 72, 73, 77D and 77E with Lesser Prairie Chicken habitat.

Fig 1b. Historic Lesser Prairie Chicken range (blue) and current habitat (green). Map by BirdLife International.

Ranch models for each MLRA are based on representative enterprise budgets published for each region. MLRA 72 and 73 were based on Dhuyvetter et al. (2014). MLRA 77D was based on NMSU (2019a, 2019b). MLRA 77E was based on Amosson (2017). Values were indexed to 2019 using index values from NASS following the procedure by Rimbey and Torell (2011). These enterprise budgets fed into the ranch models described below. The ranch models seek to maximize the present value of net ranch income as shown in Equation 1.

$$I=\sum_{t=1}^{20}\left[(L_t P_{lt}+H_t P_h-FC_t-AC_t-LC_t-LPC_t)(1+r)^{-t}\right] \quad [1]$$

Where I = Net Ranch Income

Lt = Livestock sales in year t

Plt = Price of livestock in year t

Ht = Hay sales in year t

Ph = Price of hay

FCt = Forage cost in year t

ACt = Animal cost in year t

LCt = Loan cost in year t

LPCt = Lesser prairie chicken conservation cost in year t

r = Discount rate

The model is solved subject to a variety of constraints with the most important being to balance the forage sources with the herd size in each season of the year.

$$\sum_{s=1}^{n} LC_s \, AU_c \, S_n = \sum_{s=1}^{n} \left(NR_{st} \, PPT_t + RES_{st} + FEED_{st} \right) \quad [2]$$

Where: LCs = Livestock class numbers in each season

AUc = Animal unit equivalents for livestock class

Sn = Season

NRst = Native rangeland production in season s and year t

PPTt = Precipitation index in year t

RESst = Crop residue production in season s and year t

FEEDst = Hay fed in season s and year t

What we feel is more important to a ranch family is Net Household Income (Equation 3) which is defined as,

$$HI = L_t P_{lt} + H_t P_h - FC_t - AC_t - LC_t - LPC_t + O - FAM - FIX_t \quad [3]$$

Where O = Off Ranch Income

FAM = Family living expenses

FIXt = Fixed costs in year t

Off ranch income is set at the level defined by ERS (2022; 2023a; 2023b) and ERS NASS (2022).

Results by MLRA

MLRA 72

When all rangeland areas are treated on both large and small ranches, net ranch income (NRI) and household income (HI)nly increase when NRCS pays for 100% of conservation practices regardless of cattle prices. In all other cases, the ranch would see declines. In the case of treating half the rangeland area, large ranches would see increases in NRI and HI when the ranch pays 25 or 0% of the conservation practices. Small ranches would see increases when they pay 0% of the conservation practices, except for a slight increase in HI at high prices. Brood cow numbers increase the most at low cattle prices and decline at higher prices.

MLRA 73

When all rangeland areas are treated, large ranches generally gain both NRI and HI when the ranch pays 25 or 0% of the conservation practice costs, except for NRI at low cattle prices. Small ranches generally see a decline in NRI and an increase in HI when they pay 25 or 0% of the conservation practices. When treating half of the rangeland area, large and small ranches have the same responses, but at higher amounts. Brood cow numbers increase the most at low cattle prices and decline at higher prices.

MLRA 77D

When all rangeland areas are treated, large ranches show increases in NRI and HI when the ranch pays 25 or 0% of the conservation practices. Small ranches also show an increase in NRI at high prices and HI at medium and high prices when they pay 100% of the conservation costs. Brood cow numbers increase the most at low cattle prices and decline at higher prices.

MLRA 77E

When all rangeland areas are treated, large ranches show increases in NRI and HI when the ranch pays 100, 25, or 0% of the conservation practices. Small ranches also show an increase in NRI and HI except when they pay 100% of the conservation cost at low cattle prices. When half of the rangeland area is treated, large ranches show a decrease in NRI and HI when they pay 100% of the conservation practice costs. Small ranches show an increase in NRI and HI at all levels of them paying the conservation practice costs. Brood cow numbers increase about the same number regardless of cattle prices.]

Discussion

We examined the economic impacts of lesser prairie chicken habitat improvement on small and large ranches in four Major Land Resource Areas using NRCS conservation practice scenarios. All of the scenarios show that with some level of financial assistance ranchers can implement LPC conservation practices without experiencing lasting negative impacts to their ranch or personal household incomes. However, without assistance, it is unreasonable to expect ranchers to implement conservation at the personal cost it would require. Based on the scenarios of removing trees from half or all the rangelands and implementing prescribed grazing with reduced utilization, results show varying responses across ranch sizes and MLRAs.

Conclusions and Implications

Consideration of the economic impacts of implementing conservation and management practices to LPC habitat on ranches in the 4 MLRAs addressed by this research shows that both removal of trees and grazing heterogeneously are key techniques to use (Van Pelt et al. 2013). Trees can be removed using herbicides followed by mechanical removal of the skeletons, chaining, or prescribed burning. In all cases, follow up treatment is necessary to remove trees missed in the initial treatment and to prevent reestablishment. Grazing at a light utilization rate can be used to create heterogeneous habitat that the LPC prefer at different life stages.

Specifically, our research focused on elucidation of economic impacts associated with implementing these practices on small and large ranches, using NRCS conservation scenarios. Modelling shows that restoring lesser prairie chicken habitat on private ranches may or may not be profitable for the rancher or the ranch household, depending on the size of the ranch, how much area needs to be treated, the forage response to removing trees, cattle prices, and how much of the conservation practices need to be paid by the rancher.

It is important to note that we considered representative ranches in each MLRA based on enterprise budgets for each state, rather than individual ranches in a given region. Because individual ranches vary greatly, results may not be directly applicable to every ranch. It is important for private lands and public lands ranchers to conduct an individual ranch analysis before participating in LPC conservation if profit or household income is important for the operator. The basic framework used in this study can guide such individual analyses.

Impact of flooding on rangeland condition in low-gradient multi-channel river systems of the Flinders River Catchment

Tefera, AS[1]; Koci, J[2]; Nelson, PN[1]; Jarihani, B[2]; Phelps, D[3]

Key words: Rangeland condition, Floods, Flinders River catchment, Multi-channel systems

Abstract
Across northern Australia's rangelands, riverine flooding has long-lasting impacts on landscape health, function, and productivity. This PhD project aims to improve understanding of the factors influencing the impact of flooding on rangeland condition in low-gradient, multi-channel river systems. The project focuses on the Flinders River catchment, north-west Queensland, Australia. Using on-ground and remote sensing data, the project will: (i) develop a hydrologically conditioned high-resolution digital elevation model (DEM) for enhanced flood modelling; (ii) simulate flood events using hydrodynamic modelling; (iii) determine the impact of flooding on rangeland condition; and (iv) identify the key factors influencing post-flood rangeland condition recovery. The research will provide valuable new insights into flood impact and recovery to inform land management, flood mitigation, and conservation practices, supporting long-term rangeland health and resilience.

Introduction
Australia's northern rangelands cover over 1.2 million square kilometres, including parts of Western Australia, Northern Territory, and Queensland (Russell-Smith and Sangha 2018). These rangelands provide multiple critical ecosystem services, including food production, cultural and recreational values, habitat for wildlife, water and nutrient cycling, and carbon sequestration and storage (Brown and MacLeod 2017). In northern Australia, as is the case globally, the health and function of rangelands are under increasing pressure from the combined effects of climate change and extreme climate events, invasive species, altered fire regimes, land use conversion and poor grazing land management (McKeon et al. 2004; Boone et al. 2018).

The frequency and intensity of floods has increased globally due to climate change, deforestation, poor land management, population growth, and overgrazing (Power and Callaghan 2016; Huda et al. 2022). This trend is projected to worsen, resulting in escalating flood losses and economic impacts (Taguchi et al. 2022). In northern Australia, climate change is expected to intensify floods and prolong droughts (Ghofrani et al. 2016; State of Queensland 2019a; IPCC 2023). The impacts of floods on rangeland condition in northern Australia, however, are not well quantified, and the interplay between flooding and other factors influencing rangeland recovery remains poorly understood.

Flooding in northern Australia's rangelands is a recurring hazard with significant social, economic and environmental implications (Nafari et al. 2016; McLean 2022). The 2019 Flinders River flood, for example, inundated approximately 13 million hectares (Figure 1). The flood event, coupled with an extreme wind chill event, resulted in the death of over 450,000 head of cattle, caused widespread infrastructure damage, and had long-lasting impacts on community well-being (Phelps 2019).

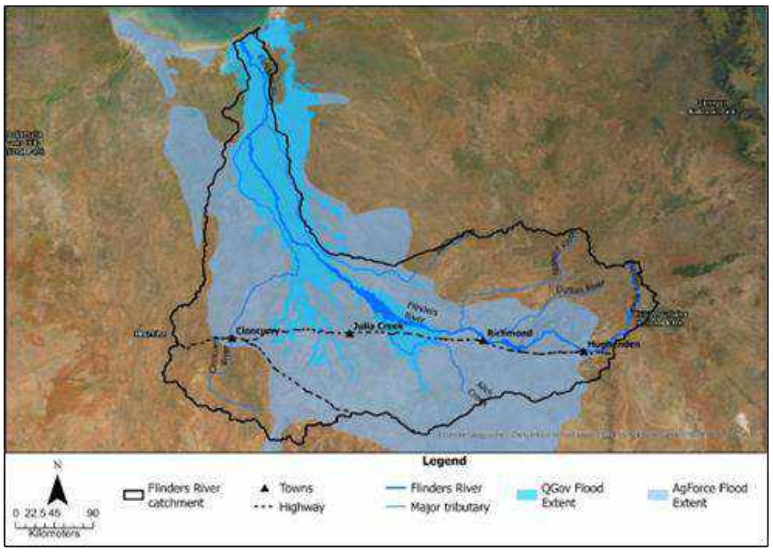

Figure 1. Inundation extent of the flood zone as mapped by the State of Queensland (2019b)and AgForce Queensland (2019).

The flood event also had severe impacts on the health and functioning of the region's sensitive natural assets (Figure 2), including widespread soil erosion, native vegetation and pasture die-back, as well as reduced water quality and availability (Hall, 2019).

Figure 2. (A) Dead Mitchell grass tussocks in a heavily washed area; (B) pedestalling of Mitchell Grass tussocks; and (C) silt deposition.

In low-gradient, multichannel systems such as the Flinders River catchment, intricate drainage networks, channel morphology and floodplain topography influence water and sediment distribution during flood events (Sockness and Gran 2021; Jacobson et al. 2022; Dawson and Lewin 2023; Shukla et al. 2024).To fully understand the flood impacts in these rangeland ecosystems, reliable flood mapping and modelling is essential. Although recent advances in satellite technology offer opportunities for developing high-resolution elevation models to improve flood modelling, gaps in coverage due to dense vegetation and clouds, and lack of sufficient details in elevation remain the main challenges for accurate flood extent mapping, especially in data-scarce low-gradient multichannel systems (Jarihani et al. 2015; Peramuna et al. 2023; Cohen et al. 2024).

This PhD project seeks to address the identified knowledge and information gaps and provide stakeholders and policymakers with the necessary information to inform decisions on effective flood management strategies, supporting land recovery and resilience in the Flinders River catchment and rangeland systems more broadly.

Methods

This study will collect data from primary sources, including on-ground elevation measurements and land condition assessments, as well as secondary sources such as Digital Elevation Models (DEMs), satellite images, and climate and hydrology information. To enhance flood mapping and modelling in the Flinders River catchment (Figure 3), the conventional 30-m DEM will be optimised by integrating higher resolution DEMs with on-ground Real-Time Kinematic GPS measurements. The optimised DEM will be utilised alongside satellite imagery to analyse flood characteristics and simulate flood events using advanced hydrological software (e.g., SWAT, HEC-RAS) integrated with Geographic Information Systems. These flood models will serve as inputs for assessing the impact of flooding on rangeland condition through ground cover change analysis before and after flood events. This assessment leverages on-ground land condition evaluations and satellite imagery and employs spatial regression models to reveal the dynamics of ecosystem resilience and recovery following flooding events.

Figure 3: The Flinders River Catchment

Result and Discussion

The project is in early stages of development and as yet, no results have been obtained.

The proposed research will enhance fundamental scientific understanding of the impact of flooding on rangeland systems in low-gradient multichannel catchments. The detailed assessment of flood impacts on land condition in the Flinders River catchment will provide valuable insights into landscape resilience and the factors that affect recovery of rangeland condition after extreme floods. Detailed information on floods and how they affect rangeland condition will enable better prediction and help mitigate the destructive outcomes of future flood events. The project will also enhance the accuracy of flood modelling and prediction tools by capturing the complexities of flooding in low-gradient multi-channel systems. In general, the outcomes of this research will provide stakeholders and decision-makers with the necessary information and data to make well-informed decisions about land management strategies in a way that will promote both flood mitigation and rangeland conservation across the Flinders catchment and beyond.

Expected outputs

The expected outputs of the research are:

- A hydrologically conditioned high-resolution DEM for enhanced flood modelling in low-gradient multichannel systems.
- Comprehensive flood maps and models for the Flinders River catchment.
- Detailed assessment reports on the impact of flooding on rangeland condition.
- Insights into the key factors influencing post-flood recovery of rangelands in the Flinders River catchment.

Key words: Rangeland plant pests, pest management

Abstract

Twolined spittlebug (TLSB), *Prosapia bicincta* (Hemiptera: Cercopidae) was first detected in 2016 in the South Kona district of Hawai´i Island where it had damaged over 2,000 acres of rangeland. In 2017, four locations were selected for monthly monitoring of TLSB activity, population dynamics, and changes in plant community composition. Two monitoring sites were at the center of the infestation while the other two were located outside the northern and southern boundaries to estimate the rate of spread. At each location a series of 100-m long transects were established along elevational gradients between 500 and 1,850 m. Along each transect, ten 0.25-m^2 quadrats were placed every 10 m on alternating sides of the transect. In each quadrat, data were collected on vegetative cover and height, plant species composition, live and dead grass cover (%), nymph and adult abundance, and nymph-plant associations. The surveys revealed that between 2017-2023, TLSB expanded its range to over 72,183 ha, primarily in pastures of Hawai´i's most important forage grasses, Kikuyu (*Pennisetum clandestinum*) and pangola (*Digitaria eriantha*). TLSB was detected between ~500-1,700 m in elevation and activity was highest during the wet season (Apr-Oct). Mean TLSB densities (126 nymphs/m^2) in pastures located between 1,000-1,300 m in elevation were significantly higher than in pastures between 500-999 m (64 nymphs/m^2) and >1,300 m (20 nymphs/m^2). Pastures with the highest TLSB densities experienced the greatest decrease in mean grass cover (30%) and greatest increase in mean forb (76%), bare ground (39%), and shrub (7%) cover. Landscape-level changes were observed in rangelands damaged by TLSB as shown by the loss of forage grass cover and subsequent replacement by invasive weeds including Pamakani (*Eupatorium adenophorum*), wild blackberry (*Rubus* spp.), fireweed (*Senecio madagascariensis*), and Hilograss (*Paspalum conjugatum*). The establishment and spread of TLSB has devastating impacts on the ecosystem services Hawaii rangelands provide.

Introduction

Twolined spittlebug (TLSB), *Prosapia bicincta* (Say), is a pasture and turfgrass pest native to southeastern United States (Shortman et al. 2002, Thompson and Carvalho 2016). Twolined spittlebug negatively impacts rangelands by feeding on important forage grasses (Byers and Wells 1966, Shortman et al. 2002). In 2016, TLSB was detected in the South Kona district of Hawai´i Island (Wilson et al. 2023). Between 2017 and 2020 the pest rapidly expanded its range at rate of over 14,000 ha per year (Wilson et al. 2023) and by the end of 2021 occupied over 72,183 ha across the South Kona district.

The Hawai´i beef industry is economically, culturally, and ecologically important to the state. Over 142,000 head of beef animals are managed across nearly 300,000 acres of rangelands (20% of Hawai´i's land mass) that are managed by over 1,300 ranches. The value of Hawai´i-raised beef cattle is estimated to be more than $48 million annually (USDA-NASS 2022). Over 60% of the beef cattle in the state are raised on the island of Hawai´i where the TLSB currently poses the most significant threat.

High density TLSB infestations often result in nearly 100% die back of key pasture grasses including Kikuyu (*Pennisetum clandestinum*) and pangola (*Digitaria eriantha*) grasses. The loss of these important livestock forages provides entry for the establishment of low-quality forage, weeds, and invasive plants, including Pamakani (*Eupatorium adenophorum*), wild blackberry (*Rubus spp.*), fireweed (*Senecio madagascariensis*), and Hilo grass (*Paspalum conjugatum*). Twolined Spittlebug's rapid rate of spread and apparent preference for Kikuyu and pangola grass creates the potential for the pest to spread throughout the islands and cause irreparable harm to large areas of valuable rangelands. Consequently, this pest threatens the economic sustainability of the Hawai´i livestock industry, reduces the ecosystem services derived from these landscapes, and ultimately harms Hawai´i communities through decreased agricultural revenue and reduced food security.

Methods

In 2017, four separate locations were selected for long-term, monthly monitoring of TLSB activity and population dynamics, and changes in plant community composition. Two the monitoring sites were at the center of the initial infestation while the other two sites were located outside of the northern and southern boundaries of the known distribution of the pest to estimate the rate of spread. At each location, a series of transects were established along elevational gradients between 500 and 1850 m. A total of 17 transects were established across the four sample sites. Along each transect ten sample points were systematically established every 10 m alternating between the left and right side of the transect line. A 0.25 m^2 ring was used at each sample point to record vegetative cover by species, percent live and dead grass by species, vegetation height by functional group (grass, forb, shrub), and a count of TLSB nymphs and adults. Along each transect, one adult sweep net sample was collected. All data were collected across all transects and sites monthly. Generalized linear mixed models (GLMM) were used to determine if season and elevation influenced TLSB nymph and adult abundance while accounting for random effects (location and year). For each GLMM, season and elevation were fixed effects grouped categorically by wet (April – October) or dry (November – March) season, and low (500-999 m), mid (1,000 – 1,300 m), or high (> 1,300 m) elevation. Tukey's pairwise comparisons were conducted to evaluate seasonal and elevational trends. Plant community data were quantified by mean percent cover by functional group (grass, forb, and shrub) or bare ground for each transect. Changes in percent cover by functional group or bare ground were assessed over the study period. A Wilcoxon-Mann-Whitney test was used to compare changes in mean grass cover and determine if grass cover varied significantly between years for each elevational category.

Results

Twolined Spittlebug Population Distribution

The monthly surveys revealed that the TLSB expanded its range from approximately 28,102 ha in 2017 to over 72,034 ha by 2021 (Fig. 1).

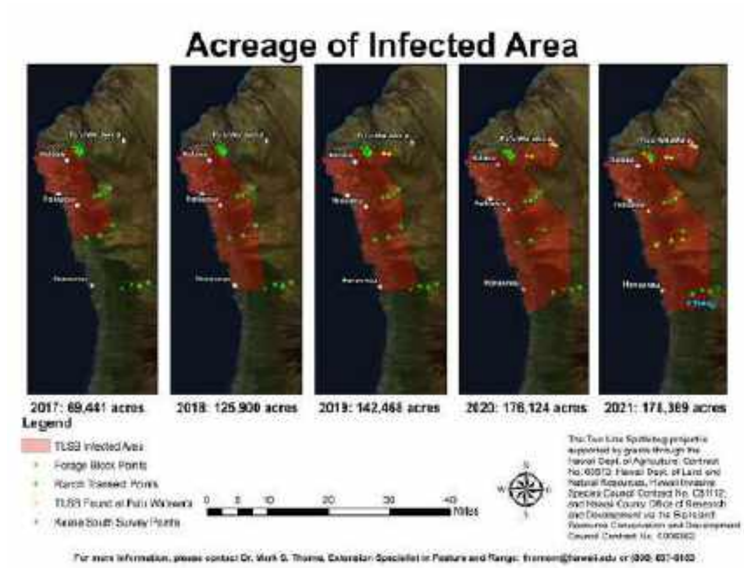

Fig. 1. Twolined Spittlebug population distribution between 2017 and 2021 within the South Kona District of the island of Hawai´i.

Results showed that season and elevation were good predictors of nymph (X^2 = 138.9, df =1, P≤0.001) and adult (X^2 = 148.79, df=1, P≤ 0.001) abundance. Mean nymph and adult abundance was significantly (P<0.0001) higher in the wet season compared to dry season months across all sites and years. Nymph abundance coincided with the wet season (April – October) with little activity between November and March (dry season). Of all nymphs sampled 95% were collected in the wet season and 5% during the dry season. Adult activity also coincided with the wet season, but peak abundance was highest between May and November and lowest from December through April. Of all the adults sampled, 94% were collected in the wet season and 6% in the dry season.

Elevation had a significant effect on the timing and abundance of both nymph and adult population dynamics (Fig. 2). The highest abundance of nymphs and adults were detected at the mid elevation (1,000 – 1,300 m), followed by the low elevation (500 – 999 m) sites. The high elevation (> 1,300 m) category had significantly lower nymph and adult abundance than the mid and low elevation categories.

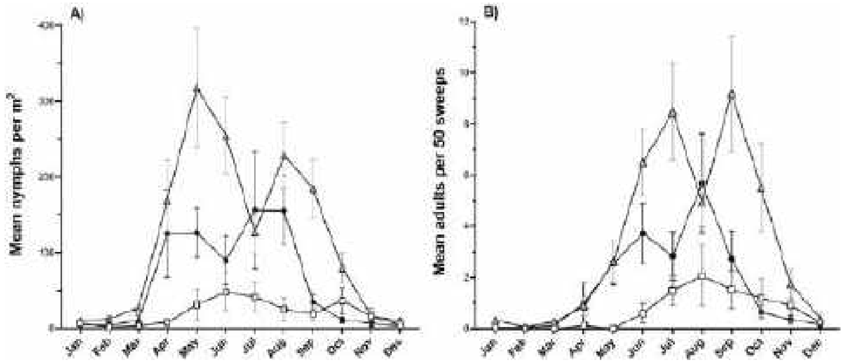

Fig. 2. Seasonal variation of Twolined Spittlebug A) nymph and B) adult abundance (mean ± SEM) by elevation. Low elevation = 500-999 m (black circles), mid elevation = 1,000-1,300 m (grey triangles), and high elevation > 1,300 m (white squares).

Plant Community Composition

Twolined Spittlebug nymphs were detected on 32 different plants. Grasses accounted for 72% of the associations, while legumes (16%), sedges (6%), and forbs (6%) made up the remainder. Mean grass cover decreased significantly over the study period at the low (73% vs 57%; W=1749, P-0.0004) and mid (68% vs. 47%, W=3852, P<0.0001) elevations, but did not vary significantly at the high elevation (89% vs 90%; W=1243, P=0.975). As grass cover decreased, forb cover and bare ground increased, while shrub cover remained constant (Fig. 3).

Discussion and Implications

The nymph and adult abundance patterns observed in our study follow closely with the lifecycle of the Twolined spittlebug in its home range. In Florida, the TLSB lifecycle from egg to egg averaged 76 days which included 19 days for egg hatch, 50 days for nymph development to adult, and 7 days until the adult female begins laying eggs (Fagan and Kuitert 1969). Under optimal conditions the entire lifecycle of duration, plus time needed for the next generation of nymphs to hatch is about 95 days. The distinct abundance peaks and synchronous activity indicate two generations of TLSB per year in the Kailua-Kona pastures. The rapid and synchronous outbreak of nymphs with the arrival of the wet season suggest that TLSB eggs enter diapause prior to the dry season followed by a period of postdiapause quiescence (Pires et al. 2000, Sujii et al. 2001). At this stage of postdapause quiescence, eggs can respond under humid conditions and stimulate immediate eclosion, resulting in abrupt synchronous first population peak (Pires et al. 2000, Sujii et al. 2001. Peck 2002).

Precipitation varies widely across the island of Hawaii and this variability becomes more extreme with drought conditions (Luo et al. 2024). The temporal differences in abundance patterns of TLSB observed in this study were likely influenced by the year-to-year variation in rainfall and the onset of drought conditions late in 2020. Likewise, the spatial variation in TLSB abundance was likely influenced by the variability in microclimates that occur over short distances due to the abrupt elevation changes across the Kona rangelands. Moreover, drought effects did not manifest evenly across the Kona rangelands, so differences in plant community responses across sites may have contributed to variation in habitat suitability for TLSB over time, impacting their distribution and abundance.

The changes in groundcover reported in this study suggest that TLSB infestations have caused widespread and long-term damage to Kona rangelands dominated by Kikuyu and pangola grasses, ultimately resulting in landscape transformation through invasion and establishment of invasive weeds and low-quality forage grasses (Wilson et al. 2023). Damage caused by the invasion of TLSB in Hawai´i will necessitate a shift in the conventional rangeland management practices. Management of TLSB in Hawai´i rangelands will need to be developed based on site-specific information due to variation in elevation, climate conditions, and plant communities across the island of Hawai´i.

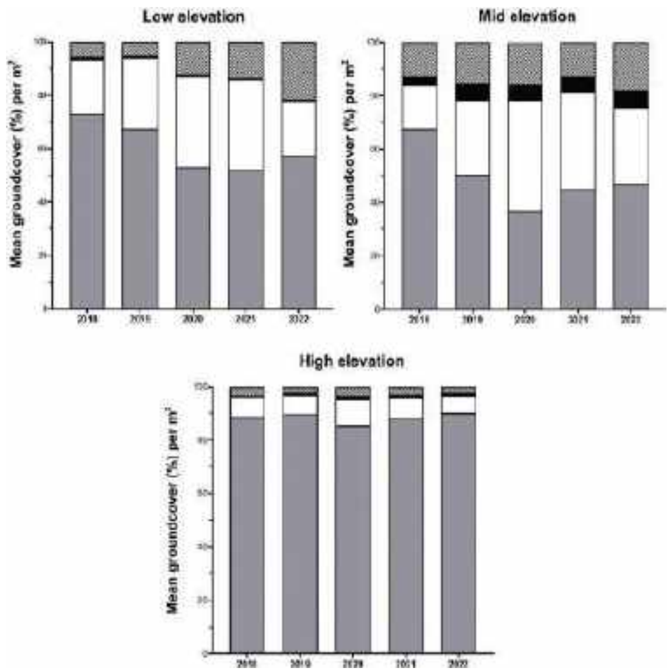

Fig. 3. Annual variation in proportion of mean groundcover in low (500-999 m), mid (1,000-1,300 m), and high (> 1,300 m) elevations groups over the study period across all four sample sites in the North and South Kona districts on the island of Hawai´i. From top to bottom of the bars, grass cover shown in dark grey, forb cover in white, shrub cover in black, and bare ground in light grey strips.

Key words: animal performance; rangeland ecology; rangeland management; woody plant encroachment

Abstract

Tree and shrub densities have increased by approximately 30-50% in many areas of southern Africa, which increase the amount of bare soil surfaces and consequently declines in soil functions, which hinders the recovery of herbaceous plants. Additionally, encroaching woody plants such as *Vachellia species*, *Seriphium plumosum* and *Senegalia caffra* may alter ecosystem services such as forage production for livestock; and thereby increase associated costs of livestock management. The expansion of woody plants in communal and commercial systems is attributed to local and global driver including but not limited to overgrazing, elevated atmospheric CO_2, erratic rainfall. In an attempt to understand the underlying causes of woody plant encroachment, and develop management interventions the following objectives were explored the 1) effect of season, burning, slope position, and their interaction on *Seriphium plumosum* L. crude protein, neutral detergent fibre, total phenolics and condensed tannins concentrations, 2) optimal tree density that will maximize forage production, 3) the use of woody encroaching species as a measure of control of endoparasites in cattle, and 4) use of encroaching woody species as fodder and their effect on animal performance, methane emission and meat quality. Crude protein concentration was higher during the wet season in post-fire treatment sites than in no fire treatment sites, which were also higher than CP concentrations during dry season at no fire treatment sites and post-fire treatment sites. The results showed that mechanical- and chemical -control, as well as fire application influences the structure and functioning of savannas by creating gaps that promote grass production. *Senegalia caffra* resulted in nearly 100 % mortality of internal parasites in cattle after just 2 hours of application. Lastly, the encroaching woody plants showed the potential for use as fodder for livestock without adversely affecting animal performance, improve carcass characteristics and reduce methane emission.

Introduction

Woody plant encroachment has increased by approximately 30-50% in many areas of southern Africa, which hinders the recovery of herbaceous plants (Kraaij and Ward 2006). Given the widespread spread of woody plants into grasslands and savannas in southern Africa and worldwide (Archer et al. 2017), there is a considerable decline in the agricultural potential of rangelands (Börner et al. 2007). For instance, the increasing rate and extent of *Vachellia karroo*, *Senegalia caffra* and *Seriphium plumosum* in South Africa will compromise ecosystem services such as forage production to support a large population of grazers, with negative impacts on the pastoral economy (Pule 2018). In contrast, tannin-rich plants such as *Vachellia and Senegalia* species do not only aid in the reduction of enteric methane emissions in cattle (Piñeiro-Vázquez *et al*., 2015) but they are also beneficial to herbivore' health and well-being by minimizing parasitism in ruminants (Mbatha et al. 2002). The expansion of woody plants in communal and commercial systems is attributed to local and global driver including but not limited to overgrazing, elevated atmospheric CO_2, erratic rainfall. In an attempt to understand the underlying causes of woody plant encroachment, and develop management interventions the following objectives were explored the 1) effect of season and burning and their interaction on *Seriphium plumosum* L. forage quality; 2) optimal tree density that will maximize forage production, 3) the use of woody encroaching species as a measure of control of endoparasites in cattle, and 4) use of encroaching woody species as fodder and their effect on animal performance, methane emission and meat quality.

Methods

The studies were conducted in 1) Bronkhorstspruit (25.76907°S, 28.67918°E), Gauteng Province, South Africa; 2) & 3) Roodeplaat experimental ranch of the Agricultural Research Council (25º 56'S, 28º 35'E) in Gauteng Province, South Africa; and 4) Agricultural Research Council - Animal Production farm (25° 53'S, 28° 11'E), Gauteng province, South Africa. Objective one: a combination of *S. plumosum*'s fine leaves and twigs from previously burned and unburned (n = 116) areas were sampled from randomly selected plants during the wet (n = 58) and dry (n = 58) seasons, respectively. The 58 samples were from burned (n = 29) and unburned (n = 29) treatment areas. *Seriphium plumosum* samples were collected in (2015) wet/growing season on previously burned areas, while on unburnt areas, samples were from previous (2014) wet/growing season. The minimum distance between sampled *S. plumosum* plants at each sampling site was approximately 10 m. Objective two: a tree-thinning study was conducted in two savanna sites that differ in soil texture and woody species. Trees were thinned to the approximate equivalents of 0% (control-no removal), 10, 20, 50, 75 and 100% (complete removal of trees), followed by herbicide application on half of the stumps for each plot. Tree stumps were treated with herbicide within 15 min after felling during the growing season (Teague and Killilea, 1990; Burch and Zedaker 2003). Objective 3: grass biomass was assessed using five randomly placed 50 cm × 50 cm quadrats in each plot, with all of the grass samples within the quadrats harvested regardless of species. Objective 3: seedlings (< 1m) and adult trees (> 1.5m) of seven woody encroaching species (namely *Vachellia nilotica*, *Vachellia tortilis*, *Senegalia caffra*, *Ziziphus mucronata*, *Vachellia karroo*, *Searsia lancea and Euclea crispa*) were sampled in addition to *Opuntia ficus-indicathat* that was used as a control. Leaf-based ethanol extract: a 20% ethanol solution was prepared in order to extract the dried-ground plant material by adding 1500 µl of ethanol 96% to 0.1 g of ground leaves from each encroacher species (i.e. *V. nilotica*, *V. tortilis*, *S. caffra*, *Z. mucronata*, *V. karroo*, *S. lancea and E. crispa*) into an eppendorf tube (McIntire, 2005-2008). Objective 4: edible *S. plumosum* (i.e. leaves and twigs) were harvested using a tractor slasher and sun-dried for three days before bailing. *Seriphium plumosum* forage material was used for chemical analysis (i.e. dry matter, crude protein, neutral detergent fibre, metabolizable energy, acid detergent fibre and condensed tannin and feed formulation. Twenty-eight Nguni steers aged 22 months with a mean body weight of 300 ± 10kg were randomly assigned to one of four treatment diets containing *S. plumosum* meal levels at 0, 10, 20 or 30 % as replacements for Lucerne hay.

Results

Seriphium plumosum forage quality

There was a significant interaction effect of season x fire on NDF and CP ($P < 0.05$), but not on CTs and TPs concentrations ($P > 0.05$). The interaction effects of season x fire on *S. plumosum* crude protein (Fig. 1) and neutral detergent fibre. The effect of dry season × fire (5.34 % g−1 DW ± 0.18 SE), as well as dry season × no fire (5.09 % g−1 DW ± 0.18), on CP percentage were insignificantly different. However, the wet season post-burning had significantly higher CP (7.33% g−1 DW ± 0.31) than the wet season on unburned treatment (6.08% g−1 DW ± 0.20; Fig. 2a).

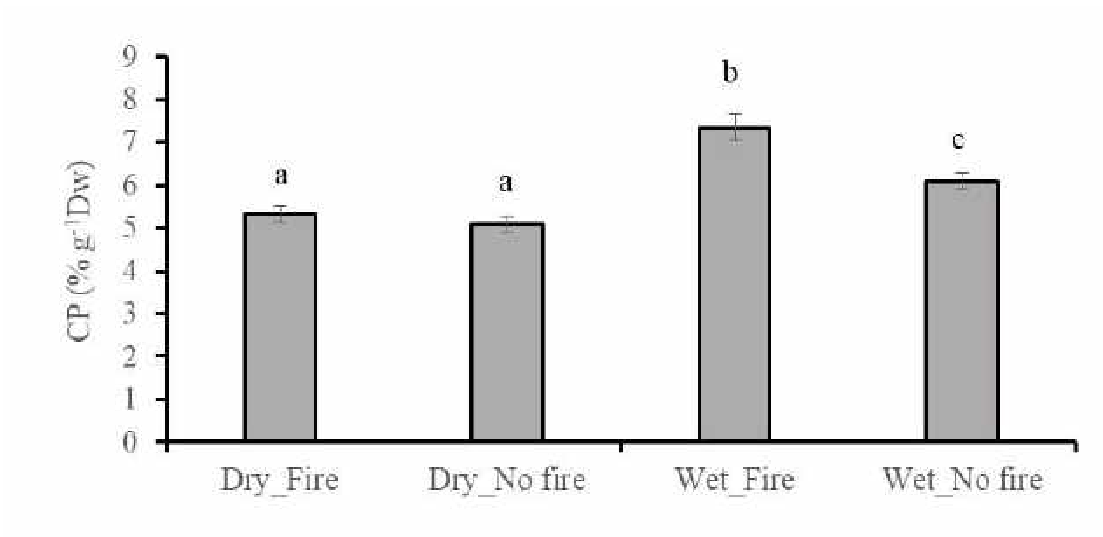

Fig. 1. *Seriphium plumosum* mean crude protein (CP) concentrations during the dry season in burned (fire) and unburned (no fire) areas and during the wet season in burned (fire) and unburned (no fire) areas.

Tree thinning on biomass production

The study revealed that the control plots (0 %) had a higher recorded grass biomass than at 75% and 100% (complete removal) removal treatments. In site 1, the control plots (0 %) had a higher recorded grass biomass than at 75% and 100% (complete removal) removal treatments. At site 2, tree removal significantly increased grass-biomass at the end of the first and second growing seasons i.e. grass biomass increased in the plots totally cleared of trees in the first growing season at site. Grass biomass increased in the plots totally cleared of trees in the first growing season at site 2. Towards the end of the second growing-season, grass biomass was greater than the previous season across all treatments, with substantial increases at 50%, 75% and 100% removal.

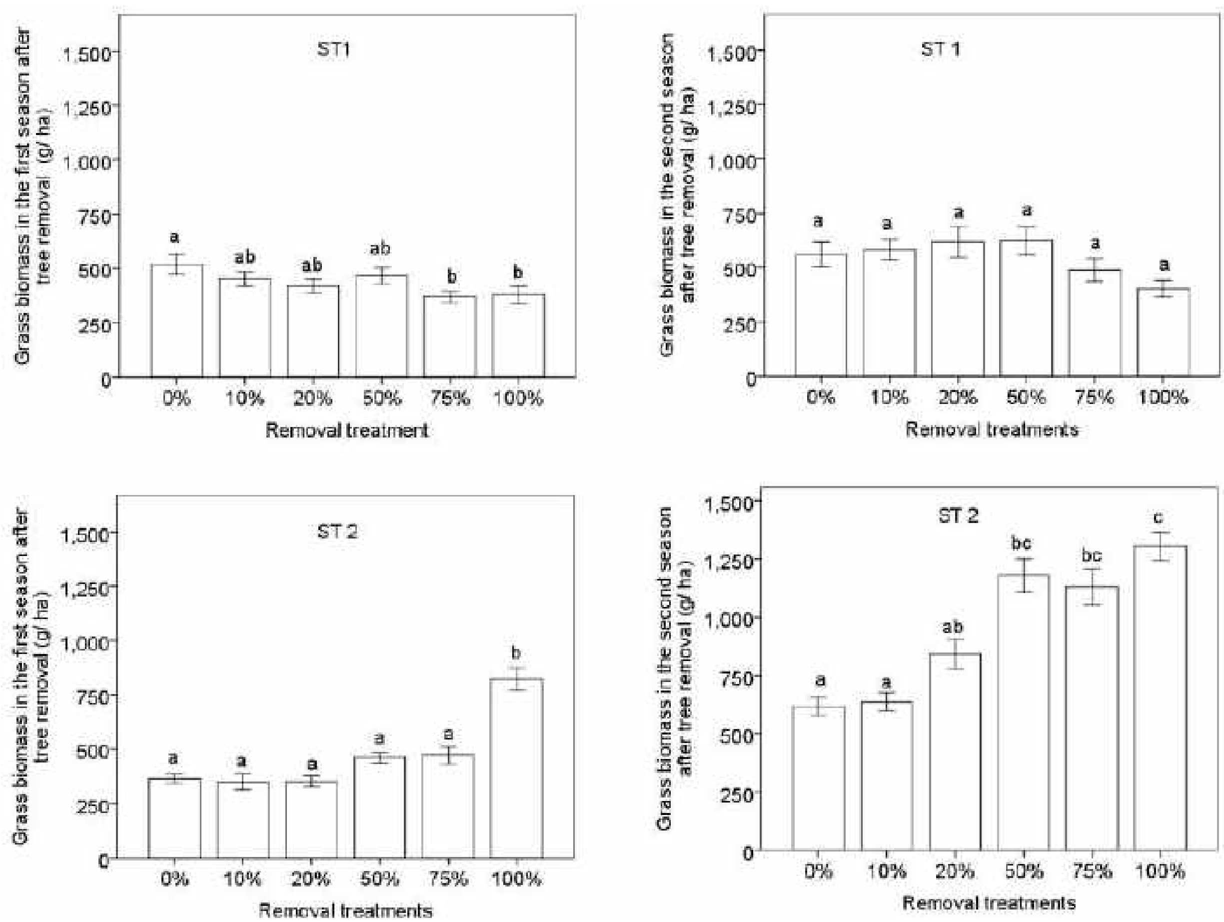

Fig. 2. Grass biomass production after tree removal in study sites 1 (ST1) and 2 (ST2). Treatments range from 0% = no removal (control) to 100 % removal = complete tree removal.

Encroaching woody plants: implications for internal parasites

Opuntia ficus-indica yielded the highest inhibition at 43.88% after 4 hours of application followed by *Vachellia karroo* at 42.26%. At species evaluated except for *Vachellia tortilis* parasitic larvae mortality was noted after 1 hour averaging 52.40% mortality at four hours. *Senegalia caffra* resulted in nearly 100 % mortality after just 2 hours of application.

Encroaching woody plants as fodder for ruminants

Seriphium plumosum meal inclusion in the diets at 0, 10, 20 or 30% did not affect live weight, feed conversion ratio and body condition score values of Nguni steers. Notably, Nguni steers fed a diet with 30 % of *S. plumusom* meal had lower significantly lower (P<0.05) CH_4 emission values than those fed diets having 10 or 20 % of *S. plumosum* meal. No significant difference was observed (*P* > 0.05) on tenderness, warmer blazer shear force, cooking loss %, beef aroma and bloody flavour of Nguni steers fed varying levels of *S. plumosum* meal.

Implications

The study has demonstrated that strategic use of fire may contribute to improve *S. plumosum* CP concentrations, especially in the wet season. This may result in improved preference and intake of *S. plumosum* by browser, thus contributing to control its encroachment on semi-arid grassland communities and livestock production. Additionally, encroaching woody plants can be used as fodder for livestock without adversely affecting animal performance, improve carcass characteristics and reduce methane emission. While tree removal may increase standing grass biomass in multi-tree-species systems on healthy soils, it may not be effective in monospecific stands especially on eroded clay soils. Thus the recovery of key ecosystem services such as an increased forage production may not be realised, regardless of investment in woody species control.

The Migration Characteristics of *cfp* Fluorescent Labeled Rhizobium in *Dolichos lablab L.* Plants and Rocky Desert Surface Soil

2.Institute of Soil and Environment Bioremediation in Karst Habitats, Guizhou Education University, Guiyang, Guizhou, China

Key words: *Dolichos lablab* L.; Fluorescent labeled rhizobium; Migration; distribution

Abstract

In this study, cyan fluorescent protein (*cfp*) labeled endophytic rhizobia of *Dolichos lablab* L. was used as the test strains which had strong nitrogen-fixing ability, low fluorescence loss rate, and good genetic stability. Through methods such as reinoculation and spot application of bacterial suspension in rocky desert mountain areas, we investigated the quantity and distribution of fluorescently labeled rhizobia in *Dolichos lablab* L. plants at different growth stages, as well as the migration characteristics of these bacteria on the surface of rocky desertified soil in the absence of hosts. The results indicate that in terms of spatial distribution, the fluorescently labeled rhizobia concentrated in the roots primarily. Specifically, during the vegetative stage, they are mainly present in the taproot, while from the budding stage to the pod-setting stage, they are predominantly found in the lateral roots. In terms of temporal dynamics, the highest count during the vegetative stage and the lowest during the budding stage. The number of labeled bacteria in the aboveground part of the plant was only 39.93% of that in the root, mainly distributed in the stem tip, flower bud and pod. During the development from flower buds to pods, the quantity of labeled bacteria shows a trend of increase-decrease-increase, with the lowest count observed inside the flowers. The surface soil of rocky desertification provides a suitable microenvironment for the survival of fluorescently labeled rhizobia. These labeled rhizobia can colonize the surface soil of rocky desertification and migrate across the soil surface over time. They can migrate from the central point O in vertical, oblique, and horizontal directions, but their distribution at various sampling points is discontinuous and unstable.

Introduction

Dolichos lablab L. is a high-quality leguminous green manure crop. It can establish a symbiotic relationship with soil bacteria-rhizobia-allowing the plant to grow in nitrogen-deficient soil conditions (Zhang et al. 2020). Rocky desertification is a significant driver of ecological degradation. Studies have demonstrated that rhizobia associated with leguminous crops can enhance the physical and chemical properties of rocky desertified soils, reduce soil pH, and significantly increase the levels of organic matter and essential nutrients, such as nitrogen, phosphorus, and potassium. These findings highlight the potential of rhizobia to improve soil quality and contribute to ecological restoration (Du et al., 2025). Therefore, introducing rhizobia into rocky desertification soils, even in the absence of leguminous crops, can improve soil properties, provide a source of nitrogen, and enhance overall soil health.

In this experiment, fluorescently labeled rhizobia of *Dolichos lablab* L. were introduced into *Dolichos lablab* L. plants and surface soils of rocky desertification areas. The study investigated the quantity and distribution of the labeled bacteria in different plant parts and at various growth stages of *Dolichos lablab* L., analyzed their movement within the plants, and examined their colonization ability and distribution characteristics in rocky desertified soils without a host plant. This research provides a theoretical foundation for the production of seeds pre-inoculated with rhizobia and offers valuable insights into improving soil conditions in the absence of leguminous crops.

Methods

Test Seeds: The experimental seeds used were *Dolichos lablab* L. of the "Rungao" variety, with a purity of over 90%.

Test Strain: The experimental strain was a genetically stable rhizobium strain (Y-1) capable of producing cyan fluorescence.

Preparation of Bacterial Suspension: After activation, strain Y-1 was inoculated into YMA liquid medium and cultured at 28°C with shaking at 120 r/min until the optical density (OD_{600nm}) reached 0.5-0.8. The culture was then centrifuged at 4000 r/min for 10 minutes to remove the supernatant, leaving the bacterial cells. The cells were resuspended in an equal volume of sterile water and dispersed to prepare the bacterial suspension.

Seed Treatment and Sowing: *Dolichos lablab* L. seeds were placed in a sterilized Erlenmeyer flask and soaked in 5% povidone-iodine solution for 5 minutes, followed by rinsing with sterile water 5-6 times. The seeds were then soaked in the bacterial suspension for 2 hours. Using the hole-sowing method, seeds were planted in plots with a spacing of 40 cm between holes and 45 cm between rows, with one seed per hole.

Bacterial Suspension Application: Every 30 days, 30 ml of the bacterial suspension was applied to each plant. Watering was adjusted as needed to maintain adequate soil moisture.

Plant Sampling: At various growth stages of *Dolichos lablab* L. (130 days [vegetative stage], 216 days [squaring stage], 226 days [Florescence], and 235 days [pod stage]), three plants were randomly selected at each stage. The selected plants, including their roots, were carefully uprooted, washed, and air-dried to remove surface moisture. Using sterile scissors, the plants were divided into different parts: root, stem, leaves, stem tip, and stage-specific parts, such as flower buds (squaring stage), flowers (Florescence), and pods (pod stage). Each plant tissue sample was surface-sterilized, ground, diluted, and plated following Zhang (2012). Colony counts were recorded for each sample, with each part tested in triplicate.

Soil Sampling in Rocky Desertification Areas: A rocky desertification site with no vegetation was selected for soil sampling. The site was located in Wudang District, Guiyang City, Guizhou Procince. Sampling points were established in three directions: horizontal (H), vertical (V), and diagonal (D), with five points along each direction. Adjacent points in each direction were spaced 30 cm apart (Fig. 1). The central point (O) was treated with 100 mL of bacterial suspension. Soil samples were collected from each sampling point on the 7th, 14th, and 21st days following bacterial application. For each sample, 1 g of soil was placed in a sterile Erlenmeyer flask, mixed with 100 mL of sterile water to prepare a soil suspension. The suspension was diluted, plated, cultured, and colony counts were recorded following Zhang (2012).

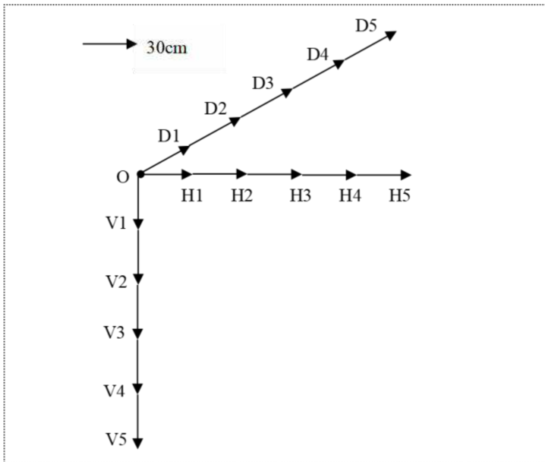

Fig.1 The distribution map of rocky deseritification mountain bacteria solution.

Results

[Quantity and distribution of labeled bacteria in different parts of Dolichos lablab L. plant at different growth stages]

Table 1 highlights the variation in the distribution of labeled bacteria across different parts of the root system and growth stages. During the vegetative stage, the quantity of labeled bacteria in the tap root was 14.58 times, 42.98 times, and 39.68 times higher than that in the squaring stage, florescence, and pod stages, respectively. Lateral roots exhibited the highest bacterial counts during the squaring stage, while the labeled bacteria in hair roots showed a gradual increase as the plant grew. In terms of timing, the root had the highest bacterial counts during the vegetative stage, with the lowest counts observed during the squaring stage. Within the vegetative stage, labeled bacteria were detected in the lower stem, lower leaves, and stem tip, with the highest concentration in the stem tip - 201.17% and 534.29% higher than in the lower stem and lower leaves, respectively. However, the distribution of bacteria in stems and leaves was discontinuous across different growth stages. During the reproductive growth phase, labeled bacteria were detected in all reproductive organs of *Dolichos lablab* L., with the highest counts observed in flower buds. The bacterial counts in flower buds were 5.59 times, 10.71 times, and 1.25 times higher than those in floral primordia, flowers, and pods, respectively.

Table 1 The number of labeled bacteria in each site of *Dolichos lablab* L. plants during different growth stage

Plant parts	The number of labeled bacteria (cfu·g^{-1}·FW)			
	Vegetative stage	Squaring stage	Florescence	Pod stage
Tap roots	71297	4577	1621	1752

V4	-	7409	535
V5	-	-	50

Table 2 reveals that the quantity of labeled bacteria at the central point (O) gradually decreases as the inoculation time increases. Horizontal direction: On the 7th day, no labeled bacteria were detected at any sampling points. By the 14th day, labeled bacteria were detected only at H1, while on the 21st day, they were detected only at H3. This indicates that labeled bacteria migrate horizontally over time and distance. Vertical direction: On the 7th day, labeled bacteria were detected only at V1. By the 14th day, they were detected at V1 and V4. By the 21st day, labeled bacteria were detected at all points except V1. Diagonal direction: On the 7th day, no labeled bacteria were detected at any point. By the 14th day, labeled bacteria were detected at D2, X3, and D5. By the 21st day, labeled bacteria were detected at all points except D1.

In conclusion, labeled bacteria can effectively colonize surface soils and demonstrate tracer effects, providing valuable insights into their distribution characteristics in rocky desertification environments.

Discussion

Most labeled bacteria were primarily distributed in the plant's root, consistent with previous studies, which have shown that while endophytic bacteria can move within plants, they exhibit a preference for specific parts (Zhang 2012; Zhang et al. 2020). Labeled bacteria within the root can migrate to the above-ground parts of the plant, but their distribution is discontinuous. For instance, bacteria have been observed moving from roots to stems and leaves in tobacco, rice, and clover plants. The variation in microenvironments across different plant parts results in endophytic bacteria occupying distinct ecological niches within various organs and tissues (Chi 2006; Gyaneshwar et al. 2001; Zhang et al. 2020). During the development from flower buds to blooms, the number of labeled bacteria in flowers decreased, likely because the nutritional environment during development failed to induce bacterial chemotaxis. Endophytic bacteria can move and adhere to root surface through chemotaxis or by chance, facilitated by root exudates. After mutual recognition and penetration of the root surface, they can colonize the host plant (Artur et al. 2019). When inoculated onto rocky desertified surfaces, the distribution of labeled bacteria in different directions was discontinuous. However, their widespread presence at greater distances from the inoculation point demonstrates that bacteria can migrate to deeper soil layers and spread through capillary water. Additionally, even in the absence of a host, labeled bacteria can colonize rocky desertified soils as independent entities. This suggests that rocky desertified soil provides a microenvironment conducive to bacterial survival and colonization.

Key words: pasture, ecological restoration, diversity, fencing, farmyard manure, mechanical drilling

Abstract:
Pature management measures such as fencing, the application of farmyard manure, and mechanical drilling have been implemented to address pasture degradation. This study explored the response patterns of grassland vegetation communities and soil nutrients under different restoration methods and compared the effects of these interventions.

The experiment was conducted in 2023 on degraded pasture in Chenbalhu Banner, Hulunbeier City, Inner Mongolia Autonomous Region. Four treatments were applied: control (CK), fencing (WF), farmyard manure (NJF), and mechanical drilling combined with farmyard manure (DNJF). In August of the same year, plant and soil surveys were conducted to evaluate the short-term restoration effects on plant community characteristics, biodiversity, and soil carbon and nitrogen content.

The results showed that WF, NJF, and DNJF significantly increased vegetation cover, density, and above ground biomass compared to CK, with notable improvements in community height and aboveg round biomass ($P < 0.05$). These treatments effectively enhanced plant diversity in degraded pastures, with WF having the most pronounced impact.

Analyzing plant functional groups revealed that perennial grasses exhibited the highest summed dominance ratio under WF, reaching 80.57%. All restoration methods promoted the growth of perennial grasses and increased the summed dominance ratio of C4 plants, thereby improving the light-use efficiency of the plant community. DNJF showed the greatest improvement in soil organic carbon and total nitrogen content

compared to WF and NJF. Correlation analysis indicated that DNJF strengthened the positive relationship between vegetation communities and soil nutrients.

In summary, the three restoration methods—fencing, farmyard manure application, and mechanical drilling combined with farmyard manure—had significant effects on degraded pastures. Fencing notably enhanced plant diversity, farmyard manure significantly boosted grassland productivity, and mechanical drilling effectively improved soil fertility. Among the methods, mechanical drilling combined with farmyard manure proved to be the most effective for the sustainable management of degraded pastures in Hulunbeier.

Introduction

Overgrazing is a key driver of grassland degradation, characterized by imbalances in grassland ecosystem structure and a diminished ability for self-regulation (Li B, 1997). This degradation is evident in reduced vegetation biomass, alteration in species composition, in increased soil compaction, higher sand content, and lower organic matter levels (Deng Y et al. 2021).

These changes adversely affect grassland productivity, leading to decreased outputs of agricultural products like livestock and herbs, while also compromising ecological functions such as air purification, water retention, soil conservation, and biodiversity protection (Zhang F, et al 2022).To mitigate pasture degradation, researchers have explored various restoration treatments, including no-tillage replanting, rational grazing, artificial grassland establishment, fencing, plowing, and fertilization, evaluating their effectiveness, advantages, and limitations (Gu C, et al. 2022, Yu S,,et al. 2019, Sun X, 2024). Each restoration method has specific applications, benefits, and constraints. Based on the characteristics of the study area, this research focuses on three treatments: fencing, farmyard manure application, and mechanical drilling combined with farmyard manure.

Given the negative impacts of pasture degradation on both productivity and ecology, as well as the economic challenges of restoring extensive grassland areas, identifying cost-effective restoration strategies is crucial. This study examines degraded pastures in Chenbaerhu Banner, Hulunbuir City, Inner Mongolia Autonomous Region, using three treatments: fencing, farmyard manure, and mechanical drilling combined with farmyard manure. The study comprehensively analyzes the responses of vegetation characteristics, soil nutrients, and the interaction between vegetation and soil to these treatments, providing a scientific basis for optimizing ecological pasture restoration.

Methods

1.1 Study area

The study area is located in Wuzhuer Gacha, West Wuzhuer Sumu, Chenbaerhu Banner, Hulunbuir City, Inner Mongolia Autonomous Region, China (latitude 48°48′–50°12′N, longitude 118°22′–121°02′E). The research site is situated within a family pasture that has experienced severe degradation due to year-round grazing. This has led to low vegetation, reduced coverage, and a decline in high-quality forage species such as *Leymus chinensis*, along with decreased plant diversity.

1.2 Field sampling and sample collection

The experiment, initiated in May 2023, was conducted on a flat land plot with four treatments: control (CK), fencing (WF), farmyard manure (NJF), and mechanical drilling combined with farmyard manure (DNJF) .Four transects were established, corresponding to the four treatments, each covering an area of 50 m × 600 m. A 10 m isolation zone was maintained between the transects to prevent cross-contamination. Farmyard manure consisted primarily of sheep and cow manure. Specialized soil drilling machinery was used for the mechanical drilling treatment, designed to drill and loosen the grassland soil. The drilling parameters included a depth of 10 cm, a hole diameter of 5 cm, and a width of 7 cm.

Vegetation surveys were conducted using sampling methods during the plant growth period in August 2023. For each sample plot, the species present, their height, coverage, and density were recorded. Following plant sampling, soil samples were collected using a soil drill at two depth layers: 0–15 cm and 15–30 cm. soil bulk density, soil organic carbon, and total nitrogen content are analyzed. The biodiversity of the sample plots was calculated using the following indices and Plant functional groups were classified based on life forms, water ecological types, and photosynthetic pathways. To quantify the dominance of functional groups within the community, the Summed Dominance Ratio (SDR4) was used as a comprehensive indicator. Data were analyzed using Excel 2021 and SPSS 22.

Results

2.1 Plant Community Characteristics and Species Diversity Under Different Restoration Treatments

2.1.1 Impact of Different Restoration Treatments on Community Characteristics

The plant community height and aboveground biomass were significantly higher under the WF, NJF, and DNJF treatments as compared to the CK treatment ($P < 0.05$). After applying WF, NJF, and DNJF, community height increased by 57.98%, 50.23%, and 57.83%, respectively, compared to CK. The increase in aboveground biomass was most pronounced under NJF, with a growth rate of 110.6% higher than that observed under WF and DNJF (Figure 1d).

There were also significant differences in the effect of the restoration treatments on the dominant species *Leymus chinensis*. Under NJF treatment, the height, density, and aboveground biomass of *Leymus chinensis* were significantly better than those under the other treatments ($P < 0.05$). In contrast, the density, coverage, and above-ground biomass of *Leymus chinensis* were lower under the WF treatment than under the other restoration methods.

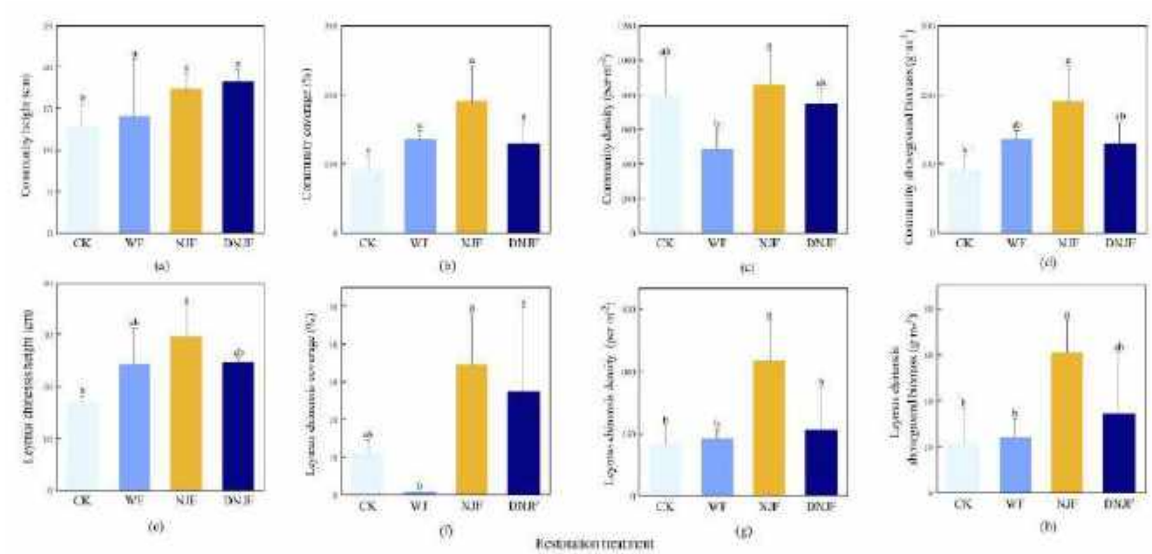

Figure 1 Effects of different restoration treatments on plant community characteristics

2.1.2 Impact of Different Remediation Treatments on the Alpha Diversity of Community Species

The Margalef richness index was significantly higher under the WF treatment than under the other treatments (P < 0.05) (Figure 2). The Pielou evenness index was highest under the CK treatment, followed by the DNJF and NJF treatments. The lowest Pielou evenness index was observed under the WF treatment. This suggests that, although species richness increased under WF, the uniformity of species distribution decreased.

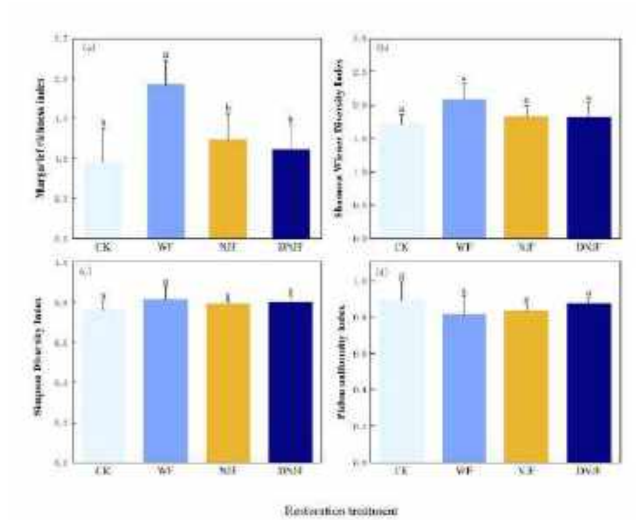

Figure 2 The impact of different restoration treatments on plants diversity

2.2 Impact of Different Restoration Treatments on the Summed Dominance Ratio of Plant Functional Groups

2.2.1 Summed Dominance Ratio of Community Life Form Functional Groups

The summed dominance of perennial forbs under WF treatment was significantly higher than that of CK, with an increase of 100.03%. Additionally, all three restoration treatments (WF, NJF, and DNJF) significantly reduced the ratio of sedges (P < 0.05). Specifically, the sedge ratio decreased by 38.59%, 24.14%, and 28.92%, respectively, as compared to CK. The ratio of annual grasses under NJF and DNJF treatments was significantly higher than CK, with increases of 216.63% and 284.32%, respectively (Figure 3a)..

2.2.2 Summed Dominance Ratio of Raunkiaer's Life Form Functional Groups

The summed dominance ratio of geophyte plants under WF treatment was the highest among the Raunkiaer life form functional groups (Figure 3b). In contrast, among the other three treatments, geophyte plants had the highest ratio under CK and NJF treatments. The summed dominance of geophyte plants in CK and NJF was significantly higher than in WF (P < 0.05), which was 1.74 times and 1.79 times greater, respectively.

2.2.3 Summed Dominance Ratio of Community Water Ecological Type Functional Groups

When categorizing plants based on their adaptability to water conditions (Figure 3c), xerophyte plants dominated the grazing plant communities. The summed dominance ratio of xerophyte plants under WF treatment was significantly lower than under CK and DNJF (P < 0.05), with reductions of 25.73% and 21.94%, respectively.

2.2.4 Summed Dominance Ratio of Community Photosynthetic Pathway Functional Groups

C3 plants dominated the plant communities under all treatments. However, the summed dominance ratio of C4 plants was higher after NJF treatment compared to the other treatments, with a significant increase of 1.47 times over WF ($P < 0.05$) (Figure 3d).

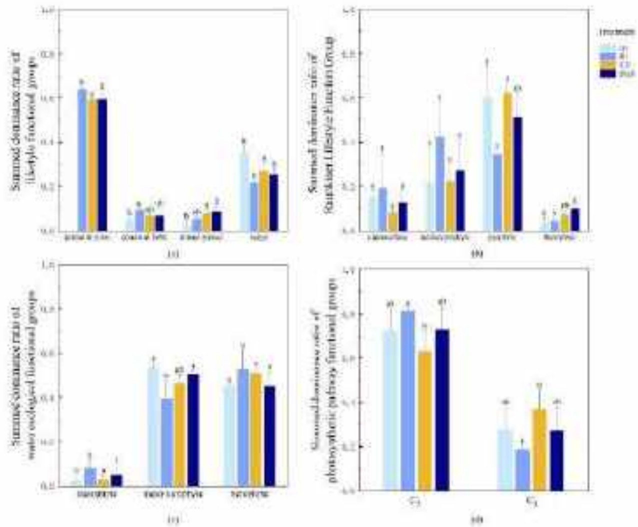

Figure 3 The impact of different restoration treatments on the comprehensive advantage ratio of plant functional groups

2.3 Impact of Different Remediation Treatments on Soil Carbon and Nitrogen Nutrients

The DNJF treatment had a significant effect on increasing soil organic carbon content in the top 0-15 cm soil layer ($P < 0.05$), with a 29.64% increase compared to CK (Figure 4a). The WF and NJF treatments increased organic carbon content by 26.19% and 23.32%, respectively, compared to CK. Among these, DNJF showed the most significant increase in organic carbon content. In the 15-30 cm soil layer, all three remediation treatments increased soil organic carbon content as compared to CK; with WF, NJF, and DNJF increased by 18.14%, 22.56%, and 20.53%, respectively. All three remediation treatments had a positive effect on increasing the total nitrogen content in the soil for both the 0-15 cm and 15-30 cm layers (Figure 4b). In the 0-15 cm soil layer, WF, NJF, and DNJF increased total nitrogen content by 8.46%, 14.97%, and 26.03%, respectively, compared to CK. In the 15-30 cm soil layer, the NJF and DNJF treatments increased total nitrogen content by 4.06% and 42.89%, respectively, compared to CK.

2.4 Impact of Different Remediation Treatments on the Correlation Between Plant and Soil Nutrients

Aboveground biomass, litter dry weight, community height, community coverage, species richness, the Margalef richness index, Shannon-Wiener index, and Simpson index were all negatively correlated with soil nutrients in both the 0-15 cm and 15-30 cm soil layers of CK treatment(Figure 5).

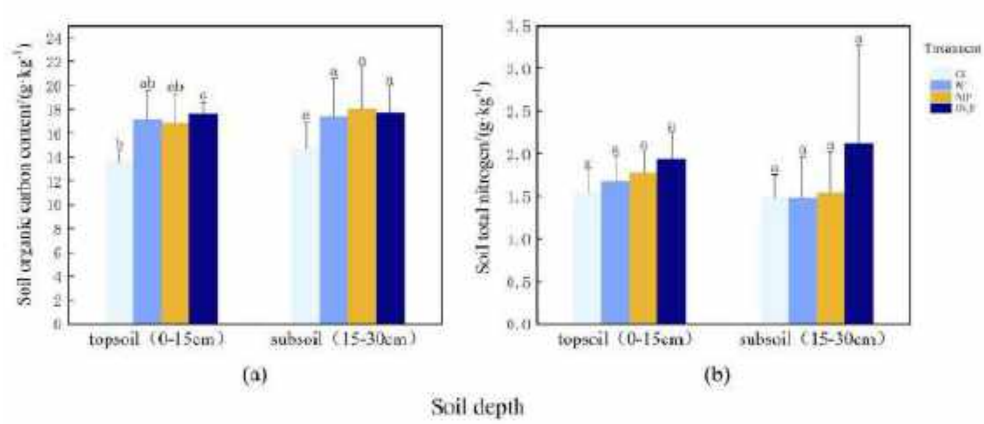

Figure 4 Effects of different remediation treatments on soil carbon and nitrogen nutrient content

Compared to CK, after the WF treatment, the correlation between vegetation indices and soil nutrients generally showed a downward trend, except for litter dry weight, community coverage, and community density. After the NJF treatment, there was a positive correlation between aboveground biomass, community height, and total nitrogen content in the 0-15 cm soil layer. Finally, following the DNJF treatment, the correlation between the Margalef richness index, Shannon-Wiener index, Simpson index, and soil nutrients became positive. Notably, compared to other remediation treatments, the positive correlation between plants and soil nutrients was strengthened under DNJF treatment.

Figure 5 Correlation between Plant Community Characteristics and Soil Nutrients under Different Restoration Treatments in pasture

Discussion

All three restoration treatments promoted the growth of key vegetation indicators, such as aboveground biomass, but their specific effects on plant communities varied. Grassland fencing, a common method for protecting and managing grasslands, restricts human activities and livestock grazing. This approach can enhance the ecological status of grasslands, boosting productivity and biodiversity (Diao Z et al. 2011, Liu T, Yang J, Yang J,et al. 2019). Our results showed that fencing significantly increased aboveground biomass and had the most pronounced effect on vegetation diversity compared to other treatments. From a community composition perspective, fencing increased the proportion of perennial grasses. However, the improvement in the growth of the dominant species, *Leymus chinensis*, was not significant. Liu Hongmei's study Hongmei L et al. 2022) indicated that under fenced conditions, the germination rate of *Leymus chinensis* seeds is lower due to the absence of livestock trampling, which may affect seedling establishment. The higher proportion of drought-tolerant plants under fencing, as compared to other treatments, aligns with findings by Yin Guomei *et al.* (2014) in Hulunbuir. The plant community in fenced areas seems more suitable for arid and semi-arid environments, but it does not restore *Leymus chinensis* to a dominant position. This suggests that further research is needed to determine optimal fencing periods for effective grassland restoration.

THEME 5. MANAGING RISK – CLIMATE AND OTHER SYSTEM SHOCKS AND TRENDS

Climate change impacts and ecological resilience

South African mesic grasslands are resistant to drought but not warming

Tedder, MJ[1]; Maziko, Y[1]; Mbambo, ST[1]; Madikizela, P[1]; Ojo, TA[1]; Kirkman, KP[1]

[1] University of KwaZulu-Natal, Pietermaritzburg, South Africa

Key words: mesic; climate change; species richness, ecosystem services

Abstract

Current climate change models predict increases in temperature, reduced frost and more variable rainfall with increased frequency of extreme weather events such as flooding and drought. Southern Africa is expected to experience more frequent drought, and the grassland biome expected to be significantly affected by this. A possible reduction in area of between 30 and 50% is predicted. Given the importance of the grassland biome from both an intrinsic and economic perspective this reduction could have serious economic and food security consequences. For these reasons, it is critical to increase our understanding of ecosystem processes under drought-stress and warming. In winter 2019 a rainfall exclusion and warming trial was established in a good condition mesic grassland in KwaZulu-Natal, South Africa. Rainout shelters reduced the incoming precipitation by 53% and open-topped chambers increased daytime air temperature by 2°C. Species abundance data was collected annually. Rainfall manipulation had a marginal effect on species composition, however warming resulted in reduced abundance of several common forbs and the loss of numerous forb and grass species, also reducing species richness. Simpson's diversity was unaffected. These reductions in species richness reduce the ability of the grassland to recover from climatic perturbations and thus rainfall reduction coupled with warming presents a significant threat to grassland ecosystem services.

Introduction

In South Africa, the grassland biome is the second most diverse, after the fynbos biome, and contains many rare and threatened species (Rutherford & Westfall 1994). However, almost 60% of the grassland biome has been modified through development and crop production (Low and Rebelo 1998) and less than 3% is conserved (SANBI 2013). The remainder is used for livestock production, predominantly cattle and sheep (SANBI 2013). After modification and degradation, the second major threat to grasslands is climate change (SANBI 2013). Current climate change models predict increases in temperature, reduced frost and more variable rainfall with increased frequency of extreme weather events such as flooding and drought (IPCC, 2022). Data gathered since 1950 has shown increased CO_2, temperatures, and frequency of extreme climatic events (IPCC 2012). Southern Africa is one of the regions expected to experience more frequent, long-lasting drought and heat waves (Trisos et al. 2022 in IPCC, 2022). This will significantly affect the grassland biome, possibly reducing the area by between 30 and 50% (Mucina and Rutherford 2006). Given the importance of the grassland biome from both an ecological and economic perspective this reduction could have serious economic and food security consequences (Kapuka & Hlásny 2021, Miranda et al. 2009). For these reasons, it is critical to increase our understanding of ecosystem processes under warming and drought-stress.

Methods

The trial was established using the Drought-Net Research Coordination Network standard protocols (Smith et al. 2024), where clear plastic roof sheeting was used to impose a statistically extreme, 1-in-100 year drought. Nine plots (5 x 3.5 m, with six 1 m^2 subplots) were arranged in a split-plot, randomised block design in a section of good-condition natural veld at the Ukulinga Research Farm, University of KwaZulu-Natal (30°24′ S, 29°24′ E). The farm has summer rainfall with a mean annual precipitation of 838 mm and a mean annual temperature of 18 °C (Ward et al. 2020). The plots were established in 2019, with the 2019/2020 growing season being the first treatment year. Rainfall manipulation took place at the whole plot level and warming at the subplot level. The rainfall manipulation treatments were drought (53% reduction), ambient and run-on (diversion of intercepted rainfall from drought). Warming was applied on a single subplot using hexagonal open-topped warming chambers made from 2 mm thick clear polycarbonate sheeting (Mu et al. 2017), resulting in an average daytime temperature increase of ~2 °C. Species composition was surveyed at the beginning of the growing season (early December) and at the peak of the growing season (late March). Maximum abundance per species was used for data analysis. In dedicated destructive sampling subplots (for rainfall manipulation only), biomass was harvested after the last rains (late April/early May) and separated into functional groups. Data analysis was conducted in R statistical software (version 4.2.0) and R studio (version 2024.9.1.394) using packages *vegan* (Oksanen et al. 2024) and *dplyr* (Wickham et al. 2023) and plots created using *ggplot* (Wickham et al. 2016) and *ggrepel* (Slowikowski 2024.). Changes in species composition between the first (2020) and the fifth (2024) treatment years were assessed using PERMANOVA and visualised using a partial canonical correspondence analysis. Data were log transformed to reduce the influence of rare species. When PERMANOVA revealed significant effects, a SIMPER analysis was conducted to identify the species contributing to the differences. Differences in species richness and Simpson's diversity were assessed using repeated measures ANOVA.

Results

After five years of treatment application PERMANOVA revealed significant effects of year and warming on species composition (Figure 1 a&b). There was a marginal effect of moisture level ($p = 0.051$) but no significant treatment interactions. SIMPER analyses ($p > 0.05$) indicated that the differences between 2020 and 2024 were driven by decreases in the abundance of two grass species (one palatable and one acceptable), which were replaced by increases in two palatable grass species. Warming resulted in two to three-fold reductions in abundance of three common forb species and an eight-fold reduction in abundance of one acceptable grass species. In addition, five grass and fifteen forb species occurring in low abundance were lost due to warming.

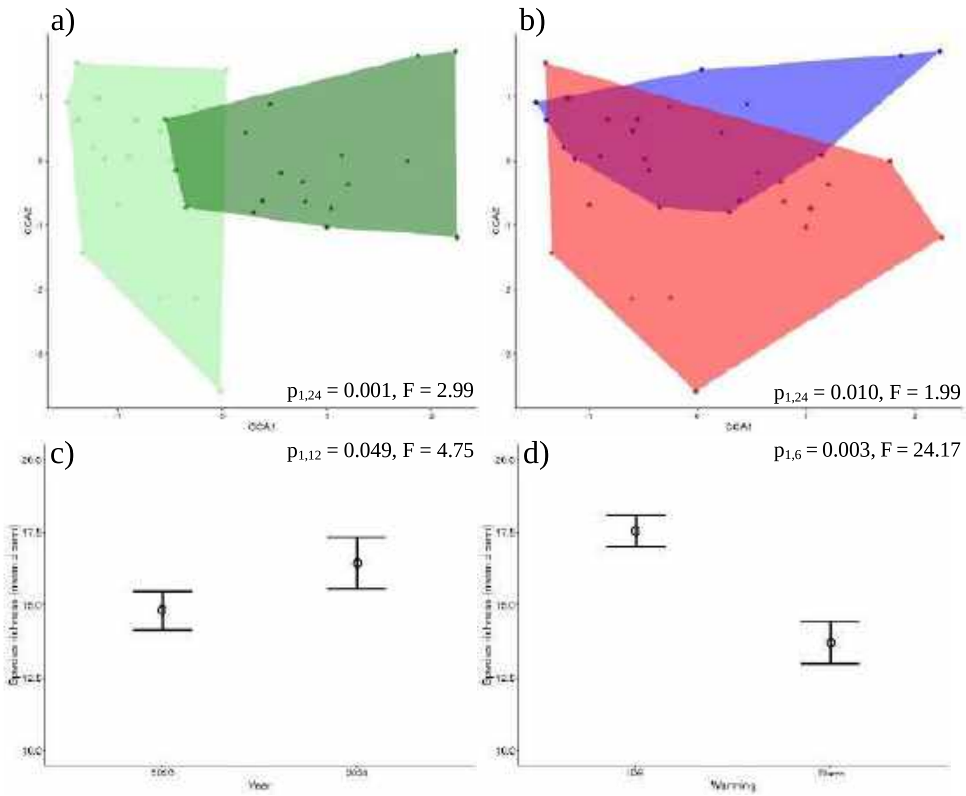

Figure 1: Partial Canonical Correspondence Analysis (pCCA) biplots showing the relationship between species composition (a) Year (2020 in light green and 2024 in dark green), (b) Warming (IDE/unwarmed in blue and warmed in red) after accounting for spatial effects using blocking. Eigenvalues of the axes (CCA1 and CCA2) are 0.218 and 0.171, explaining 18.48% and 14.51% of the constrained variation, respectively. The analysis was conducted after a significant PERMANOVA. The effect of (c) Year and (d) Warming on mean (± SE) species richness after a repeated measures ANOVA revealed significant effects.

Simpson's diversity showed no significant effects. Species richness was also significantly affected by year and warming. Overall species richness increased from 2020 to 2024, while warming reduced species richness compared to ambient conditions (Figure 1 c&d).

Discussion

The distribution of the grassland biome is strongly driven by climate, occurring across a rainfall range of 400 – 2000 mm (Department of Environmental Affairs 2015, Mucina and Rutherford 2006). Mesic grasslands are currently predicted to become 10 – 15% drier (Department of Environmental Affairs 2015). This level of rainfall reduction has been found to significantly reduce grassland productivity and diversity (Miranda et al. 2009), however, the duration of drought has a greater impact on the ecosystem than the intensity (Sala et al. 2015). Single-year drought studies tend to produce more variable responses than multi-year studies (Griffin-Nolan et al. 2018, Petrie et al. 2018) but in general, drought reduces productivity (Balachowski and Volaire 2018) through altered species composition and tuft morphology, and reduction in basal cover. Over the last 14 years, annual rainfall in the study site was observed to fluctuate by over 250 mm above and below the long-term annual mean of 838 mm (unpublished data). The lack of response observed over five years of rainfall reduction is likely due to the adaption of these mesic grasslands to regular rainfall fluctuations, however, with extended exposure to drought the vegetation is expected to lose this resilience (Midgely et al 2011).

The reduction in species richness observed after five years of warming to 2° C above ambient supports the predictions made by SAEON (2015). Since species richness is expected to influence the capacity of the vegetation to withstand and recover from perturbations like droughts (Van Ruijven & Berendse 2010) the combination of warming and long-term exposure to drought puts these grasslands at risk of degradation and woody invasion through reduced fire frequency and intensity. By contrast, diversity was unaffected, likely because the dominant species were unresponsive to the treatments.

Although South African mesic grasslands have been resilient to five years of extreme drought, they have suffered significant degradation through species loss because of warming. Extended exposure to drought, particularly given the marginal significance observed after five years of rainfall reduction, coupled with warming is expected to cause future vegetation degradation. This will result in the loss of numerous ecosystem services which are likely to have economic and food security consequences. This response observed in mesic grasslands, near the centre of the biome's rainfall range, is concerning and highlights the need for research closer to the limits of the rainfall range as these areas are likely to exhibit more rapid and extreme responses.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Temperature change in central Australia: episodic warming

Curran, GC

[1] Animal and Climate Investigations, 160 Cornish Street, Broken Hill, Australia…

Key words: Temperature, episode, breakpoint, change plot, vegetative cover, central Australia

Abstract

From 1871 to 2024, central Australia experienced distinct warmer and cooler episodes, delineated by breakpoints in mean monthly maximum temperatures (maxima). Early episodes trended cooler; some warmer; later episodes trended warmer. Cooler and warmer components of the maxima both trended warmer in recent years. A system constant of 2.57^{o}C (the difference in episode averages between warmer and cooler components of maxima) was found across the 109 sets of records examined. Changes in Alice Springs maxima from 2001 to 2024 were strongly related to changes in certain oceanic climatic indicators and rainfall. Changes in arid South Australian vegetative cover were related to changes in maxima and changes in rainfall. Monthly changes in components of its vegetative cover were associated with changes in a complex of maxima, rainfall, and different ocean indicators.

Introduction and Methods: *Expecting the average, knowing the unexpected*

Each day, each month, each year, we expect the temperature to be average, despite its continuing rise and fall, while wanting to know whether it will be, is, and has been hotter or colder than we expected. This difference to the average ("*the unexpected*") is as important to us as the average. When Alice Springs maxima are plotted by month, the difference to the average surges up and down (Fig. 2), different to the structured if ragged maxima (Fig. 1). (Figs. 1 to 5 use Alice Springs Post Office 1887-1953; Fig 6 shows Alice Springs Airport 1941-2024)

When you add these differences together in sequence, you form the Change Plot (Fig. 3), showing how maxima have changed over time, once you've allowed for temperature increase or decrease. A Change Plot depicts what you didn't expect, and have not known, including episode duration and the large difference between each and all warmer and cooler episodes (Fig. 1.4).

In any change plot, all measures in an incline were above average, and below average in any decline, but not increasing nor decreasing significantly within each episode. The peaks and troughs are the sharp breakpoints between warmer and cooler episodes.

Change plots were used to visualise and analyse the interrelationships of maxima, rainfall, vegetation, and oceanic climatic indicators. Regression analysis, ttest, tabulation and chi test were statistical methods employed (Stata: www.stata.com). Alice Springs maxima and the vegetative cover of arid South Australia are used as examples for central Australia.

Monthly temperature and rainfall data were downloaded from Australian Bureau of Meteorology (BOM: www.bom.gov.au/climate/data). Ocean indicators were from BOM and National Oceanographic and Atmospheric Administration (https://www.ncei.noaa.gov/cdo-web/). Vegetative cover data were from Rangelands and Pasture Productivity (https://map.geo-:rapp.org).

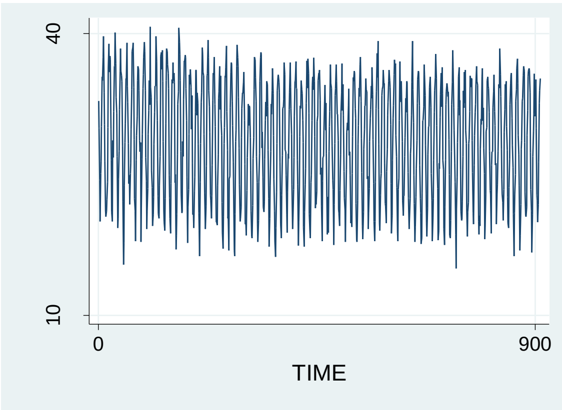

Fig. 1 Monthly maxima

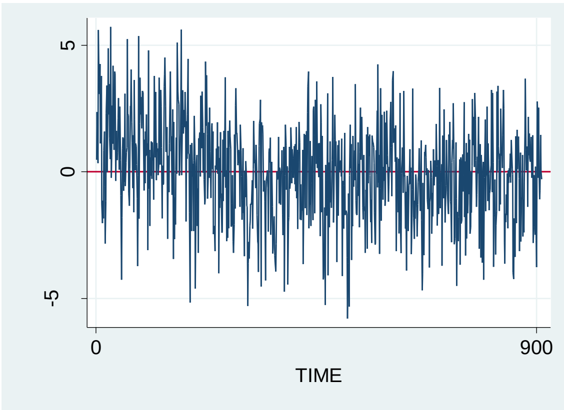

Fig. 2 Difference to monthly average

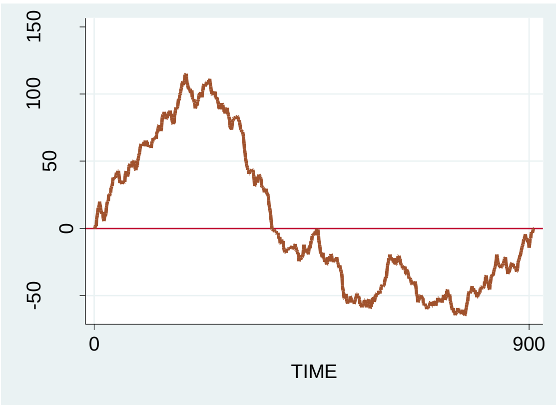

Fig. 3 Change Plot

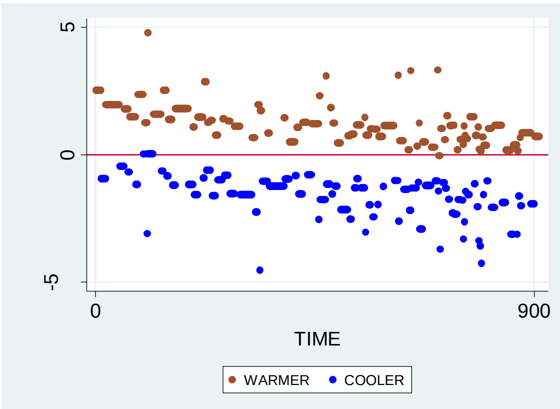

Fig. 4 Episode Mean Difference to Average

Results:

Seeing temperature change

The numerous short episodes that can be seen in the change plots of Alice Springs Post Office (159 between 1878-1953 – Fig. 3) and Airport (343 between 1941-2024) can be grouped into 28 longer episodes (Fig. 5). These episodes have two features:

- Large episodic oscillations between cooler and warmer episodes
- A distinct fall then rise

The duration of longer oscillations can vary from less than 1 year to decades.

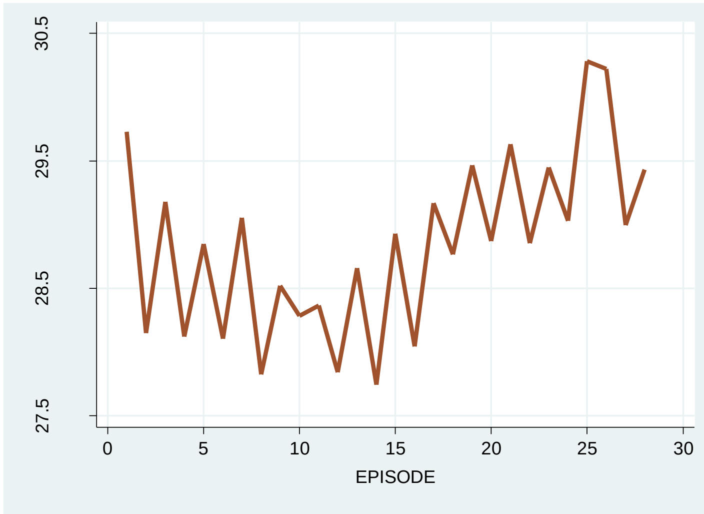

Fig. 5. Longer cooler and warmer episode maxima for Alice Springs 1878 to 2024

These oscillations in maxima were found in all 109 central Australian records examined, together spanning 1871 to 2024. See locations in Appendix.

Warmer and cooler episodes of the maxima oscillate about a constant

Parsing the change plot of monthly maxima for Alice Springs (1941 to 2024) found 172 warmer and 171 cooler episodes. Each mean episode difference to the average is plotted in Fig. 6. The warmer episode means averaged 30.45 ºC lasting 3.1 months; the cooler episode means averaged 27.10 ºC and 2.6 months, compared with general mean of maxima: 28.92ºC.

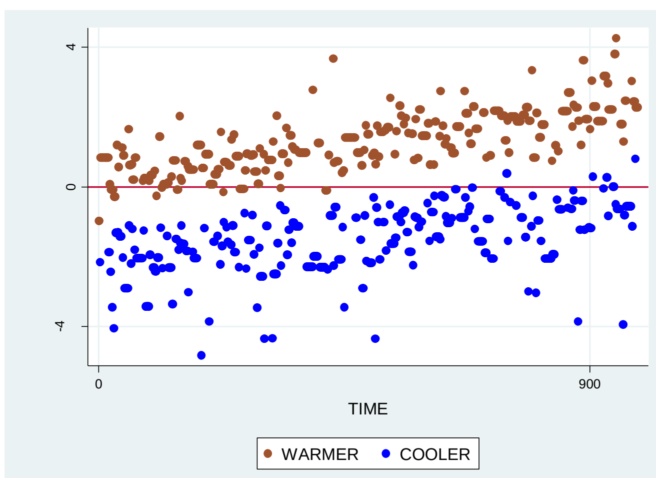

Fig. 6. Episode mean difference to average monthly maxima: Alice Springs 1941 to 2024

The trend in warmer and cooler maxima averaged 0.0128 ºC per warmer episode and 0.0098 ºC for cooler episodes. The maxima had a lower trend of 0.0012 ºC. The decadal change for warmer episodes was 0.266 ºC; 0.198 ºC for cooler episodes, and 0.234 ºC for all maxima. Over the 83 years, the mean episode difference between warmer and cooler episodes of the maxima averaged +2.81 ºC, larger than the total change in maxima (+1.93 ºC). The total change in maxima for Alice Springs 1878-1953 (see Fig. 4) was a cooling of -1.44 ºC.

Falls in maxima were common in records beginning before 1940 (21 of 32 sites) across central Australia. Rises in maxima were observed in all records beginning from 1940. Decadal trend averaged +0.032ºC for records commencing before 1940, and +0.310 ºC for later sets of records.

For 109 sets of records from 1871 to 2024, the difference between the warmer and cooler shorter episode means centred around a constant: +2.57 ºC (95% CI: 2.53 to 2.61). The varying durations of shorter episodes determined the timing of the larger oscillations, together with varying maxima. The average durations of shorter episodes at any site varied from 2.2 to 5.7 months, with a mean of 3.63.

The oceans influenced maxima

Changes in and over surrounding oceans were related to changes in maxima. For monthly maxima of 4 Alice Springs area sites (Airport, Jervois, Kulgera, Grape Farm) from 2001 to 2024, change in amplitude of the MJO (Δ_MJOAmpl) accounted for 43% of changes in maxima on regression analysis. Including changes in SOI, AO and IOD explained 75% of maxima changes; adding changes in rain raised explanatory power to 90% for changes in monthly maxima:

Δ_maxima ~= +2.25 Δ_MJOAmpl – 0.052 Δ_SOI + 0.67 Δ_AO - 0.95 Δ_IOD -0.048 Δ_rain - 3.393977

*[*Abbreviations*: Δ_parameter: change in a parameter; SOI: Southern Oscillation Index; AO: Antarctic Oscillation; IOD: Indian Ocean Dipole; MJO: Madden-Julian Oscillation - Ampl Amplitude; Phase-Phase; RMM1 -RM1; RMM2 -RM1]*

Maximum temperature changes influenced vegetative cover

Monthly changes in vegetative cover (2001 to 2024) were related to the warmer and cooler episodes when considered with changes in rainfall across central Australia. In one example, the relationships for arid South Australia (see Appendix) were stronger for %green cover and %bare ground than for %non-green cover on regression analysis.

- Δ_Green ~= +1.20*Δ_max +0.38 *Δ_rain +19.1 (R^2 - 0.67)
- Δ_Non-Green ~= +2.80*Δ_max +0.32*Δ_rain +51.7 (R^2 - 0.39)
- Δ_Bare Ground ~= -4.00*Δ_max - 0.75*Δ_rain - 75.5 (R^2 - 0.52)

Maxima and rainfall were for 6 sites (Oodnadatta, Moomba, Woomera, Marree, Yunta, Ceduna).

Maxima, rainfall and the oceans influenced vegetative cover

Changes in vegetative cover of arid South Australia were related to changes in oceanic climatic indicators combined with changes in maxima and rainfall on regression analysis:

- Δ_Green: Δ_[maxima, rain. amplitude of MJO, SOI] (R^2 - 0.85)
- Δ_Non-Green: Δ_[maxima, rain, SOI, IOD] (R^2 - 0.60)
- Δ_Bare Ground: Δ_[maxima, rain, SOI, AO, {Phase, RM2 of MJO}] (R^2 - 0.76)

- Δ_Total Cover: Δ_[maxima, rain, SOI, AO, {Phase, RM2 of MJO}] (R^2 - 0.76)

Discussion, Conclusions and Implications

This study found central Australian maximum temperatures from 1871 to 2024 had structured variability in a binary (warmer/cooler) system with breakpoints delineating episodes. This system may be determined by or interact with oceanic and continental influences, as well as rainfall, from analysis of 2001 to 2024 records. Changes in vegetative cover may be a part of this systemic interaction. The Madden-Julian Oscillation was found to be important in maxima changes, and vegetative cover change.

Changes in maxima were important in vegetative cover changes. Intuitively, the observed large jumps in maxima between cooler and warmer episodes are likely to be important for vegetation. The marked increases over time in both cooler and warmer components of the maxima across central Australia are concerning due to the anticipated manifold effects of global warming, and the likelihood of episodic, extended, widespread large increases in maxima; correlated reduction in rainfall; and consequent widespread falls in vegetative cover.

The widespread cooling from early 1900s may reflect the severe loss of vegetation and soil with the rabbit invasion of eastern Australia and overstocking of its rangeland areas (Barnard 1962, Rolls, 1984; Lunney 1994), with subsequent buildup of airborne particulates, as with "*global dimming*". It is also possible that the limited evidence of warming from the early 1870s to 1890s may reflect the cessation of indigenous burning practices to manage vegetative cover, thereby reducing airborne particulates, as their populations and culture were affected by Europeans from late 1700s and first part of 1800s onwards (Gammage 2012).

Using change plots to visualise and analyse empirically and statistically the dynamics and interrelationships of vegetation, climate and other phenomena opened new ways to understand and quantify Australian rangelands. Change plots remove the cyclic elements of temperature and vegetation that obscure underlying linear change and discontinuities.

Episodicity and episode duration can be included as climate characteristics (Foley 1957, Curran 2023).

The episode mean [*warmer-cooler*] difference is a system constant, in the same sense that each location has a characteristic average rainfall, and differences between wetter and drier episodes centre on constants (Curran 2023), despite varying considerably around that constant from year to year, by month-of-year, and within each day.

Wealth creation, income distribution, and adaptation among Sahelian (agro)pastoralists in a shock-prone environment

Wane, A[1]; Touré, I[2]; Mballo, AD[3]; Ndiaye, A[4]; Souli, Z[2]; Botoni, EY[5]; Tankari, I[5]; Diao, MB[6]

[1] International Livestock Research Institute (ILRI), [2] French agricultural research and cooperation organization (CIRAD), [3] International Fund for Agricultural Development (IFAD), [4] Practical Action, [5] Permanent Interstate Committee for Drought Control in the Sahel (CILSS), [7]Regional Agency for Agriculture and Food (RAAF)

Abstract
Sahelian (agro)pastoralists face significant undervaluation of their livelihoods. A 2017-2021 comparative study across six Sahelian countries, involving 3,070 households initially and 2,216 later, examined income trends and coping strategies. Household incomes stabilized at around 2 million FCFA annually from 2017 to 2020, with notable disparities across countries. Burkina Faso, Mali, Mauritania, and Senegal saw income growth, while Chad experienced a decline. Livestock sales and reliance on subsistence farming influenced these differences. Despite challenges, livestock sales remained crucial, though declining in some areas. Adaptive strategies like destocking and mobility were employed, but limited capacity hindered stronger responses.

Introduction
In developing countries with large livestock sectors, the challenge is to promote efficient production systems that meet rising demand while minimizing environmental and health impacts and improving smallholder farmers' well-being. Pathways for growth include genetic improvements, better nutrition, disease control, environmental risk management, and infrastructure development. However, each country's livestock sector is shaped by its unique context. A critical issue for policymakers is the lack of reliable, up-to-date data (Alary et al., 2011; Wane et al., 2009a, 2009b, 2018, 2020, 2024). Incomplete data and improper economic modeling can hinder effective policymaking and overlook indirect contributions like draft power and manure (Pica-Ciamarra et al., 2014; Kebebe, 2019).

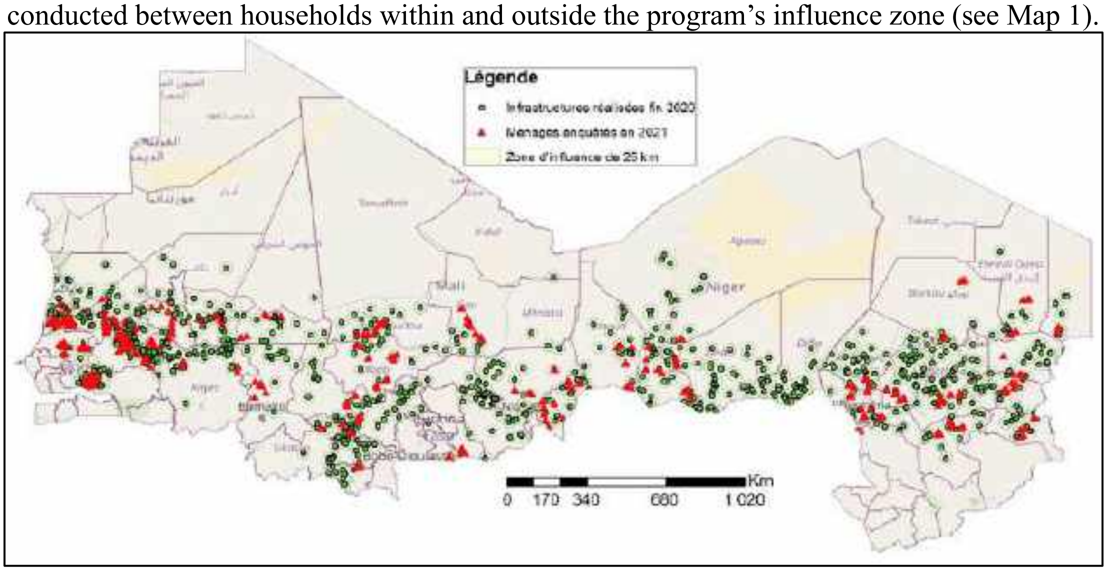
Method
This study examines household income dynamics within Sahelian agro-pastoral communities, utilizing data from two survey periods (2016-2017 and 2020-2021) to enable both aggregated and disaggregated comparative analysis. The primary focus is on the evolution of income inequality, framed within Sustainable Development Goal (SDG) No. 10, which aims to reduce economic disparities. In addition, the study develops an approach to assess the multifaceted shocks experienced by pastoral households and the priority strategies they adopt to address threats to their income, assets, food security (including both production and

purchasing capacity), food stocks, and livestock holdings. The analysis draws on 3,070 agro-pastoral households surveyed in 2016-2017 and 2,352 households in 2020-2021 across six Sahelian countries.

Table 1. Strategic Selection of Study Sample Sizes

	Survey sample 2016-2017	Survey sample 2020-2021
Mauritania	527	353
Senegal	948	359
Mali	579	360
Burkina Faso	513	404
Chad	503	359
Total (without Niger)	**3 070**	**1 835**
Niger	NC	517
Total (including Niger)	**n.a.**	**2 352**

This study analyzes income evolution by revisiting a sample of 350 households from a 2016-2017 survey in 2020-2021. During this period, the PRAPS1 program significantly invested in infrastructure (boreholes, vaccination parks, livestock markets, production routes, dairy units, etc.) and economic services (Support for agro-pastoral organizations, capacity building, etc.). A comparative analysis was conducted between households within and outside the program's influence zone (see Map 1).



Map 1 – Location of Surveyed Households in PRAPS Countries in 2021 marked with red triangles, and infrastructural investments marked with green circles.

Results and discussions

Impact of Multidimensional Shocks on Sahelian Agro-Pastoral Households: Income, Assets, and Livelihoods

Between the two survey periods, 27% of households in six Sahelian countries reported climate-related, 36% health-related, 26% economic, 8% security-related, and 3% social shocks. Analysis of shocks over the past three years reveals varied impacts on daily life. Climate shocks primarily involved droughts (71% of households), particularly in Mauritania (92%) and Burkina Faso (89%), with flooding reported in Chad (51%) and Mali (49%). Health shocks, notably animal diseases, affected 50% of households, with significant global disparities. The COVID-19 pandemic also had severe economic and health consequences. Economic shocks included rising food and livestock feed prices, while security shocks involved livestock theft and bushfires. Social shocks included reduced financial transfers (remittances from migrants across and outside Africa), notably in Mali and Niger.

Adaptation Strategies and Coping Mechanisms of Sahelian Agropastoral Households in Response to Multidimensional Shocks

Sahelian (agro)pastoralists have employed various strategies to safeguard their livelihoods amid multifaceted shocks. Key adaptive strategies include destocking (22%) and mobility (14%). However, a concerning 15% of households reported no response, reflecting limited coping options.

Table 2. Prioritized Strategies of Sahelian Households in Response to Multifaceted Shocks

Description	First priority	Secondary priority	Tertiary priority	Description	First priority	Secondary priority	Tertiary priority
Community Support	0%	1%	2%	Seasonal Migration	2%	2%	2%
NGO Assistance	2%	2%	2%	Permanent Migration	0%	0%	0%
Government Aid	2%	2%	2%	Long-Term Migration	1%	1%	1%
Help from Relatives	4%	6%	8%	Family Labor	7%	7%	6%
Alternative Income Activities	1%	2%	3%	Wage Labor	3%	4%	3%
Placing children with other families	0%	0%	0%	Mobility Strategies	14%	5%	4%
Destocking	22%	15%	10%	No Response/No Strategy	16%	17%	27%
Borrowing/Loans	5%	8%	8%	Meal Reduction	3%	3%	2%
Market Garden Fencing	2%	2%	2%	Reduced Food Portions	2%	3%	3%
Fodder Storage Enclosures	1%	1%	1%	Use of Food Substitutes	3%	3%	2%
Savings Strategies	4%	7%	4%	Selling Non-Productive Assets	1%	1%	1%
Adoption of Resilient Species	1%	1%	1%	Selling Productive Assets	0%	1%	1%
Additional Employment	2%	3%	2%	Selling Food Reserves	2%	2%	1%

The COVID-19 pandemic further exacerbated challenges by restricting mobility and market access, causing a decline in destocking (from 15% to 10%) and an increase in inaction (from 16% to 27%). Borrowing also rose from 5% to 8%. These trends indicate a weakening of adaptive capacity, emphasizing the need for targeted interventions to strengthen resilience. Country-specific responses varied, with notable increases in inaction and reliance on external support.

Adapting Livelihoods: Income Generation in the Context of Multidimensional Shocks

In the context of multifaceted shocks, Sahelian (agro)pastoralists primarily generate income from livestock, with subsistence consumption playing a pivotal role in securing their livelihoods. Between 2017 and 2020, total income, including livestock sales, crop sales, foraging, transfers, and subsistence, remained stable at around 1.9 million FCFA annually per household. Income increased by 0.6% when including Niger and by

6% excluding Niger, although regional disparities persist. In countries like Burkina Faso, Mali, Mauritania, and Senegal, income grew (9%, 14%, 7%, and 13%, respectively), while Chad saw a 13% decline.

Table 3. Summary of income indicators and their variations over time

Country	Overall income 2016	Overall income 2021	Variation 2016-2021
Burkina Faso	1,501,293	1,647,793	10%

The Role of Self-Consumption and Collective Investments in Reducing Income Inequality in Sahelian Agro-Pastoral Systems

Economic contributions of agro-pastoral households remain threatened by high levels of inequality despite slight reductions between survey periods. These inequalities stem from unequal access to productive resources. Little et al. (2001) and Wane et al. (2020) highlighted that high inequality in Sahelian pastoral and agropastoral systems is linked to limited access to economic resources such as infrastructure and land. A major challenge is addressing these disparities, measured through Gini monetary and total income indices. Between 2017 and 2020, PRAPS zone countries showed high-income inequality (Gini indices between 0.47 and 0.71) in the (agro)pastoral areas. However, Gini indices for monetary income generally decreased, reflecting improved economic conditions, especially in Mauritania (-25%). Total income inequality, including subsistence, also declined across all countries. In Niger, while income inequality remained high, areas influenced by PRAPS programs showed slightly less disparity. A key takeaway is that self-consumption (the equivalent income value of consuming what the agropastoralists produce themselves) significantly reduces income inequality, especially during disruptions like COVID-19. High inequality often reflects unequal access to productive resources and poses a source of instability. Reducing inequality aligns with targeted investments in agropastoral economies, reinforcing the value of PRAPS initiatives.

Conclusion

The analysis of income among Sahelian agropastoral households, though partial due to the lack of data for Niger in 2016, reveals significant trends. Between 2017 and 2020, total household income remained relatively stable at around 2 million FCFA. However, disparities were observed: incomes rose in Burkina Faso, Mali, Mauritania, and Senegal, while a decline occurred in Chad. Subsistence consumption played a crucial role in reducing income inequalities. Regarding shocks, 27% of households reported climate-related, 36% health-related, and 26% economic shocks, with varied coping strategies. Security-related shocks were less reported, likely due to inaccessible regions for investments and surveys. The COVID-19 pandemic worsened uncertainty, emphasizing the need for regular surveys and targeted aid programs.

Acknowledgments

CILSS unwaveringly supported these surveys and the subsequent syntheses through the World Bank-funded Regional Sahel Pastoralism Support Project, ensuring comprehensive and sustained assistance.

Key words: Grassland, Mediterranean, Sustainable management

Abstract
Grassland systems are one of the most important ice-free ecosystems on Earth. They are important suppliers of ecosystem services such as carbon sequestration, biodiversity support, or pollination. However, in the last decades, there has been evidence of climate change linked to higher temperatures and reduced precipitation. In this study, we provide insight into the long-term dynamics of grassland systems that could help guide sustainable management. Grasslands in Spain are commonly located in the northern regions but also extend inland, where herbaceous and shrubby vegetation have adapted to thrive despite water scarcity conditions. Our study targets the region of Madrid, at the heart of the Iberian Peninsula, where grasslands cover almost 41% of territory. With reference to the Sixth Assessment Report from the Intergovernmental Panel on Climate Change, we established a 5×5 km grid to assess the proportion of grassland coverage. We employed proximity to a soil pit and a minimum grassland coverage of 40% within each grid cell as selection criteria. We gathered daily historical climate data on temperature and precipitation from 1950 to 2014 and future projections from 2015 to 2100. The future projections were SSP-4.5 and SSP-8.5 scenarios based on Shared Socioeconomic Pathways. First, we used MODIS data (2000–2024) to identify grassland coverage anomalies. Then, we applied the SIMPAST model, which required climate data, hydrological balance, solar radiation, and an initial seed count. Vegetation species were identified from September to May 2024–2025.

Introduction
Grasslands provide essential ecosystem services such as forage production, carbon sequestration, and biodiversity maintenance. They support extensive livestock systems and contribute to ecological stability. Additionally, they act as carbon sinks, regulate the hydrological cycle, and serve as habitats for diverse

plant and animal species (Bengtsson et al. 2019). Shaped by climate and human activity, Madrid's grasslands host a mix of herbaceous and woody species, creating ecologically valuable landscapes with notable differences between the north and south. However, their dynamics are highly sensitive to climatic, edaphic, and hydrological factors, as well as human management practices, making them vulnerable to climate change (Zhao et al. 2020). Projected climate trends for the Iberian Peninsula suggest rising temperatures, intensified heatwaves, and decreasing precipitation, leading to more frequent droughts and extreme weather events (Sanz-Elorza et al. 2003). These changes threaten water availability and ecosystem resilience, particularly in grasslands dependent on seasonal rainfall and soil moisture retention (Joyce et al. 2016). Such climatic shifts pose a major challenge to pasture productivity, a key resource for livestock. Reduced biomass and declining forage quality may jeopardize traditional grazing systems, increasing production costs and undermining economic sustainability, especially in extensive livestock farms that rely on natural pastures (Carozzi et al. 2022). Understanding the dynamics of herbaceous biomass under different climatic scenarios is crucial for developing sustainable adaptation and management strategies. The present study addresses this issue through an integrated approach that combines modeling based on climatic, edaphic, and hydrological data with fieldwork for the empirical characterization of herbaceous biomass. We selected three study areas representative of different environmental conditions within the Mediterranean environment at Central Iberian Peninsula: Buitrago del Lozoya (northern zone 975 m of altitude, influenced by a mountain climate), Colmenar Viejo (central zone 883 m, in the transition between *dehesa* (open forest pasture) and grassland systems), and Tielmes (southern zone 585 m, with a drier climate and greater agricultural pressure).

The study has the following main objectives: 1) Analyze the evolution of herbaceous biomass in relation to climatic and soil conditions. 2) Develop a predictive model to estimate pasture productivity under different climate change scenarios. 3) Provide information for livestock management and the conservation of herbaceous ecosystems.

Through this multidimensional approach, we aim to contribute to the design of climate change adaptation strategies and the optimization of pasture management, promoting the sustainability of agricultural systems and the conservation of ecosystem services associated with these ecosystems. Additionally, the results may be useful for the formulation of environmental management policies and informed decision-making in territorial planning and biodiversity conservation.

Methods

The study was conducted in three regions within the Community of Madrid, Spain, each selected for their distinct climatic and edaphic characteristics (Figure 1). These sites represent a gradient of environmental conditions, from humid mountain areas to semi-arid agricultural landscapes, allowing for an assessment of pasture biomass response to climate regimes. 1) Buitrago del Lozoya (North): A mountainous area with cooler temperatures, higher rainfall, and deeper soils that enhance drought resilience. 2) Colmenar Viejo (Central): A transitional zone with moderate precipitation and high sensitivity to drought, where land use and grazing influence pasture productivity. 3) Tielmes (South): The driest and warmest site, with shallow soils and low water retention, making it highly vulnerable to climate change impacts.

A process-based biomass simulation model, based on the SIMPAST framework (Etienne et al. 2008), was used to estimate pasture productivity under different climate scenarios. The model integrates climatic and edaphic variables to dynamically assess biomass production over a hydrological year. Climatic inputs include daily precipitation, maximum, minimum, and mean temperatures, as well as solar radiation and potential evapotranspiration, derived from six IPCC AR6 models (IPCC,2023) under four SSP scenarios

(SSP1-2.6, SSP2-4.5, SSP3-7.0, SSP5-8.5) for 2021–2100, with historical data from 1975–2021 (Kriegler et al., 2014; Riahi et al., 2017). Edaphic factors such as soil water retention, field capacity, wilting point, and effective soil depth were incorporated to evaluate moisture availability and its influence on pasture dynamics.

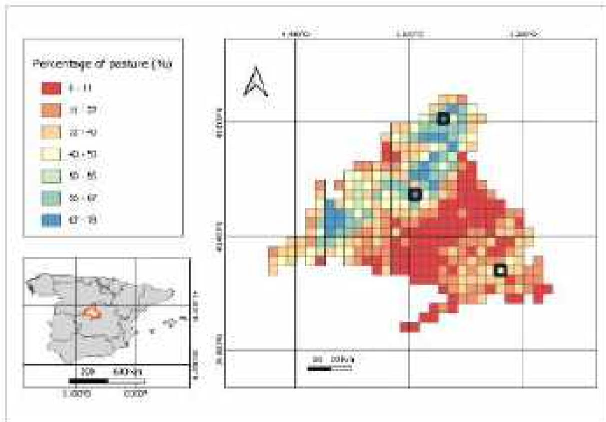

Figure 1. Geographic distribution of pasture percentage per pixel within the study area in the region of Madrid, Spain, derived from SIGPAC data and analyzed using QGIS (black circle).

The model calculates net primary productivity (NPP) and incorporates the leaf area index (LAI) as an indicator of vegetation cover. The hydrological balance is simulated by analyzing interactions between precipitation and soil moisture retention capacity, allowing for the assessment of biomass dynamics under historical and future climate conditions.

Results

Projected climate trends for the Madrid area (Spain) show a significant increase in annual mean temperature across all four SSP scenarios (Figure 2). By 2100, the highest-emission scenario (SSP5-8.5) suggests temperature increases exceeding 4 °C, while even the most optimistic scenario (SSP1-2.6) predicts warming above historical averages. These changes will likely intensify heatwaves and reduce seasonal thermal variability, impacting vegetation cycles and water availability.

Pasture biomass projections reveal strong spatial and temporal variability (Figure 3). The northern region (Buitrago del Lozoya) maintains relatively stable biomass levels due to higher precipitation and deeper soil. The central region (Colmenar Viejo) exhibits greater sensitivity to precipitation fluctuations, with biomass reductions during drought years. In contrast, the southern region (Tielmes) experiences the sharpest decline in biomass availability, highlighting its vulnerability to prolonged dry conditions and rising temperatures.

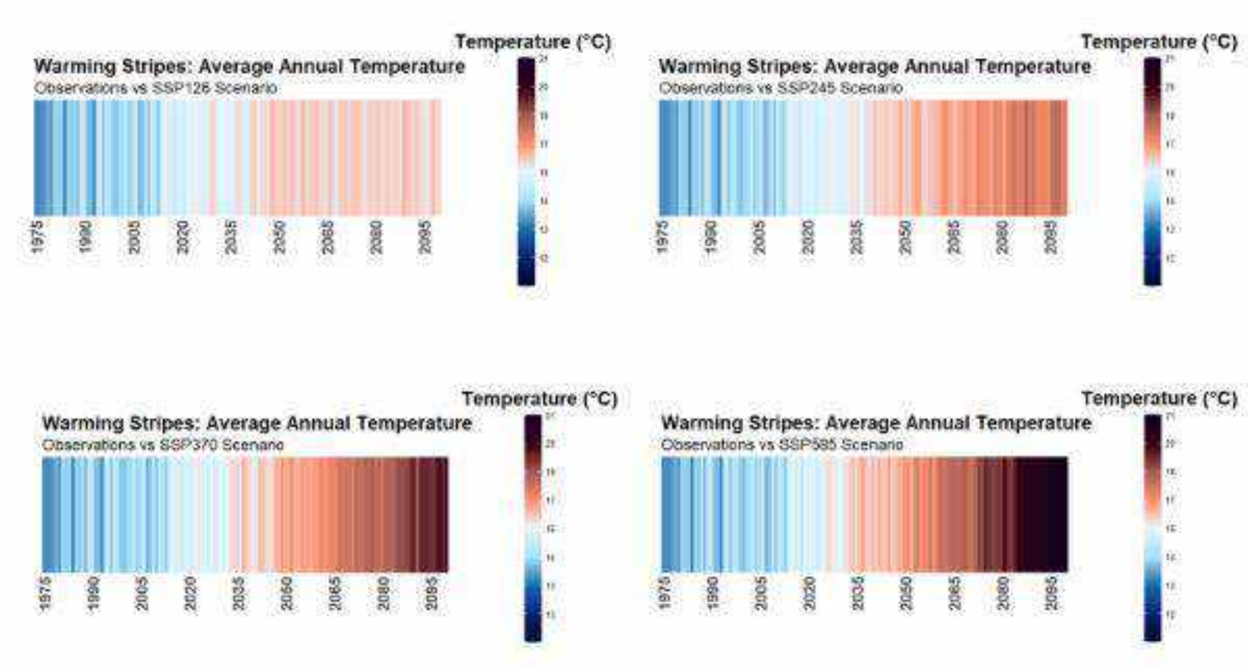

Figure 2. Annual mean temperature trends from 1975 to 2100 across the four SSP scenarios (SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5) in the region of Madrid, Spain (Central Iberian Peninsula).

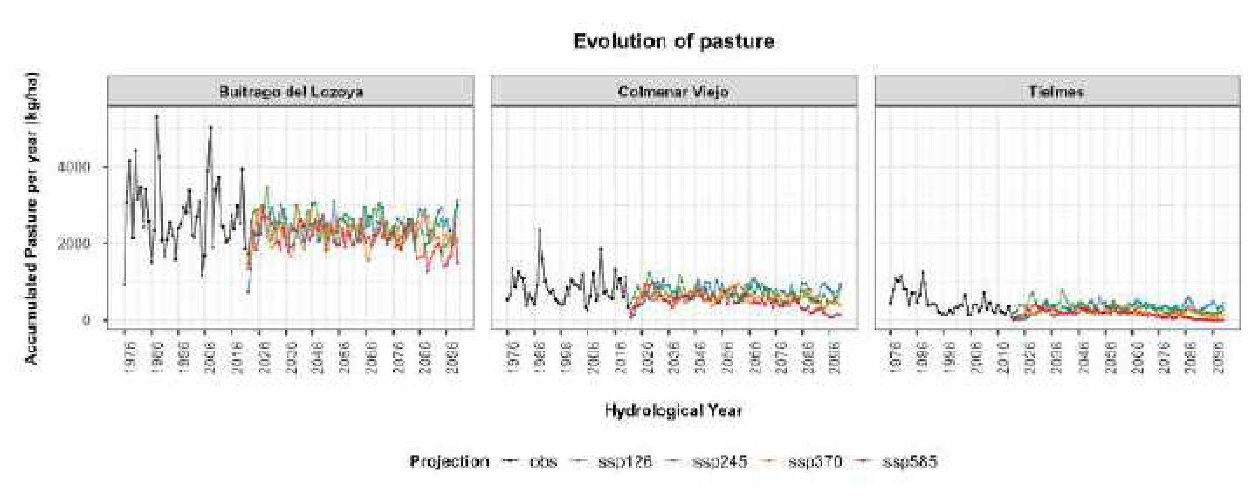

Figure 3. Temporal changes in simulated pasture biomass (dry matter) across the selected grids, showing interannual variability influenced by climate projections (Obs: observed climate; ssp126: SSP1-2.6, ssp245: SSP2-4.5, ssp370: SSP3-7.0, and ssp585 SSP5-8.5 scenarios).

Our results indicate that climate change will significantly affect pasture productivity, particularly in water-limited environments. While higher-altitude areas like Buitrago del Lozoya (North) may retain relatively stable biomass, warmer and drier regions such as Tielmes (South) will likely face severe reductions in forage availability. These findings align with previous studies on Mediterranean grasslands, where increasing aridity reduces primary productivity and alters species composition (Oesterheld et al. 1999; Peñuelas et al. 2007; Wang et al. 2022). This project highlights the importance of land management practices in mitigating productivity loss. Strategies such as adaptive grazing, improved soil conservation, and drought-resistant forage species may help sustain livestock systems under changing climatic conditions.

Conclusions and Implications

This study highlights the potential impacts of climate change on pasture productivity in the Madrid area of Central Spain, emphasizing regional differences in vulnerability. Northern grasslands may remain productive, while central and southern areas could experience substantial biomass reductions, affecting livestock sustainability. These findings underscore the need for adaptive management strategies to mitigate productivity losses and ensure the long-term viability of extensive livestock systems, key for economy and ecosystems. Future steps will include field validation through biomass sampling and species inventories, analysis of extreme events and integration of land management practices into the model as well as stakeholder engagement with local farmers and other land managers.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

How are global megatrends likely to provide opportunities and challenges for Northern Australian rangelands?

Penrose, B[1]; Greenwood, S[2]; Mayberry, D[2]; Perry, L[1]

[1] Research Institute for Northern Agriculture, Charles Darwin University, Ellengowan Drive, Brinkin, NT; [2] CSIRO Agriculture and Food, 306 Carmody Rd, St Lucia, QLD

Key words: global megatrends; northern beef industry; cattle industry; Australia

Abstract

Over half of Australia's beef cattle are managed in extensive rangeland systems in the north and are vulnerable to climate challenges, infrastructure and labour limitations, and disruptions to trade. In this paper we consider research and industry viewpoints to explore opportunities for the northern Australian beef industry to ensure a sustainable, productive and profitable future. Our analysis is framed by the following megatrends; (1) adaptation to a **warmer and more variable climate** to protect livelihoods, infrastructure, and quality of life, (2) the **technology revolution and expansion** into northern Australia, providing new solutions to old problems, (3) **geopolitical shifts**, which change trade dynamics, disrupt supply chains, and offer alternative domestic and international markets, (4) the push for **more efficient resource use, with reduced impacts** on animals and the environment driven by changing consumer and market expectations, and (5) changing **regional demographics and human capital constraints**, which limit operational efficiency and social capital. While all megatrends will create some universal magnitude of effect, the unique landscapes and agricultural systems of the northern Australian rangeland system require a tailored, place-based assessment.

Introduction

Northern Australian rangelands encompass the tropical savannas, woodlands, shrublands and grasslands of the Northern Territory, Queensland, and Western Australia. Land use is dominated by cattle production based on unmodified native pastures, with other areas used for conservation, mining, defence, and as designated Indigenous Protected Areas. Livestock production in this region is typified by extensive pastoral properties used for cattle breeding operations and managed by a mix of family-owned and corporate enterprises. Production is orientated towards live-export, with cattle often transported long distances to one of four northern ports, before being shipped to Indonesia, Vietnam and other international destinations. The harshness of the landscape and unreliability of seasonal rainfall on a marginal feedbase is reflected by low livestock growth rates, sub-par reproductive efficiency and high mortality in both breeding stock and calves (McCosker et al, 2023). Complex land tenure rights, a sparse population that limits investment and expansion of infrastructure and historically poor phone and internet connectivity have all contributed to slow development. However, recent advances in technology and shifting overseas markets have the potential to be transformative. In this paper, we explore the influence of global megatrends, and the unique challenges and opportunities they present for northern Australian beef production systems going forward.

Adaptation to a warmer and more variable climate

The climate of northern Australia is characterised by distinct wet (October and April) and dry (May and September) seasons, though total annual rainfall is highly variable between years. There is high certainty that average temperatures and extreme heat events will increase into the future (CSIRO and Bureau of Meteorology, 2015), impacting the productivity and welfare of both livestock and people. Northern Australian cattle production systems are already adapted to hot conditions, with the region currently dominated by tropically-adapted *Bos indicus* breeds and their crosses. However, this region may also experience an increase in the frequency and/or intensity of extreme events such as heatwaves, cyclones, floods and bushfires (CSIRO and Bureau of Meteorology, 2015). These events affect the northern beef industry via impacts on livestock (reduced feed intake, mortalities), landscapes (soil erosion, damage to pastures) and infrastructure (loss of roads, fences, buildings), in turn impacting supply chains and rural communities. In addition, changing climates may be accompanied by biosecurity challenges, with changes in the range of endemic pests and diseases combined with new incursions.

While producers already make tactical decisions such as adjusting herd sizes to cope with harsh conditions and seasonal variability, extreme events are harder to prepare for because they are difficult to predict at local scales (temporally and spatially). There is also often very little that producers can do in advance to mitigate the impacts of these events in such extensive systems. Advice from local and state government agencies focuses on pre-emptively moving livestock out of high-risk areas, but the effectiveness of such approaches relies on having sufficient warning, human resources and capital to move animals, and the existence of safe refuge areas.

The technology revolution and expansion into northern Australia

With such expansive rangeland properties, remote resource monitoring and animal management are almost essential for any measurable improvement in operations and productivity. The commercialisation of connectivity options has borne a strong focus on cloud-supported robotics, the Internet of Things (IoT) and sensors, artificial intelligence (AI) and drone capability as well as renewable energy options for operations such as solar-powered bore pumps. For example, remote monitoring of water resources, feed biomass, and land condition combined with in-field animal weight sensors and monitoring of diet quality via eDNA can support decisions on stocking rates and paddock allocations, which could in turn be facilitated by virtual fencing and the use of drones for mustering. The adoption of such technologies can potentially help to improve animal welfare and productivity and reduce landscape degradation, whilst concurrently reducing human labour resource requirements. As the use of this technology increases, there will likely be changes in animal management protocols, for example the incorporation of drones allowing cattle to be mustered at night when there is a lesser risk of acute heat stress.

At the animal level, IoT and sensors, including water intake sensors, GPS and accelerometer tags and collars for behaviour monitoring provide an opportunity for remote data collection as well as decision-making and treatment at the individual animal level. Machine learning and AI are being used extensively on the developmental phase of product creation, for example as a mechanism to refine algorithms and eliminate arduous video annotation for animal behaviour and health monitoring and is also critical for the proceeding data aggregation step (Tedeschi et al. 2021).

While all purposeful technology can support the goal of informed decision-making, the accumulating breadth of technology options is also creating a clear signal that thoughtful yet simplified data analytics is also needed so that it is understandable, useful and real-time for informed decision-making that is appropriate for current conditions. Commercialised systems that master integration of data types are a necessity given the diverse sensor monitoring for non-confined, extensive rangelands. Development of predictive technologies to support management decision-making will rely on data accrual; however, historical data availability is a limiting factor and data ownership and privacy continue to be challenges.

Geopolitical shifts

As an export dependent nation, global trends provide opportunities and challenges for northern Australian beef. Climate challenges, political tension and conflicts influence price volatility and supply chains. However, an estimated increase in beef consumption over the next decade (in Australia and key live export markets Indonesia and Vietnam; ANZ Group Holdings Limited; MLA 2024) provides confidence in beef export demand. High Australian cattle prices and public animal welfare concerns lead to frequent disruptions in live trade (a cornerstone market for northern beef supply chains) in addition to the risk of trade disruption if Australia loses its disease-free status from lumpy skin disease or foot and mouth. Domestic efforts to improve access to premium market supply chains (EU, Japan) are challenging due limited potential to diversify land use across the pastoral zone both due to inherent land productivity and to restrictive (and inconsistent) State legislated lease terms. A dominant live export market, limited opportunity to diversify the feedbase and sparse road and rail infrastructure, impacted by seasonal cyclones and floods all contribute to a vulnerable northern beef supply chain. Yet half of the Australian beef herd is produced under these conditions. Where land productivity and legislation align pivot irrigation or dryland cropping as well as vertically integrated cattle businesses that move cattle to more fertile regions provided opportunities for diversified trade and access to higher value markets.

The focus of premium markets on sustainability has resulted in declining EU per capita beef consumption and an 8% shrinkage of the EU beef herd (European Union, 2021). Australia's response to welfare breaches has resulted in a 'clean, green beef' ethos underpinned by the Exporter Supply Chain Assurance System (ESCAS) (Windsor 2021). This leadership has encouraged Vietnam to set equivalent welfare standards providing opportunities for trade expansion. Megatrends affecting Brazilian supply chains indicate welfare compliance will be mandatory by 2040 (Malafaia et al. 2021). Australia's commitment to welfare, and the relative sustainability of northern beef production provide opportunities to capitalise on these markets where integrated supply chains allow for feedbase improvement.

As de-globalisation looms, the low tariffs negotiated through Australia's 1980s-2020s Free Trade Agreements (FTAs) are met by similar FTAs negotiated with other nations, increasing competition in export markets. At home, global volatility in key import markets imposes price volatility and supply chain instability on imported minerals (phosphorus and nitrogen from the Middle East, China and Russia). Development of domestic green ammonia plants and circular economy initiatives may provide cost-savings, food security and a sustainability advantage for Australian livestock producers. Potentially northern Australian producers can capitalise on broader megatrends influencing affluent Asians; digitisation of shopping, tailored personal experiences and Gen Z and Alpha as the largest consumer demographic. Could northern beef supply chains capitalise on a direct, personal shopping experience, emerging welfare-based priorities and build brand based relationships in the secure beef markets of Asia?

More efficient resource use, with reduced impacts on animals and the environment

Arguably, as long as grazing is managed to limit its negative impact on the landscape, beef produced in the northern Australian rangelands has the opportunity to be among the most sustainable in the world.

Therefore, northern Australian producers are perfectly placed to capitalise on consumer preference for beef certified for sustainability credentials. To achieve this, measurement and monitoring of biodiversity, natural capital and other sustainability metrics needs to occur, and the marketing of the products needs to be clear and tailored to the market preferences. Whether consumers are willing to pay for sustainable practices or simply demand them as standard is yet to be seen. Furthermore, existing nature-based markets enable producers to gain financially from not only potential price differentiation for sustainable practices, but also directly from implementing practices that reduce carbon emissions/sequester carbon (carbon markets) or improve/protect biodiversity (e.g. Nature Repair market). The northern rangelands are extremely well placed to enter these markets due to large property areas (e.g. average property size in NT in 2010 was >2700 km^2) and naturally high biodiversity due to limited land clearing. Additionally, projects using the Australian Government's savanna burning methodology have been able to earn significant carbon credits, mainly on the Indigenous estate (Edwards et al. 2021), and it is possible that the pastoral industry could also benefit from such schemes in the future.

Improving production efficiency of northern beef systems is also likely to be a focus into the future- particularly regarding identifying and removing non-performing animals, improving the quality of the feedbase and using the land for multiple purposes (e.g. solar farming and beef production using agrivoltaics). As long as stocking rates are maintained or reduced, improved efficiency also has the co-benefits of reduced methane intensity and less impact on the pasture. While the outlook holds promise, improving resource efficiency in remote and dispersed locations has inherent challenges. Additionally, there is increasingly a tension between using the northern rangelands for beef production and other land uses- particularly energy production, and mining for critical minerals. Satisfying the needs of a growing population and their future requirements is likely to put the northern rangelands under pressure.

Changing regional demographics and human capital constraints

In 2020, 76% of people in Australia lived in urban areas (Hill et al. 2021), and this urbanisation of the population is predicted to increase into the future. Attracting and retaining skilled workers in the northern beef industry is currently a challenge, but is potentially an opportunity, particularly for First Nations peoples and remote communities. For example, according to the 2021 census, the percentage of employed people aged ≥15 years in the NT was 76% for non-Indigenous people compared to 28% for Indigenous people (Australian Bureau of Statistics, 2021). However, as Indigenous Business Australia (2023) have said '*Aboriginal people are the most overtrained people in the country and still can't get a job*' and therefore investing in linking talent, training and opportunities is important. As well as attracting and retaining more on-ground staff, the rise of remote working (e.g. working online) is likely to also start to apply in the northern beef industry with the adoption of technologies and remote management opportunities outlined above. Recent climate modelling has suggested that due to rising temperatures, the duration people are able to work outside in northern Australia will be reduced by 20-50% by 2080 in comparison to a 1986-2005 baseline (Hunt et al. 2023). This could increase remote working, as it is likely to affect people's ability to work in the northern rangelands, as well as their desire to live in these conditions.

Conclusions

The global megatrends discussed above provide both opportunities and challenges for Australia's northern beef industry. Access to knowledge and upskilling for livestock producers remains critical for businesses to access new opportunities and compete. Potentially, a review of the varied and complex legislative requirements for diversification needs to be adapted to cover a northern Australian based land system, rather than different and complex rules between arbitrary State borders. This is particularly true where large land holdings span jurisdictions. In summary, future climate challenges will not be insignificant, and primary producers will need access to knowledge, tools, supportive legislation and novel markets to remain competitive in a secure market for animal protein.

Abstract

In the context of high and increasing rainfall variability in southern South America, animal production systems in subtropical *Campos* grasslands would benefit from adaptive drought management. To better understand the ability of forage species to cope with, and recover from, water stress episodes of variable intensity, a greenhouse experiment was carried out to evaluate two C3 grasses *(Bromus auleticus, Lolium arundinaceum*) and three C4 grasses (*Andropogon lateralis, Paspalum dilatatum, P. notatum*). To assess resistance to water deficit, plants growing in individual 12-L pots were kept for 52 days at four levels of constant water availability: 10, 30, 50 and 70% of soil field capacity (SFC). To assess the recovery capacity, pots were re-watered and maintained for 42 days at a constant 75% SFC. During the stress phase, the minimum proportion of SFC that allowed maximum forage productivity was lowest in *P. notatum* (39%), intermediate in *P. dilatatum (50%), B. auleticus* (61%) and *A. lateralis* (64%), and highest in *L. arundinaceum* (70%). During the recovery phase, the minimum proportion of SFC from which maximum growth was re-attained was ~30% in all species, except for *P. notatum*, which was able to fully recover even from the 10% SFC treatment. Therefore, species differed in their ability to resist drought, but less so in their capacity to recover post-stress, with the notable exception of *P. notatum*, which exhibited the lowest critical soil moisture for both resistance and recovery. Integrated with information on the potential of each species to stockpile forage, these results could inform the design of adaptative drought management strategies targeted to specific plant communities of the highly diverse *Campos* grassland, so that extensive animal production systems can be effectively buffered from recurrent, frequent, but difficult to predict in their timing and intensity, episodes of water deficits.

Introduction

Water availability is a major factor limiting grasslands productivity in southern South America (Huxman et al. 2004; Rodríguez Palma et al. 2024). Future climate change scenarios are expected to further increase inter- and intra-annual rainfall variability (Grim 2010). Severe droughts sometimes induce large plant mortality, thus decreasing livestock production (Breshears et al. 2016) or increasing supplementation costs (Cazzuli et al. 2024). Therefore, understanding the implications of different rainfall regimes on dominant native and naturalized species of high-diversity *Campos* grasslands is key to adaptive management strategies that help these grasslands resist and recover from drought episodes.

The response of productivity to extreme rainfall variability varies among species (Jentsch et al. 2011), ranging from minor effects to severe declines accompanied by prolonged recovery periods (Breshears et al. 2016). Such variability in grass species' drought resistance (capacity to grow under drought) and drought recovery (production after drought) (Tilman and Downing 1994) depends on grass species attributes and the magnitude, duration, and season of the drought. Since effective plant strategies under drought depend on drought-stress intensity (Lüscher et al. 2022), dominant grasses response (productive response) must be evaluated concerning this climatic driver (drought) at different available water levels.

Soil water availability is a primary factor limiting grassland productivity (Knapp et al. 2002). When soil water availability increases, an increase in forage plant growth is observed. However, this relationship between soil water availability and plant growth has a limit. Once an optimal level of soil water is reached, adding more water may not result in extra plant growth. In this context, different species have different water requirements, so some plants may be more drought-tolerant.

Estimating the impacts of droughts on high-diversity grasslands is challenging due to a limited understanding of the nonlinear responses of plant species to increasing drought conditions (Ingrisch et al 2022), specifically the ability of dominant forage species to cope with and recover from water stress periods of varying intensity. The main hypotheses of this study are: i) water stress periods of variable intensity generate different responses in forage production in five native and naturalized grasses and ii) drought-resistant species exhibit the highest capacity for recovery following water stress periods.

Methods

Experiment Location

The experiment was carried out with potted plants in a glasshouse at the INIA Tacuarembó research station, Uruguay (31°44´19.30´´S, 55°58´41.48´´W). The experiment began on 07/01/2021 and ended on 14/04/2021. The mean air temperature was 24°C in January and 21°C in April, similar to historical averages (24 and 18°C).

Treatments, Experimental phases and Measurements

Two C3 grasses (*Bromus auleticus* and *Lolium arundinaceum* (Schreb.) Darbysh.) and three C4 grasses (*Andropogon lateralis*, *Paspalum dilatatum,* and *Paspalum notatum*) were planted in a 12-L pot (30 cm diameter) three months before the start of the experiment. The soil substrate contained 38 ppm of Bray 1 phosphorus; 0.46 meq/100 g of potassium; 11 % organic matter, 16.6 meq/100 g of calcium and pH=5.8. Furthermore, the equivalent of 40 kg N/ha (urea) and 10 kg P/ha was applied. The soil field capacity (SFC) was calculated as 0% when the substrate was completely dry and 100% at full capacity after 48 hours of free drainage.

Plants were subjected to four constant water availability treatments (10, 30, 50, and 70 % of SFC) for 52 days, from 07/01 to 03/03/2021 (Phase I "resistance"). Then, pots were re-watered to bring them to 100% field capacity for 3 days, and then all the pots were maintained at 75% SFC for 42 days, until 14/04/2021 (Phase II "recovery"). Pots were weighed daily and watered to the required level according to the treatment. The foliage was harvested in all the pots at the beginning of the experiment, at the end of phases I, and II by cutting plants at 2 cm. Fresh shoot mass was weighed and then dried at 60 ºC for 72 hr to determine dry matter concentration.

Experimental design and statistical analysis

Treatments were arranged in a completely randomized design with four replications (pots). Analysis of variance (ANOVA) of forage production was performed for the drought phase and the recovery phase, using the Tuckey method to compare means with a 0.05 significance level.

The relationship between shoot growth and SFC percentage was modelled using nonlinear segmented regression to find threshold SFC percentages for maximal shoot growth of each species (i.e. critical SFC) and estimate the range using the SFC mean +/- two standard errors. Afterwards, to check whether the most resistant grass species has a greater capacity for recovery at different percentages of soil field capacity (SFC) a regression analyses were performed to analyse the relationship between critical SFC and recovery ability, calculated as the relative rate of shoot growth in a specific SFC treatment compared to the 70% SFC treatment. All the statistical analyses were performed with the INFOSTAT program.

Results

Drought resistance

The magnitude of the reduction in grass shoot growth in response to lower water availability in Phase I was species-dependent (Fig. 1). *P. notatum* had higher biomass production than C3 grasses when water was most limiting (10% SFC). During the drought resistance phase, the modelled critical relative moisture content -the minimum percentage of SFC that allows maximum forage productivity- was lowest in *P. notatum* (39%), intermediate in *P. dilatatum (50%), B. auleticus* (61%) and *A. lateralis* (64%), and highest in *L. arundinaceum* (>70%).

Post-drought recovery

An interaction between species and SFC treatment was also identified for biomass production in the recovery phase (Fig. 1). Like in the previous phase (resistance), *P. notatum* had a higher biomass production than C3 grasses after the 10% SFC treatment. However, after 30% SFC treatment, *L. arundinaceum* produced more forage than both species of *Paspalum*, and *B. auleticus* produced more than *P. dilatatum*.

Relationship between drought resistance and recovery phases

Paspalum notatum combined greater drought resistance with better recovery from the most limiting water level (10% SFC) than any other species. In both species of *Paspalum*, forage production in the resistance phase was not related to recovery phase production. However, *L. arundinaceum, B. auleticus,* and *A. lateralis* showed some positive linear relationships between their growth in the resistance phase and during the recovery phase (Table 1) but only for the most extreme drought treatment (10% of SFC). Nonetheless, the water needed to reach the optimal productive level was negatively correlated with subsequent recovery only in the most limiting water level of 10% SFC (Fig. 2).

Table 1. Relationship between forage production at 10% SFC in the moisture stress phase and that grown during post-stress recovery.

Festuca arundinacea	Recovery = 8,22 + (0,28 x Resistance)	(R^2= 0,39; P<0,01)
Bromus auleticus	Recovery = 5,02 + (0,69 x Resistance)	(R^2= 0,56; P<0,01)
Andropogon lateralis	Recovery = 2,66 + (0,72 x Resistance)	(R^2= 0,60; P<0,01)
Paspalum dilatatum	No significant relationship	
Paspalum notatum	No significant relationship	

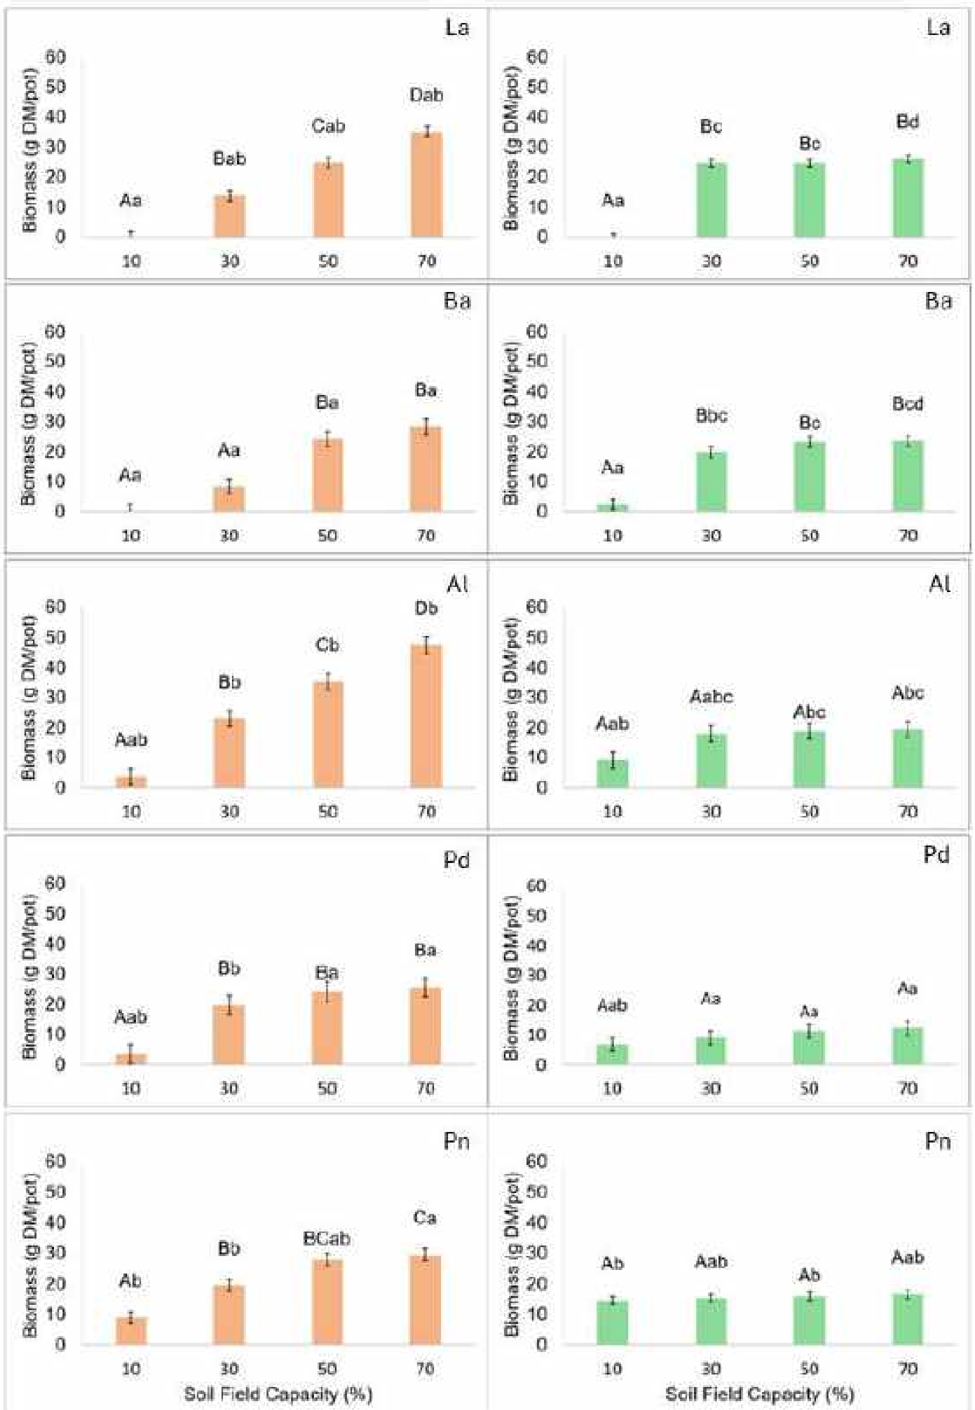

Fig. 1. Resistance (orange) and recovery (green) of forage grasses depending on the soil water content. 100%=Soil Field Capacity (water remaining in soil after 48 hours of drainage) and 0%=dried soil. La (*Lolium arundinaceum)*; Ba (*Bromus auleticus)*; Al (*Andropogon lateralis); Pd* (*Paspalum dilatatum);* Pn (*Paspalum notatum)*. The uppercase letters indicate statistical differences between the different levels of available water (SFC), while the lowercase letters represent the statistical differences between the species assessed for the same level of water in the soil (SFC).

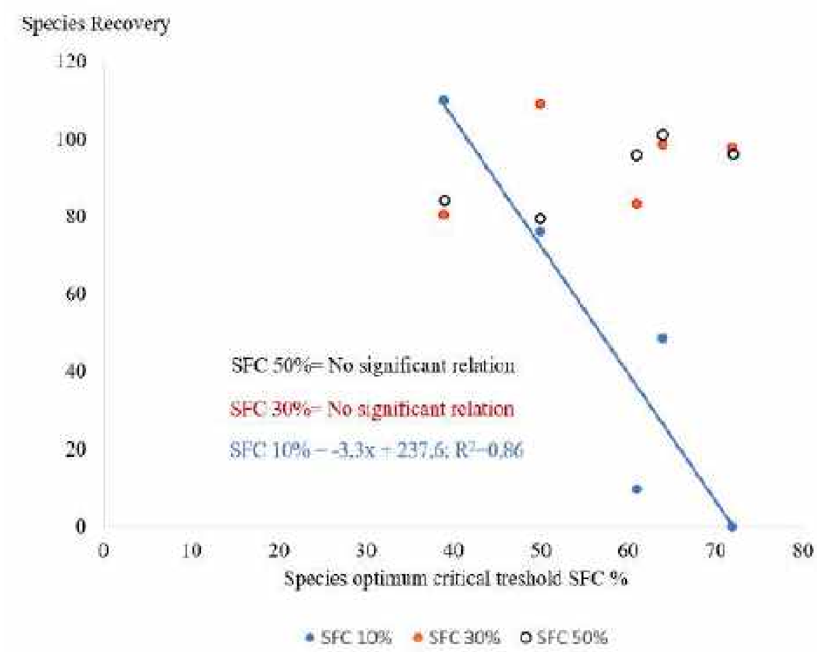

Fig. 2. Relationship between critical grass SFC water threshold and their recovery ability, calculated as the relation of species water threshold (% SFC) with their shoot production recovery in a specific SFC to the 70% SFC treatment.

Discussion
Grass species showed different growth responses to reduced soil moisture, confirming the first hypothesis that drought resistance was species-dependent. The most drought-tolerant species were *P. notatum* (39% SFC) and *P. dilatatum* (50% SFC), while *L. arundinaceum* requires wetter conditions (>70% SFC). Therefore, our results are in line with Mackie et al. (2019) who suggested that drought resistance and recovery are more sensitive to plant community composition than to community productivity. The higher resistance of *P. notatum* to drought and its full productive recovery from low levels of water means that its management in communities where *P. notatum* is dominant is key for stability during drought disturbance. This may explain why *P. notatum* was one of the most frequent species in the *Campos* grasslands (Andrade et al. 2018). However, its advantage in subsequent recovery applies only in the most limiting water conditions, partially confirming the second hypothesis.

The negative relationship between drought recovery and forage production under severe moisture stress may be useful to improve grassland adaptive management decisions in the face of droughts. However, such responses need to be evaluated in grassland communities and integrated with information on the potential of each species to stockpile forage. Such a synthesis would provide a framework for the development of decision support systems to help design adaptative drought management strategies targeted to the specific plant communities present on individual farms in *Campos* grasslands.

Key words: Tactical decisions; climate variability; drought; systems modelling

Abstract

Making management decisions (e.g. livestock sales and feeding) that involve predicting future weather conditions is difficult, especially in variable climates like the southern Australian rangelands. This project assessed tactical management options and trigger points using modelling to inform flexible stocking decisions. The study focused on a lamb production system on chenopod shrubland at Balranald, NSW Australia. A focus group of producers held in March 2019, during a lengthy drought, identified August as a key decision point for adjusting ewe numbers based on available feed. The SGS pasture model was validated for this location against historic vegetation and animal data from grazing studies, the GRASP model and producer experience of feeding periods between 2016 and 2020. Five different grazing systems were modelled. A base system of Merino ewes with lambs sold on 1 November that were containment fed with grain during periods of feed deficit was compared with two flexible options that adjusted livestock numbers in relation to available feed. The first was to reduce ewe numbers by half when green herbage mass was <0.7 t DM/ha in August (Flex ewe). The second was to retain lambs to 50 kg if green herbage mass in October was either > 1.2 t DM/ha (Flex lamb – 1.2) or >0.5 t DM/ha (Flex lamb – 0.5). The fifth system was to retain lambs to 50kg regardless of available feed (50kg lamb). The flexible ewe sale strategy reduced gross margin by 11% from $23.04 to $20.55 (per DSE; based on the long-term carrying capacity), due to lower income in the recovery years. The flexible lamb sale strategies (Flex – 1.2 – $26.76 and Flex – 0.5 – $33.30) were also lower than retaining lambs to 50 kg ($35.84). While modelling suggested lower returns from adjusting stock numbers in relation to trigger points identified by producers, other practical considerations such as experience with supplementary feeding also need to be considered.

Introduction

Livestock production in the southern Australian rangelands faces the difficult challenge of reconciling the dynamic nature of forage availability with relatively stable feed demands from domestic livestock. The region is characterised by high seasonal and annual fluctuations in vegetation growth, primarily driven by climate variability and its consequent impact on soil moisture. While livestock populations remain relatively constant, the underlying feed resources can vary dramatically—sometimes changing by orders of magnitude within a single growing season or across different years. Further, producers may only have contact with livestock 3-4 times per year so have limited opportunities to make and act on decisions.

These environmental uncertainties create significant management challenges for producers. This inherent unpredictability is typically managed by adopting conservative stocking strategies and maintaining lower herbage utilisation rates (Godde *et al.* 2019). This approach helps mitigate risks associated with potential feed shortages, such as the need for expensive supplementary feeding or forced destocking and prevents long-term environmental degradation of rangeland ecosystems (Hacker and McDonald 2021).

However, such conservative management strategies come with substantial economic trade-offs. By limiting stocking rates and forage utilisation, producers potentially sacrifice productive potential and economic returns. The critical question emerges: Can more adaptive management approaches be developed that balance economic efficiency with environmental sustainability and decrease risk?

This research project was designed to address this fundamental challenge in southern Australian rangelands. Its primary objective was to assess tactical decision-making frameworks that could help producers optimise their management strategies to maintain their feedbase whilst maximising economic return. The central hypothesis proposed that introducing more flexible management systems would yield improved financial outcomes while maintaining ecological integrity.

Methods

This study examined different flexible decisions and trigger points to make decisions for a sheep production system at Balranald (34.64 °S, 143.56 °E, average annual rainfall of 317 mm), NSW Australia.

Producer consultation

In March 2019, during an extended drought period, researchers conducted a focus group with local producers to explore their decision-making processes regarding livestock destocking and feeding under variable seasonal conditions. The consultation revealed that August was a critical trigger point for adjusting ewe numbers, with numbers often reduced by half when feed is limited. One producer illustrated this approach, stating, "Rainfall at the end of the winter growth period is the trigger point. Last winter [we] went from 3000 to 1500 ewes because of the rainfall deficit." The discussion also revealed considerable variation in lamb sale strategies, with some producers incorporating regular supplementary feeding while others did not, highlighting the variation in rangeland livestock management in response to environmental uncertainties.

Modelling

The SGS pasture model was used to simulate the rangeland grazing systems. The model has four main modules (water, nutrients, pastures and animals) that are interconnected. The model is hierarchical in structure and most processes are described in terms of a series of fluxes (or, more specifically, flux densities) that have dimensions of amount per unit area per time step (for details see Johnson et al. 2003).

The livestock system modelled was Merino ewes (60 kg reference weight) joined to a terminal sire with lambing on the 1 June and lambs sold on the 1 November or at 50 kg and run at a stocking rate of 0.1 ewes/ha. The pasture in the model was a C4 native grass and subclover (representing naturalised/native annual grasses and forbs) that had been calibrated to be slightly higher than ground level herbage to account for browse from perennial shrubs (e.g. *Atriplex spp.*; based on data from Wilson *et al.* 1969). The soil used had low hydraulic conductivity and low organic matter. Long Paddock weather data were used for Balranald (https://www.longpaddock.qld.gov.au/silo/). Since this area has a low level of trees, the tree level was set at 30% to account for the natural patchiness of semi-arid rangelands, which concentrate and retain resources in fertile patches that are interspersed with bare areas. Further validation of seasonal conditions was achieved using GRASP (Rickert *et al.* 2000), a pasture growth model commonly used in rangelands. Model output from 2016 to 2020 was presented to producers to confirm that predicted feeding periods matched their experience. The simulation was run for the 1910 to 2019 production years.

Flexible decisions

The base system was as described above, with all ewes retained and supplemented with grain as required in a drought feedlot. Two flexible decision scenarios were simulated; 1) adjusting ewe numbers, with half ewes sold when green herbage mass in August is <0.7 t DM/ha (flex ewe) and 2) adjusting sale time of lambs in the base system, by retaining lambs to 50 kg when green herbage mass in October is >1.2 t DM/ha (flex lamb – 1.2) or is >0.5 t DM/ha (flex lamb – 0.5) or selling on 1 November when not. A final scenario retained lambs until 50 kg regardless of herbage mass (50kg lamb).

Gross margin and analysis

A gross margin analysis was undertaken using the biophysical model output with costs and prices from NSW DPI 2020 gross margins (https://www.dpi.nsw.gov.au/agriculture/budgets/livestock). The sheep prices and feed grain prices were assessed against High, Medium and Low CPI-adjusted prices for the last 20 years. The sheep meat and the feed grain prices were based approximately on the 9th decile (High; lamb AUS$7.20 /kg cwt), average (Medium; lamb AUS$5.00 /kg cwt) and 1st decile (Low; lamb AUS$3.00 /kg cwt) years. The gross margins per DSE are reported, based on the long-term average DSE capacity of the system (rather than DSEs in a particular year). As the model feeds to meet animal requirements, differences in profitability are primarily driven by the cost of supplementary feeding rather than production differences. All analyses were performed using ANOVA in Genstat (22nd edition).

Results

Developing trigger points

The number of days of confinement feeding that occurred from 1 August onwards for 12 months was assessed against average green herbage mass in August (Fig. 1a). In 9% of instances there was feeding for >150 days and this always occurred when green herbage mass was below 0.7 t DM/ha in August. There was also a relationship between average October green herbage mass and average per head supplement intake, with high levels of feeding only occurring below 1.2 t green DM/ha (Fig. 1b).

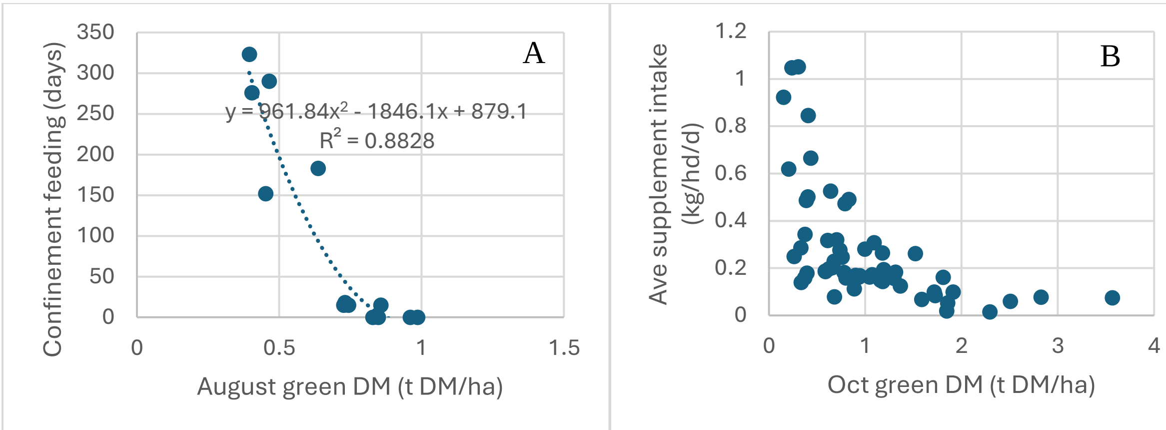

Figure 1. a) The green herbage mass in August (instances where green herbage mass was < 1 t DM/ha) compared to the average days of confinement feeding over the following 12 months. b) October green herbage mass and average per head supplement intake.

Flexible decisions

Flexible ewe numbers did not greatly influence gross margin compared to the base system. On average the base system was $2.49/DSE more profitable (P < 0.001; Table 1) with a lower CV (90% v 113%). There was an interaction between sheep price and the difference between the flex ewe and base system gross margins (P < 0.001). At a moderate sheep price there was no difference between selling or retaining ewes, while there were benefits to the base system at the high and low sheep prices.

In the year the flex ewes were destocked there was no difference in gross margin when compared with the base system, but in the following year there was a higher gross margin for the base system than for the flex ewe system (P<0.001).

Under all price and feed scenarios, the more often lambs could be retained to 50 kg, the greater the average profitability (Table 1) and the lower the CV (Flex lamb - 1.2 – 89% Flex lamb - 0.5 – 78% 50 kg lamb – 69%). Even with significantly increased supplementary feeding below 0.5 t DM/ha of green herbage mass, there was still an advantage in retaining lambs to 50 kg as supplementary feeding was required for a relatively short period of time (2 months) and increased the value of lambs.

Discussion

The research revealed nuanced complexities in livestock management strategies during poor seasonal conditions. Reducing ewe numbers did not consistently provide the expected financial advantages initially anticipated by producers. While selling ewes generated additional income and reduced feeding costs in the first year, the strategy's effectiveness was compromised by instances where ewes were purchased back within a month, negatively impacting overall profitability. Even excluding these short-term repurchases, the financial benefits remained marginal. In the second year, the flexible ewe sale approach encountered increased repurchase costs and lower lambing rates due to delayed rejoining, further diminishing its comparative advantage. The analysis suggested that a more gradual, staged approach to selling ewes might offer greater operational flexibility.

Many rangeland livestock producers lack experience, specialised infrastructure or labour resources for confinement feeding. In these instances, selling livestock may be a seemingly lower risk management option, despite generating slightly lower returns. The modelling, while quantifying risks, potentially underestimated complexities such as animal health considerations associated with prolonged feeding. The research also identified an alternative adaptation strategy: growing lambs to heavier weights when feed was adequate, which could help offset increased drought-related expenses and price differentials. Confinement feeding to the target sale weight of 50kg was the most profitable strategy and had the lowest risk.

The study's assumptions included access to confinement feeding infrastructure, recognising that paddock feeding could cause significant vegetation damage. Any substantial infrastructure investment would require a thorough return-on-investment assessment. Moreover, the researchers acknowledged the model's limitations, emphasising that the identified herbage mass thresholds would likely vary across individual farms, particularly in rangeland systems where saltbush browsing contributes significantly to feed availability under low rainfall conditions.

This study reveals that while flexible decision-making strategies may appear promising, their advantages were not conclusively demonstrated under the cost and price assumptions examined. The economic benefits of flexible decision making may have been understated without considering the potential additional labour and infrastructure costs associated with confinement feeding. Recognizing that modelling inherently simplifies complex real-world scenarios, the nuanced insights of experienced managers could potentially reveal subtleties and opportunities that were not captured by this analysis. Nevertheless, the research identified a clear advantage in strategically feeding lambs to a target weight across all seasonal conditions, which consistently demonstrated improved economic returns, with lowered risk.

Table 1. Average gross margin per DSE (long-term average) for different management treatments, sheep prices and grain prices. The management treatments included: 1) Base system - all ewes retained, lambs sold 1 November; 2) Flex ewe – ewes reduced by half when August green DM <0.7 t DM/ha, lambs sold on 1 November; 3) Flex lamb - 1.2 - all ewes retained, lambs retained to 50 kg when October green DM >1.2 t/ha; 4) Flex lamb – 0.5 - all ewes retained, lambs retained to 50 kg when October green DM >0.5 t/ha; and 5) 50 kg lamb: all ewes retained and lambs retained to 50 kg. High (9th decile; or based on 2020), Medium (average) and Low (1st decile) sheep prices CPI adjusted over 20 years. High (9th decile; or based on 2020), Medium (average) and Low 1st decile) feed grain prices CPI adjusted over 20 years. P values and least significant difference (P<0.05) are presented.

System		Treatments					lsd	P-value

Resilient livelihoods: re-examining mobility social solidarity for climate change adaptation in east Africa's drylands.

Tahira Shariff, M[1]

[1]International Livestock Research Institute (ILRI), Supporting Pastoralism and Agriculture in Protracted Crisis (SPARC), Jameel Observatory for Food Security Early Action.

Key Words: Resilience; social protection; mobility and safety net

Abstract

The Horn of Africa has recently faced one of the worst droughts in over forty years, resulting in the death of nearly 11 million livestock, displacement, and loss of livelihoods. The drought condition is exacerbated by the compounding structural conditions arising from protracted conflict, marginalization, malnutrition, disease, and food insecurity. Notwithstanding these challenges, pastoral livelihood has persisted and often thrived due to adaptive practices, such as strategic mobility, livestock diversification, intensifying income portfolios, and investing in solidarity relationships and external support. Owing to the proliferation of transport, communication, and mobile money transactions, including in the remote pastoral villages in Northern Kenya's drylands, the adaptive capacities of the pastoralists to share information, transport produce, and engage with a growing market have improved.

The customary social solidarity and redistributive practices through moral economy have rekindled, thanks to the connectivity to urban and diaspora communities. Drawing on ethnographic data collected between 2018 and 2024, this research re-examines social solidarities in enhancing pastoralists' capacity to withstand and transform their livelihoods in response to climate shocks. In a context characterized by a lack of financial services, restricted mobility, and limited government support, local solidarity and redistribution provide continuous access to resources, including labour and cash, to support livelihoods. The reliance on a social solidarity network allows for a more agile and timely response, not only to co-variate shocks but also to idiosyncratic pressures arising from everyday calamities. However, such practices remain unrecognized and sometimes undermined by the mainstream social provisioning, cash transfers and relief aid that provide inflexible finance with sedentary bias without considering the changing pastoral context and adaptive practices. The findings will contribute to the recent approaches to link humanitarian and development action with local resilience-enhancing practices.

Introduction

Pastoralism has been persisting in the Horn of Africa despite multiple indications that pastoralism is under pressure and needs to be replaced by alternative livelihoods. Pastoralists have often been blamed for causing desertification and keeping livestock beyond the land's carrying capacity (Hardin, 1968). These assumptions led to agricultural and environmental policies and investments that promoted forced sedentarization, large-scale irrigation and land grabbing for nature conservation, undermining pastoralists' mobility (Behnke and Kerven, 2013; Eriksen *et al*., 2021). Although pastoral drylands are predisposed to multiple shocks, including climatic-induced drought, floods, animal diseases and other social instability, the livelihoods are sustainable. Pastoralism is a viable livelihood suited to variable and non-equilibrium environments (Krätli *et al*., 2013). Still, pastoral development has often remained in classic thinking that sees pastoralism as backward and vulnerable in constant needs. This paper examines how external interventions such as social protection and livestock insurance intersect with local social solidarity in pastoral drylands. Can social protection from above (external interventions) be connected to pastoralists' solidarity networks to improve livelihoods in the face of multiple shocks and stresses?

The recurrent disasters in the Horn of Africa, including drought, compounded by protracted conflict, political instability, and food insecurity, have attracted manifold interventions, including humanitarian and development support. Humanitarian assistance includes emergency food aid, water and sanitation and cash assistance. In contrast, development response includes rangeland rehabilitation through re-seeding, market infrastructure development, and projects that support diversification out of pastoralism (see Mohamed et al., 2025). Following the 2011 famine in Somalia and subsequent severe drought in the greater Horn, countries in this region adopted resilient strategies through IGAD Drought Disaster Resilience and Sustainability Initiatives (IDDIRSI) (see IGAD, 2013). Countries domesticated IDDIRSI through country-specific programming, and robust drought management institutions emerged, including Kenya's National Drought Management Authority (NDMA). Resilience building later topped the national agenda for drought response (Hargreaves et al., 2012). The focus of resilience-building initiatives included market infrastructure development, rehabilitation of water systems and investment in social protection, specifically cash transfers and livestock insurance, as a route to de-risking pastoral settings (Lind *et al*., 2022; Johnson *et al*., 2023).

In Kenya, the Hunger Safety Net Programme (HSNP) provides unconditional cash transfers of US$27 to vulnerable households across eight pastoral counties every two months. In Ethiopia, the Productive Safety Net Program provides cash or food to vulnerable populations against public works or unconditional cash to more vulnerable households. Later, linked to protecting livestock assets, Index-based Livestock Insurance (IBLI), grounded on statistical analysis and modelling of vegetation index, emerged as a form of state-private sector-led intervention (Bageant and Barrett 2017). All three forms of social assistance (HSNP, PSNP, and IBLI) have predictive and targeting mechanisms that identify households based on geographical region, vulnerability status and individualized contributions to premium, often ignoring the predominant characteristics of pastoral societies and knowledge (Derbyshire et al., 2024). Although these social assistances have contributed to household-level food security, the coverage is limited to a few households. It does not provide adequate long-term resources for herd reconstruction post-disaster.

On the other hand, pastoralists have relied on different forms of informal social solidarities, some founded on cultural norms and values, while others rooted in religious obligations (Mohamed, 2023). Among the pastoralists in Northern Kenya, these practices are sometimes called' moral economies'-a redistributive practice that helps pastoralists respond to a crisis. Such practices can be institutionalized redistribution, labour sharing, and the moral economy of diversification (see Mohamed 2022) for a broader overview of the concept. Examining the changes and continuities of the moral economy through time (between 1975 and 2020), space (rural-urban) setting and within generations (young, wealthy and old), Mohamed highlighted that such informal social solidarity remains essential and has been modified by the dynamic social, technological and market transformation in the drylands. Mohamed noted that the moral economies in near urban areas and remote areas differed. In remote areas with limited infrastructure and weak government support, pastoralists invest primarily in comradeship, reciprocal labour exchange and redistribution. In contrast, pastoralists near urban centres invest more in diverse economic relationships and saving groups.

In the ensuing section, I present the methods used for data collection, examine both formal and informal social protection and highlight its role in helping pastoralists respond to different crises.

Methods

This study is based on qualitative ethnographic research conducted between 2018 and 2024 among the pastoralists in Northern Kenya's Marsabit and Isiolo Counties. It combines data collected for different but related research on pastoralists' livelihoods, resilience, and the evolving social safety nets in responding to various shocks and crises. Among these projects are the politics of social protection in Kenya undertaken through the Effective States and Inclusive Development (ESID) project at Manchester University. It also largely emerged from the author's PhD research within the Pastoralism, Resilience and Uncertainty (PASTREs) programme in Northern Kenya, which explored social safety net and the moral economies among the diverse pastoralist's social groups. It also drew on an ongoing qualitative postdoctoral research that examines the nexus between humanitarian aid and resilience programmes in the Horn of Africa in managing crisis, using institutional-based interviews and stakeholder workshops.

The data is also drawn from various policy convening and discussions examining the disconnect between pastoralism and social protection. Secondary data from academic, conferences and policy papers were used to guide the discussion. The data is analyzed thematically, comparing the pastoralist's social security with the conventional social assistance in the Drylands of Eastern Africa.

Contrasting social protection and the pastoralist's social solidarities

a. **Pastoralists social solidarity**

Pastoralists have traditionally managed different forms of crisis within the variable and erratic drylands and mountainous regions of the world. Among the most notable practices are movement to relatively better-resourced areas for adaptive utilization of water, pasture and security. This movement sometimes entails splitting livestock into different categories, the milk animal, weak, dry and young (Dahl, 1979; Mohamed, 2022). Labour organization is essential to enable spatial utilization of the resources and manage different animal needs. Owing to the various seasons of plenty and scarcity, sharing resources among families, neighbours, clans, and religious ties is a central survival strategy (Mohamed, 2023). This redistribution strengthens social relations among the groups but also ensures resources are accessed at differing times, primarily due to the uncertain nature of production. Such sharing is reinforced by religious and cultural norms embedded in daily practices and shown through sayings, such as a Borana proverb, '*Ollomaf duudaan ejjaani'* (we could only stand because of our neighbours and our backbone) (See Mohamed, 2022).

In a study that examined 'resilience from below', we mapped critical networks and forms of solidarity that people turn to in a time of crisis (Mohamed et al., 2023). We found herders at the centre of these networks, but they must also link with other motorcycle riders to transport goods, deliver medicines and scout for safe grazing. They also rely on mobile money agents that provide cash for urgent needs, to purchase medicine and animal feeds. The agrovet dealers offer advice on animal disease and loan medicines. At the same time, a livestock market broker links the herders to the market and provides the herd owners with upfront cash to manage different needs. At the heart of these is also redistribution and sharing of resources, especially herders pulling labour to reduce the high cost of livestock management and exchanging animals for milk access. All these essential services are accessed through mutual relationships and trust. It is often based on flexible, reliable and attuned to different needs, but is not equally distributed among the pastoralists.

b. Livestock Insurance system

The index-based livestock insurance (IBLI) has recently emerged as a ‘de-risking’ tool for individual protection against drought peril. IBLI has been scaled in Kenya’s ASAL counties through the Kenya Livestock Insurance Programme (KLIP) in the early 2000s as a form of private-public partnership and involved international research institutions, the World Bank and the government (see Fava *et al*., 2021). The insurance systems are designed based on the correlation between rainfall distribution and pasture availability through a forecasted Normalized Difference Vegetation Index (NDVI). The assumption is that a payout is given to the affected premium holders whenever pasture levels reach certain thresholds (Johnson *et al*., 2023). The new De-risking and Value Enhancement (DRIVE), a regional livestock insurance programme, has been scaled in the Horn of Africa to enhance pastoralists' access to innovative climate risk financing and boost disaster resilience. But who does insurance benefit, and for how long?

A study by Taye (2022) challenged key assumptions in insurance and revealed that drought is not a singular peril that affects a singular area but a process involving constant livestock mobility. Its risks are experienced and perceived differently, depending on wealth and gender. The study noted that livestock insurance is mainly utilised by wealthier male herd owners, with others excluded. Bageant and Barrett 2017 have also cautioned against the potential gendered exclusion of IBLI owing to the paternalistic culture in most pastoral areas. Insurance tools are based on continuous data collection, which, if well-coordinated with the existing early warning institutions, might prove effective but remain costly. IBLI has recently adopted a bundled approach, and the policy is tied to other services like veterinary and feed support (Banerjee et al., 2024) to increase policy uptake among pastoralists. There is a potential for livestock insurance to prevent distress sales and improve food security. The challenge remains on how to sustain such a costly investment for the long-term, protect families from falling back into poverty and whether insurance has the potential to survive outside government subsidy.

c. Social protection for humanitarian assistance

Uganda’s social assistance is primarily implemented by the humanitarian agencies through disaster risk financing following government withdrawal linked to the structural adjustment programmes of the 1980s. Cash transfers are tied to workforce and feeding programmes to protect vulnerable households during emergencies. Third Northern Uganda Social Action Fund (NUSAF), a disaster risk finance safety net programme supported World Bank, provides labour-intensive public works after a disaster. NUSAF has contributed to short-term household food security during disasters but promoted sedentarization and dependency among the beneficiaries, undermining productive mobility (Caravani, 2024). In Libya, the Government created the Zakat Fund, which was co-financed by the national government and local religious leaders and distributed by young volunteers. Caravani et al., 2021 highlighted that the Zakat fund, through its robust delivery mode, has delivered effective aid in line with social and moral obligations and revealed a high level of accountability in a politically unstable state.

Both Libya and Uganda’s social assistance are forms of disaster risk financing, but the mode of delivery has shown a significant degree of effectiveness. Trust and accountability are improved when delivered through local systems and capitalizing on existing infrastructure such as Zakat. On the contrary, conventional humanitarian and social assistance is often forward with fixed plans that guide humanitarian response and is less adaptable to pastoralists' planning and response to shocks.

Conclusion

Social protection and insurance in pastoral areas potentially improve short-term food crises; they are not enhancing sustainable food security nor improving long-term livelihoods due to their short-termism and crisis-driven intervention. These programmes sometimes disrupt pastoral systems by creating perversive incentives, mainly in sedentary camps near urban centres and operate in parallel to pastoralists' social solidarities. The disconnect between these forms of assistance can be summed into four: first, properties and assets are not individualized but collectively owned through large family alliances and networks, and individual policy holding is parallel to pastoral systems. Secondly, crisis response requires collective efforts for safety and strengthening labour relations for livestock management and future security. Thirdly, formal assistance is often tied to quotas, fixed amounts and predictive targeting, with high chances of excluding eligible households. Such fixed targeting does not consider dynamic commodity prices that undermine people's purchasing power. Moreso, it needs to attune to pastoralists' mobile context and access to infrastructure as the experiences of pastoralists in remote and urban connected areas are much different (See Mohamed 2022).

Finally, overlapping social provisioning, especially around severe drought, creates confusion for pastoralists but also for government entities as well. For instance, some insurance is subsidized, and others are not, while some cash transfers are upscaled in crisis time and reduced in lean seasons.

As the Horn of Africa grapples with poly-crisis, climate change, conflict and structural problems, bringing external and local assistance together is essential; otherwise, the longstanding disaster and emergency response will continue, and the most anticipated resilience will not be built. Both insurance and social protection must go beyond pro-poor emergency assistance limited to the availability of funding to supporting existing relational and networked solidarities that strengthen continued food security and long-term resilience. For social protection to be adequate, it must capitalize on linking public-private partnerships, while centring community practices. Future studies should explore how formal social protection crowd out informal social assistance and ways to align the two systems better.

Impacts of covid-19 lockdown measures on pastoralism on the Tibetan plateau: risk analysis of pastoralism under increasing marketization

Puhua X; Qin Q; Li WJ.

Department of Environmental Management, College of Environmental Sciences and Engineering, Peking University, Beijing.

Key words: Pastoralism; COVID-19; Marketization; Risks; Tibetan Plateau

Abstract

With the animal husbandry production transformed from subsistent to commercial, the marketization in China pastoral areas has been increasingly developed. It is characterized by increasing dependency on fodder purchase, pasture lease, microcredit, and strategic livestock sale in response to market fluctuations. Marketization is a double-edged sword, offering both opportunities and challenges. However, the mechanisms leading to negative outcomes, especially in pastoral areas, have been understudied. The COVID-19 pandemic and subsequent lockdowns provide a natural experiment to understand the impacts of sudden shocks on marketized pastoralism. Here we examine the lockdowns' impacts on herders' daily life and livestock production in two counties with different marketization degree on Tibetan Plateau, using data from semi-structured interviews and field surveys conducted from December 2022 to August 2023. We find that the lockdowns' effects on herders' daily life and livestock production, revealing a direct link between market engagement and vulnerability of facing lockdown. This vulnerability stems from lacking local risk-management institutions through the nascent marketization in Tibetan pastoral areas. The replacement of traditional uncertainty management by market mechanisms has also amplified market risks. Therefore, we recommend enhancing herders' involvement in designing markets to reduce risks and integrating traditional pasture knowledge with market mechanisms to build a more resilient and sustainable pastoral economy.

Introduction

The pastoral rangeland is a complex nexus of social, economic, and ecological systems. Over millennia, the interplay between human activities and the natural rangeland ecosystem has culminated in an intricate and inseparable triadic system of "grass—livestock–humans".Pastoralism–the extensive use of rangelands through mobile livestock—is a vital livelihood practice globally（Scoones and Nori, 2023）. Today, rangelands are home to billions of people, providing food that feeds us. Rangelands are vast and diverse, covering over half of our planet’s land（ILRI et al., 2021）. This system delivers key ecosystem services and contributes to landscape functionality, thereby benefits a broader demographic (Hoffmann et al., 2014).

Pastoralism has encountered risks from natural disasters such as droughts, heavy snow, and storms, yet the nomadic practices rooted in traditional customs have demonstrated resilience and adaptability. However, nowadays, herders confront a wider spectrum of risks and uncertainties, which are caused by structural shifts within global political and economic spheres, including land acquisition and marketization as well as climate change (Scoones and Nori, 2023). In China's pastoral regions, along with the privatization of livestock ownership and rangeland management rights, marketization mechanism has been increasingly applied to cope with the risks and uncertainties, rather than the traditional nomadic practices. . Consequently, the livestock production and herders' livelihoods have been becoming more market-dependent (Dalingtai et al., 2010; Gongbuzeren, 2019). The dynamics of pastoralism under marketization needs to be in-depth studied..

Following the emergence of COVID-19 in China in December 2019, the pandemic outbroke and spread across the nation. Consequently lockdown was taken as the main measure to control the pandemic in China in the next 3 years until the official lifting on December 5, 2022, although the stringency and timing of lockdown varied by regions. For herders on the Tibetan Plateau, the primary lockdown period was from June 2022 to the early December 2022, which lasted around half year. The COVID-19 crisis presents a unique opportunity to re-evaluate the human-environment relationship. Additionally, the lockdown provides a natural experiment to study the impacts of sudden external shocks on pastoralism under a marketized context.

Current researches related to the impacts of the COVID-19 pandemic on pastoralism mainly focus on two aspects. Firstly, some studies examined pastoral health conditions and disease prevention from health and safety perspectives, proposing comprehensive public health measures such as the "One Health approach" (Egeru et al., 2020; Elsevier, 2020; Griffith et al., 2020; Griffith et al., 2021). Secondly, by rapid surveys and interviews during the pandemic, scholars investigated the immediate and direct effects of the lockdown on herders' lives(Gelgelo and Tsedu, 2022), focusing on human and livestock mobility(Simula G, et al.,2020; Gelgelo and Tsedu, 2022), livestock product sales(Ilukor J et al., 2022;), children education(Simula G, et al.,2020;), and herders' coping strategies(Maryam R et al., 2020). These studies underscored the flexibility, innovation, and resilience of herders in the face of restrictions of lockdown (Simula G et al., 2020; Simula G, 2023; Joana et al., 2023). However, the lockdown's impacts on pastoralism transcends regional and temporal boundaries, affecting not only the immediate and local system but also continuous and broader ones, particularly in the context of increasing marketization.

In this paper, taking two pastoral counties with varying degrees of marketization on the Tibetan Plateau as case study sites, we assess the impacts of the COVID-19 lockdown on herders' lives and livestock production, including both immediate and post-pandemic impacts. By using comparative analysis, we evaluate the lockdown's impacts on these areas, and explore the the causes behind the different outcomes from the perspective of institutional risks

The marginal contributions of this article include two aspects. First, in addition to the immediate impacts, our studies report the subsequent impacts on post-pandemic pastoralism. Second, we report the new challenges that market and credit brings to pastoralism, which are often considered effective ways to avoid or mitigate risks caused by climate or natural disasters (Lu, et al., 2022). We suggest that increasing herders' participation in market design to mitigate risks and integrating traditional pasture knowledge with market mechanisms to foster a more resilient and sustainable pastoral economy.

Methods

1. Case areas

This study examines two case areas on the Tibetan Plateau: Qilian County within the Haibei Tibetan Autonomous Prefecture of Qinghai Province, and Maqu County within the Gannan Tibetan Autonomous Prefecture of Gansu Province (Figure 1). Both regions are characterized by their high-altitude pastoral settings. Qilian County is nestled in the central part of the Qilian Mountains in northeastern Qinghai, whereas Maqu County is positioned on the eastern periphery of the Tibetan Plateau. Despite their similarities in altitude, topography, and climate, the two areas exhibit distinct marketization levels, with livestock husbandry being the principal economic activity for the local herders. Yak, Tibetan sheep, and a modest number of horses constitute the primary livestock, and the herder demographic is predominantly Tibetan.

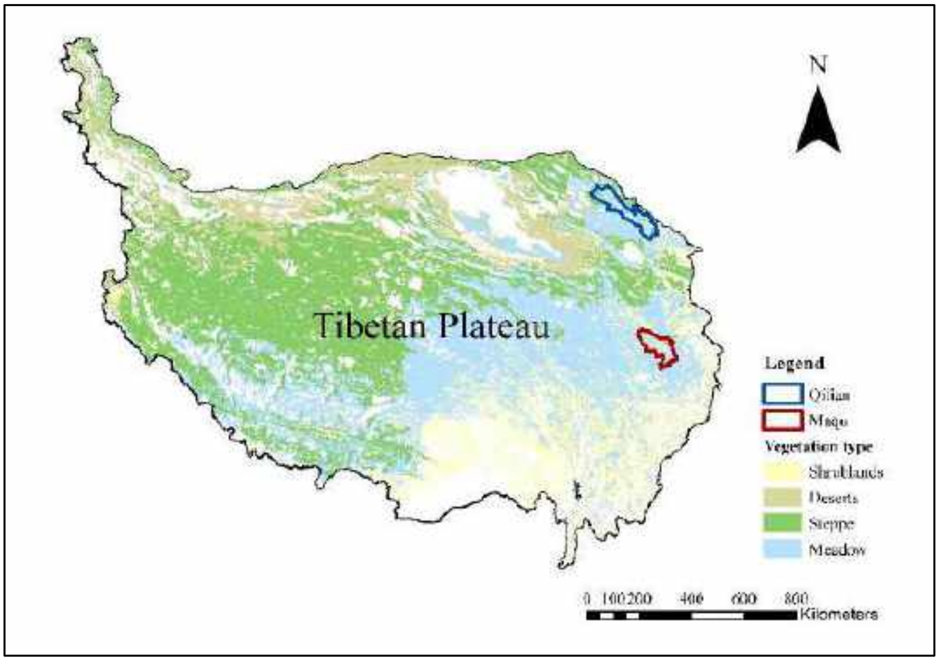

Figure 1. Map of the study case areas, Qilian and Maqu

2. Data collection

The research methodologies encompassed in-depth interviews and the administration of questionnaires, with key informants including village authorities, and the survey was directed at herder households within the villages. The in-depth interviews with principal stakeholders delved into lockdown protocols, overall impacts, coping strategies, and timelines, which shaped the questionnaire's content and pinpointed potential variables of impact. Employing a snowball sampling technique, one village per case area was selected for the survey, yielding data from 51 households: 20 from H Village in Qilian County and 31 from G Village in Maqu County. The study captured the strict lockdown period from June to December 2022, with the nationwide lockdown being rescinded on December 7, 2022. Data was collected for one year prior to and one year following the lockdown, encompassing 2021 (pre-pandemic), 2022 (pandemic period), and 2023 (post-pandemic), facilitating a comparative analysis. However, certain variables, such as loans livestock mortality and reproduction exhibited delayed effects: the majority of herders procured bank loans in early 2023 to meet heightened living and production expenses, suggesting that 2023 loan data is indicative of the 2022 pandemic impacts, while 2022 loan data reflects pre-pandemic cash needs from 2021. Similarly, despite the stringent lockdown measures being implemented in the autumn of 2022, the production impact leading to increased livestock mortality and decreased reproductive rate occurred in the following spring. Therefore, the data for 2023 represents the effects of the 2022 lockdown, while the data for 2022 represents a normal year before the lockdown. Other variables align with this pattern: 2022 data signifies the lockdown's impacts, 2021 pre-lockdown, and 2023 post-lockdown conditions. The questionnaire's first section evaluated the lockdown's overall impacts on herders' lives, including effects on routine herding practices, healthcare accessibility, shopping, and education. The second section concentrated on livestock production data across eight dimensions: livestock, pricing, fodder costs, pasture leasing or quota trading, loans, livestock mortality, reproduction and growth. Additionally, as ancillary data, the study collected temperature and precipitation statistics for the case areas from the EU and the European Centre for Medium-Range Weather Forecasts. Moreover, the principal author of this paper, being a Tibetan scholar, ensured that language barriers were surmounted during interviews and surveys.

3. Research Hypothesis

During our fieldwork in the two case study areas, a striking disparity was observed by the research team regarding the perceived impacts of COVID-19 lockdown measures on herders. Despite the lockdown's duration and nature being uniform across both locations, the experiences of herders in Qilian and Maqu diverged markedly. Herders in Qilian articulated a significantly heightened impacts from the lockdown, which impeded their ability to sell yak and sheep. Consequently, they encountered substantial financial strain, resulting in economic losses, accumulated debt, and the looming threat of insolvency. Conversely, Maqu herders reported a negligible impact from the lockdown. Although they also encountered challenges in livestock sales, they viewed the deferral of such transactions as a minor inconvenience, confident in their ability to sell their animals in the subsequent year. This observation begets a critical inquiry: under seemingly identical geographical and social conditions, how did uniform lockdown measures yield such divergent outcomes?

Considering transportation, regional connectivity, and pasture usage methods in our two case studies, we speculate that Qilian's pastoral region exhibits a higher degree of marketization compared to Maqu. This leads us to wonder if the marketization levels affect a region's resilience to external shocks or disaster mitigation. Consequently, we advance the central hypothesis of our study: There is a positive correlation between the level of marketization in pastoral areas and the severity of the impacts on livestock production due to pandemic-induced lockdowns.

4. Variables and Measurements

4.1 Life and Production

From initial in-depth interviews, it emerged that China's "zero-COVID" policy had kept COVID-19 infections nearly non-existent in pastoral regions prior to the lockdown's end in late 2022. The pandemic's influence in these areas was largely indirect, stemming from lockdown measures' disruption to the daily lives and livestock operations of herders. Consequently, this study identifies two key dependent variables: the lockdown's impacts on herders' lives and on livestock production (Table 1). The effects on herders' lives are distilled into four core domains: herding, healthcare, shopping, and schooling. Herding, while a production component, is primarily a daily life aspect for herders, encompassing tasks like looking after livestock, watering, feeding, and so forth. Healthcare captures non-COVID-19 hospital visits for illnesses, check-ups, childbirth, and medication. Shopping pertains to the procurement of daily necessities, and schooling covers the educational continuum from primary to university levels for students in pastoral regions.

The pandemic lockdowns' influence on livestock production is primarily evident in three key areas: impediments to sell, increased herding expenses, and production losses. This study employs these indicators to gauge the lockdowns' production effects. Firstly, livestock sale, a vital economic activity for herders, were disrupted by lockdowns that hindered mobility and transportation, affecting the trade between herders and traders. The impact on sale is twofold: timing and volume. Timing refers to sale delays or cancellations due to lockdowns, typically aligning with the optimal selling period from September to mid-October when livestock are in peak condition. In 2022, this period coincided with strict lockdowns, severely limiting trader movement and livestock transport, obstructing sales during this critical time. Volume indicates whether the number of livestock sold decreased or vanished due to lockdowns, compared to planned sales. Although some traders re-entered pastoral areas post-lockdown in December 2022, the prime selling window had passed, with livestock in poorer condition, leading to lower purchase offers. Consequently, some herders refrained from sale or sold only a portion of their livestock due to unsatisfactory prices, while others remained unsold due to lack of trader contact. Thus, livestock sale is deemed the primary indicator for assessing the lockdowns' impacts on production in this study. Secondly, restrictions on livestock sale pose dual financial challenges for herders: a cash flow crisis for livelihoods and increased costs for retaining livestock over winter, which demands more capital for feed and herding. To cope, herders often turn to loans to cover both living expenses and production costs. Therefore, this study analyses production costs for herders by examining expenses related to feed purchasing, pasture leasing, and loan status. Thirdly, the impediment to livestock sale not only raises production costs but also indirectly results in production losses. Herders may prolong their stay on overgrazed pastures, reduce feed to cut costs, or neglect livestock care due to pandemic-related distractions like assisting with online education. These practices can degrade livestock health, leading to higher mortality rate in spring and reproductive issues like infertility or miscarriages, thereby affecting breeding success. Hence, this study employs mortality and reproductive rate of livestock as metrics to evaluate the production losses incurred by pandemic lockdowns.

4.2 Degree of Marketization

To substantiate or refute the hypothesis that increased marketization in pastoral regions exacerbates the impacts of pandemic lockdowns on livestock production, this study adopts the level of marketization as the independent variable. It encompasses four precise indicators: the status of pasture use rights transactions, the ratio of feed purchases and pasture leasing costs to overall production expenses, the ratio of livestock sold relative to the total herd size, and the ratio of breeding livestock to the total herd (Table 1).

Sudden impact of pandemic lockdown measures shares similarities with natural disasters. Under market mechanisms, when faced with disastrous weather, herders need to purchase more fodder externally, rent more pastures through the market, or buy herding quotas to supplement the shortage of forage (Gongbuzeren, 2016). Conversely, in areas lacking market systems, herders, confronted with reduced natural forage during disasters, often resort to selling more livestock unless they practice communal rangeland use. In such cases, by reallocating pastures, they can optimize the use of remaining natural rangelands, thereby internalizing external costs. Hence, the exchange of pasture use rights, including leasing and quota trading, and feed purchases are pivotal metrics for gauging marketization levels. The volume of livestock sale by herders is indicative of their integration with the market. Herders with a higher degree of marketization typically sell more livestock annually to maximize economic returns. Thus, the paper adopts the ratio of livestock sold to total livestock as the third marketization indicator. As marketization intensifies, so does the proportion of female livestock in herds. Herders in market-accessible regions, aiming to maximize commercial profits (Scoones, 1994), prioritize output under constrained rangeland resources and herd size. In profit-driven livestock farming, after accounting for the production costs of male livestock, herders opt not to raise males beyond a few breeding animals. The herd predominantly consists of females, with young livestock being sold annually (in Qilian, female livestock can comprise up to 70% of a herder's herd). Post-sale, the remaining livestock are mostly female. Traditional subsistence farming, focused on herd expansion rather than direct economic profit, sells mature males over six years old and maintains a higher proportion of males aged two to six. Consequently, non-breeding females may constitute nearly half the herd, with the remainder being females. Hence, the proportion of female livestock serves as the fourth indicator in this paper for assessing marketization levels.

4.3 Meteorological Conditions and Infrastructures

Additionally, variations in infrastructures and extreme weather events significantly affect livestock production. On the Tibetan Plateau, the presence of shelter facilities for livestock can mitigate mortality and boost reproductive rate during winter and snowy conditions. Moreover, extreme climate events like snowstorms and droughts can escalate production costs and diminish livestock output. Consequently, this study incorporates these factors as control variables to isolate their effects from the study's competitive explanations.

Table 1 Variable Definitions and Measurements

Variable		Indicator		Measurement	Assessment Criteria
Dependent Variables	Life	Herding, Healthcare, Shopping, and Schooling		The proportion of affected households to the total sample, but in schooling only to samples with students	Higher affected proportion indicates more severe impact
	Production	Livestock Sale		The proportion of households affected in terms of selling time or quantity out of the total sample size.	Higher proportion of affected households compared to pre-lockdown indicates more severe impact
		Herding Costs	Foder and Pasture rent	Per household expenditure on foder purchase + pasture rent (unit:10 thousand yuan)	Higher increase compared to pre-lockdown indicates more severe impact
			Loans	Loan coverage rate (loan households/total sample households, %); Loan amount (households with different loan amount /total sample households, %)	Higher increase compared to pre-lockdown indicates more severe impact
		Production Loss	Livestock Mortality Rate	Per household livestock deaths/total livestock number (%)	Higher increase compared to pre-lockdown indicates more severe impact
			Reproductive Rate of Female Livestock	Number of offspring born and survived in the year/number of breeding female livestock (%)	More significant decline in reproductive rate compared to pre-lockdown indicates more severe impact
Independent Variables	Marketization Level	Pasture Use Rights Transactions		Whether there are pasture lease or herding quota transactions	Yes indicates high marketization level; No indicates low marketization level
		Total Foder Expenditure (purchase of foder + rent cost + purchase of herding quotas)		Proportion of foder expenditure/total production cost (%)	Higher proportion indicates higher marketization level
		Per Household Selling Rate		Number of sold livestock/end-of-year livestock number (%)	Higher proportion indicates higher marketization level
		Per Household Female Livestock rate		End-of-year female livestock number/total livestock number (%)	Higher proportion indicates higher marketization level
Control Variables	Infrastructures	Shed Construction		Whether there are modern warm sheds	Yes requires excluding the impact of shed facilities from the study's

				competitive explanations
	Meteorological Conditions	Abnormal Weather	Whether there are abnormal changes in temperature and precipitation before and after the lockdown	Yes requires excluding the impact of climate factors from the study's competitive explanations

Results

1. Marketization Level in the Case Areas

In Qilian, with winter pastures managed and fenced individually, pasture use rights are commonly traded among herders, which all sampled households participate in. Despite summer and autumn pastures being collectively managed, there is a clear system for herding quotas and compensations. Conversely, in Maqu County, pastures are collectively managed without clear household boundaries, and pasture leasing is absent. Although a quota system exists, it is restrictive, and none of the sampled households partake in pasture leasing or quota transactions. To sum up, the marketization level in Qilian County is higher than in Maqu County, as evidenced by four key indicators (Figure 2).

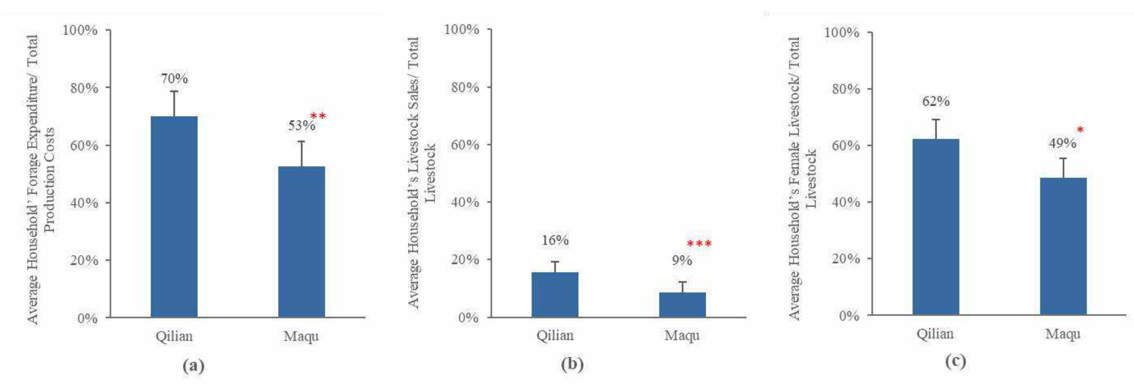

Figure 2. Marketization Level: a) Proportion of Average Household' Foder Expenditure to Total Production Costs ; b) Proportion of Average Household's Livestock Sales to Total Number; c) Proportion of Average Household's Female Livestock Number to Total Livestock Number

2.Impacts of Herder's Lives

Analysis of interviews indicates that daily life was moderately disrupted in both areas, with Qilian experiencing slightly greater impacts than Maqu (Table 2). More households in Qilian report difficulties with herding, healthcare, shopping, and schooling. Disruption to students' schooling is the most severe impact across both areas. Our findings (Table 3) detail specific disruptions to herding activities, with herders unable to reach herds 7–10 kilometers away during lockdowns, leading to water shortages for yaks and conflicts over stray animals (Case #1). Healthcare access was impeded, with some herders missing timely medical care (#2) and facing disruptions back to pasture after hospital quarantine (#3). Lockdowns also led to increased expenses and difficulties in procuring food (#4) and daily necessities (#5). Education was severely impacted, with families buying additional phones for online classes, renting accommodations in town (#6), or driving over 30 kilometers daily for internet access to continue their children's education (#7). In both areas, lockdown's impacts led to increased household expenses and indirectly effects on livestock production.

Table 2. Number and Percentage of Households Affected by Lockdowns in Daily Life (The "Schooling" Category Includes Only Households with School-Aged Children)

Case Areas	Herding	Healthcare	Shopping	Schooling
Qilian（20 in total, 12 with students）	4(20%)	4(20%)	2(10%)	12(100%)
Maqu(31 in total, 18 with students)	1(3%)	5(16%)	1(3%)	18(100%)

Table 3. Case Descriptions of the Impacts of COVID-19 Lockdowns on Herders' Lives

Case	Aspect of Life	Description of the Impacts During the Lockdown	Case areas
#1	Herding	I come from a single-parent household with a school-age son, residing in our village's pastoral area while our livestock were herded 7-10 kilometers away in the mountains. With only yaks in my herd, which are confined by barbed wire, I usually visit them every few days on my motorcycle to provide water. However, lockdown measures sealed all roads, preventing me from reaching the pasture. After several days, I learned from a villager that my yaks had broken the fence and entered another's pasture, prompting a demand for my immediate presence or risk losing my livestock. Despite my pleas to the roadblock guards, I was denied passage. Left with no alternative, I embarked on a grueling journey, traversing mountains and streams, to reach the pasture on foot. It consumed an entire day, but I managed to resolve the conflict by compensating the affected villager and returned my herd to safety.	Qilian
#2	Healthcare	My wife, who has a chronic stomach condition, was hospitalized for two months before the lockdown and was due for a follow-up in six months. However, her condition worsened during the lockdown, making it impossible to reach either the provincial or county hospital. We had to postpone her treatment until late 2023, resulting in a three-month delay.	Maqu
#3	Healthcare & Herding	In late August 2022, I was admitted to a Tibetan hospital in the prefecture for a minor ailment, planning a week-long stay. However, a COVID-19 outbreak in a neighboring county led to a prefecture-wide lockdown on my third night, halting all traffic. Initially, I received basic care, but within days, most staff were redirected to COVID-19 testing, leaving only a few nurses for us stranded patients. Treatments ceased, and we were confined to the inpatient building, receiving meager meals from centralized distribution. I remained stranded for nearly a month, coinciding with my family's seasonal pasture migration, which was also impeded by travel bans. Unable to move without me, my family managed to pick me up under cover of night and we evaded checkpoints via a mountain path, effectively "escaping" to our home.	Qilian
#4	Shopping	Over the pandemic's three-year span, pastoral area prices saw a notable uptick. The cost of flour, a staple for herders, escalated from 90 yuan per bag in 2019 to 95 yuan in 2020, then to 105 yuan in 2021, and during the 2022 lockdowns, it spiked to a range of 125 to 150 yuan per bag. Similarly, a 5-pound bag of tsampa climbed from 10 yuan in 2021 to 12 yuan in 2022.	Qilian
#5	Shopping	From early to late November 2022, our county faced a severe "smoke shortage", prompting the emergence of cigarette smugglers who inflated prices drastically—selling packs that normally cost 5 yuan for 30-40 yuan, and individual cigarettes, like Black Lanzhou, for over ten yuan, despite the market price being 18 yuan per pack. Compounding this, a gasoline shortage arose during the continuous mass nucleic acid testing period, when we were confined to our village and all stores and gas stations were shuttered. The dilemma was	Qilian

		exacerbated by the need to drive or ride a motorcycle for tests, often leading to cars running out of fuel. Fortunately, the lockdown was short-lived, and in its final days, restrictions were relaxed, permitting one person per household to refuel.	
#6	Schooling	I have two sons, one in the first and the other in the third year of middle school, both studying at our county's ethnic middle school. During the pandemic, our greatest wish was for our children to return to school as online learning was challenging for us. I initially bought each son a phone for online classes, but after two months in the autumn pasture, their phone bills soared past 400 yuan. The situation deteriorated further when we moved to the winter pasture, where there was no internet signal. Unable to provide for their online education despite the expenses, I rented a small house in town for them to study. Their mother would join them occasionally due to our busy home life.	Qilian
#7	Schooling	I have a son in high school and another in elementary school, both of whom required online classes during the 2022 pandemic. Lacking signal or electricity on our farm, I had to drive them daily to an area with reception, a round trip exceeding 30 kilometres. This daily commitment to their education significantly reduced my time for tending to our yak and sheep, leading to a high mortality rate among our livestock that year.	Maqu

3. Impacts on Herders' Production

3.1 Livestock Sale

In both areas, livestock sale constitutes the predominant source of income, with Maqu over 75% and Qilian 85% out of total household's income. Notably, Qilian's reliance on livestock sale is 10% greater than Maqu's, suggesting a higher dependence on such sell to cover living and production costs. Among the sampled herders in Qilian, 90% encountered impediments to livestock sell due to pandemic-induced lockdowns, significantly higher than the 31% reported in Maqu. This result underscores the more pronounced adverse effects of lockdown on livestock sale in Qilian. The description of herder household BC (Table 6) provides a typical example of the lockdown's effect on livestock sale.

3.2 Herding Costs

（1） Expenditure on foder purchases and pasture rentals

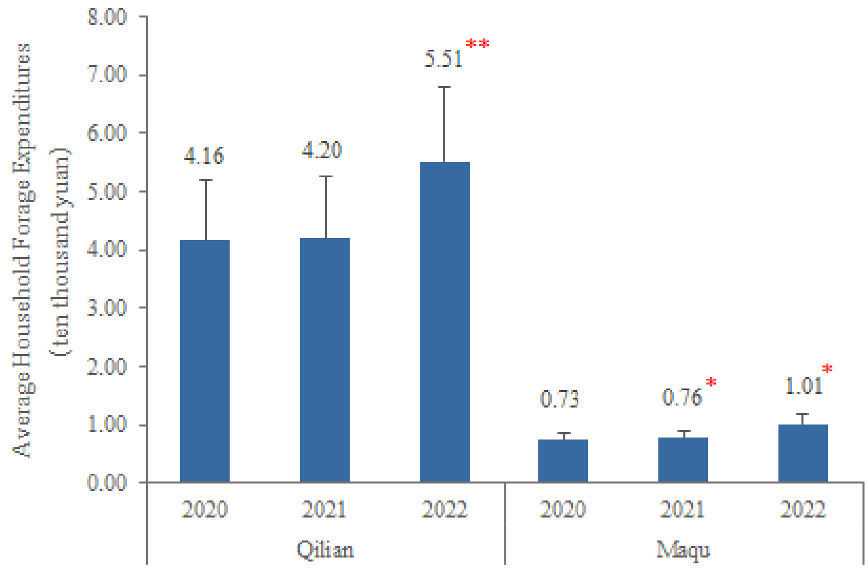

Figure 3. Average Household Foder Expenditures (Foder Purchases + Pasture Rentals + Herding Quota Purchases) (Note: Asterisks indicate significant differences, *p<0.05, **p<0.01, ***p<0.001)

Table 5. Comparison of Foder Prices in Qilian County from 2020 to 2022(Unit: Yuan)

Year	Mixed Foder (per ton)	Alfalfa Hay (per bale)	Oat Hay (per bundle)
2022	3100-3500	45-60	6
2021	2800-3100	35-50	3
2020	2800-3000	34-48	3

（2） Loans

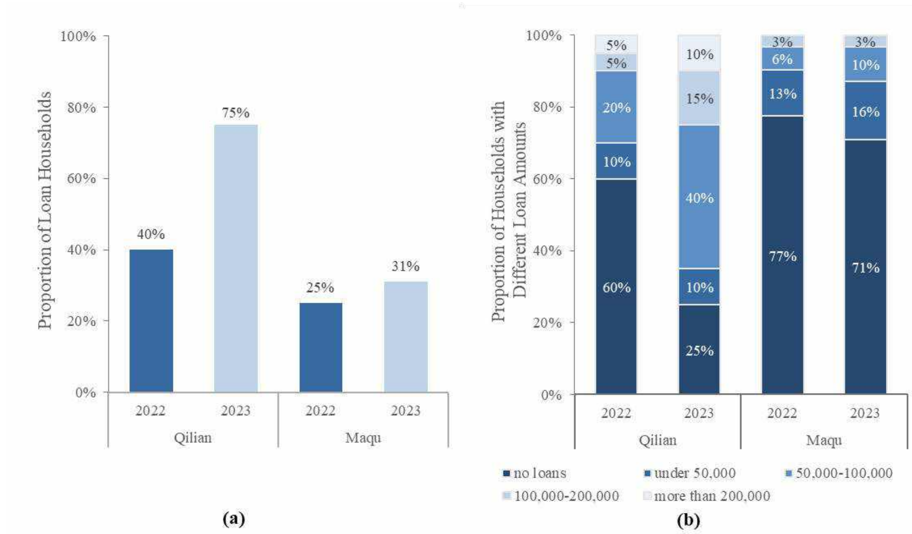

Figure 4. Loans: a) Changes in the Proportion of Loan Households Pre-and Post-Pandemic Lockdown; b) Changes in the Proportion of Households with Different Loan Amounts Pre-and Post-Pandemic Lockdown

3.3 Production Loss

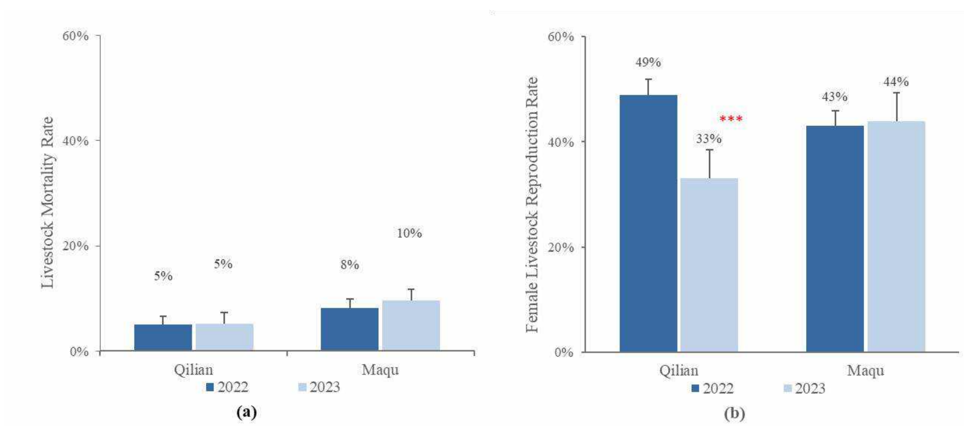

Figure 5. Livestock Morality and Reproductive rate: a) Changes in Average Household Livestock Mortality Rate Pre-and Post-Pandemic Lockdown; b) Changes in Average Household Female Livestock Reproductive rate Pre-and Post-Pandemic Lockdown (Note: Asterisks indicate significant differences, *p<0.05, **p<0.01, ***p<0.001)

Table 6. Case Descriptions of the Impacts of the Lockdown on Herders' Production

Case	Aspect of Production	Descriptions of the Impacts During Lockdown	Case areas
#BC	Livestock Sale & Loans	Herder BC, a relatively well-off member of his community with a family of four, started 2023 with a livestock count of 500 sheep (350 ewes) and 280 yaks (180 female), with over 65% being female. His usual strategy is to sell 90% of the lambs and culled animals annually, constituting 60% of his stock. He had planned to sell 300 sheep and 60 yaks in late 2022, expecting 1,300 yuan per ewe and 850 yuan per lamb. The pandemic lockdown disrupted these plans, and he could only sell a fraction in November 2022 at reduced prices—900 yuan per ewe and 700 yuan per lamb. Consequently, he sold only 35 ewes and 65 lambs, totalling 100 sheep, which was one-third of his intended sales, with no yak sold. Being unable to sell as anticipated meant he had to buy additional foder for the winter to feed his livestock. To cover these costs, BC took a bank loan of 250,000 yuan, of which 44,000 yuan was used to purchase foder and 100,000 yuan was allocated for pasture rental, totalling 144,000 yuan in production costs for 2022.	Qilian
#MJ	Rise of Production Cost	Herder MJ’s household consists of five members, with herding rights to two portions of pasture (800 mu). In 2023, he had a livestock inventory of 510 sheep and 106 yak, compared to 100 sheep and 206 yak in 2022. From 2020 to 2022, he leased an additional four portions of pasture (1,200 mu), with rental costs rising from 30,000 yuan in both 2020 and 2021 to 50,000 yuan in 2022—an increase of 20,000 yuan compared to the previous year. In 2021, MJ's feed expenses were 3,000 yuan, which jumped to 30,000 yuan in 2022. His foder costs also increased from 5,000 yuan to 12,000 yuan over the same period. Overall, pasture rental costs tripled, while foder and feed expenses quintupled from 2021 to 2022.	Qilian
#Q	Livestock Sale, Production Cost & Loss	Herder Q, part of a four-member household with rights to two pasture sections (800 mu), had a herd of 180 yak and 718 sheep in 2023. Due to pandemic restrictions in 2022, he missed the optimal time to sell livestock and had to rely on supplemental feeding to maintain and fatten the herd. His foder-related expenses included 74,000 yuan for pasture rental, 79,000 yuan for foder, 50,000 yuan for renting wheat fields, and 10,000 yuan for other production costs, totalling 213,000 yuan—a 67,300 yuan increase compared to 2021. After three to five months of fattening, the selling price was nearly the same as it would have been during the regular season. However, the fattening process required significant labour and herding resources, reducing the attention available for other livestock. Additionally, to cut costs, he delayed moving to winter pastures by staying on (communal) summer pastures for an extended period, which not only damaged the summer pasture but also led to higher livestock mortality rate and lower reproductive rate in spring 2023. Livestock mortality more than doubled from 2022, with 14 yak and 28 sheep deaths, to 40 yak and 53 sheep in 2023, with a significant number of losses among the young.	Qilian
#Z	Livestock Sale, Production Cost & Loss	Herder Z's household, comprising three members with herding rights to two pasture sections (350 mu), owned 56 yak and 226 sheep in 2023. Pandemic lockdowns in 2022 resulted in the sale of only 15 yak, generating 90,000 yuan. However, that year's production costs escalated to 96,550 yuan, including 47,000 yuan for additional pasture rent, 18,750 yuan for foder, and 40,800 yuan for feed. The household also suffered the loss of 37 sheep and took a 300,000 yuan loan, leading to expenses that dwarfed income and brought the family to the brink of financial ruin.	Qilian

1. Meteorological Conditions and Infrastructures

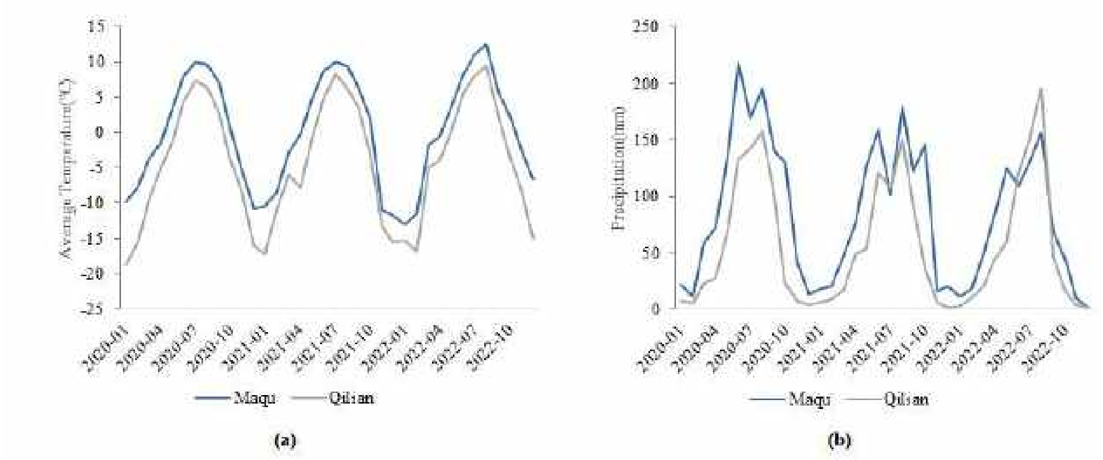

Figure 6 Meteorological Conditions: a) The Monthly Average Temperature Changes From 2018 To 2022; b) The Cumulative Monthly Precipitation From 2018 To 2022.

In terms of livestock infrastructure, Qilian herders are all equipped with at least one modern warm shed, which is crucial for protecting new-born lambs from freezing during winter lambing. Conversely, Maqu herders lack access to such facilities, including warm sheds, which are essential for livestock management.

5.Argumentation: The Closer the Connection with the Market, the Greater the Impacts of Lockdown

Drawing from the research data and information presented, it has been observed that the pandemic-induced lockdown had impacts on herders' daily lives in both areas, with Qilian experiencing a marginally greater effect than Maqu. However, when considering production, the lockdown's effects on Qilian were markedly higher than those on Maqu. In the following analysis, we will first delve into the factors contributing to the lockdown's influence on livestock production in Qilian. Subsequently, adopting a marketization lens, we will elucidate the divergent impacts of identical lockdown measures on the two areas, thereby validating or refuting our initial research hypotheses.

5.1 Lockdown Hindered Livestock Sale

As previously highlighted, the sale of livestock constitutes the principal source of household revenue for herders in both areas, implying that their annual earnings are contingent upon the sale of livestock considerably. The COVID-19 lockdown imposes constraints on livestock sale for that year, impacting both the transaction avenues and price.

The lockdown restrained the transaction avenues for herders. Within China's pastoral regions, the sale of livestock is heavily reliant on the role of "middlemen," who function as intermediaries in the procurement of yak and sheep. Customarily, the livestock selling season spans from early September to mid-October, a period during which middlemen from diverse regions converge on herders to engage in livestock purchases. However, the 2022 selling season coincided with the most stringent phase of the pandemic lockdown. The lockdown's restrictions on human and vehicular movement impeded middlemen from accessing herders, thereby preventing herders from executing their planned sales (Table 6, herder BC, Q, and Z).

The pandemic lockdown exerted indirect influences on livestock sale prices, diminishing the herders' willingness to sell. Following the relaxation of restrictions in mid-December 2022, while some middlemen ventured into the pastoral regions, the livestock had passed their optimal selling condition. On one hand, the livestock's condition had declined relative to the peak selling period. On the other hand, middlemen, who have the pricing power, lowered the purchase price as they predicted an increased livestock inventory (Table 6, herder BC). From the perspective of market demand, the pandemic lockdown also impacted the market price indirectly. Interviews with middlemen revealed that during the lockdown, tourists to the Tibetan Plateau were significantly depressed. Restaurants and butcher shops experienced prolonged closures, leading to a contraction in local demand for beef and mutton. Concurrently, slaughterhouses grappled with inventory backlogs acquired before the pandemic. Resulted surplus ultimately depressed the prices of beef and mutton, influencing herders' selling decisions.

Different levels of marketization have precipitated distinct pastoral strategies, amplifying the lockdown's impacts on herders with higher marketization. In Qilian, a substantial 90% of herders encountered obstructions in their sale, contrasting with only one-third of Maqu herders who perceived an inability to execute their livestock sale as anticipated. Despite of equivalent lockdown durations and measures, under distinct pastoral strategies generated from different marketization level, their reliance on livestock sale is varied.

Maqu herders, with a lower degree of marketization, adhere to a more traditional, subsistence-based pastoralism. They invest less capital in livestock production and prioritize herd stability over economic profit maximization. Their annual sales are relatively modest (Figure 2.b), directed at covering basic livelihood expenses, thereby reducing their dependence on any certain livestock sale round. In contrast, Qilian herders engage in a more commercially oriented pastoralism. They frequently incur debts to augment investments in foder, feed, or leased pastures, leading to a significantly higher cash outlay expenses in livestock production compared to Maqu herders (Figure 3). In Qilian, the proportion of breeding livestock is more substantial (Figure 2.c), and a larger segment of the herd is marketed (Figure 2.b), with an emphasis on little livestock (mainly lambs) for enhanced output. Livestock sale serve two purposes: meeting living expenses and covering current production costs. Consequently, Qilian herders exhibit a heightened dependence on every livestock sale round to satisfy both subsistence and investment demands. Thus, the pandemic lockdown's restrictions on sale had a more remarkable effect on Qilian herders, attributable to their increased reliance on sale to fulfil cash flow and production cost.

5.2 The Increasing Number of Livestock in Hand Lead to Increased Feeding Costs and Greater Production Losses

Impediments to livestock sale leading to herders with higher levels of marketization incurring higher production costs and losses. The blockage of livestock sale resulted in an increased livestock on hand, which subsequently rose the demand for fodder and natural pastures, thereby augmenting production expenses. The impacts on the two areas are distinct, characterized by varying degrees of marketization. Qilian herders, already heavily reliant on market-procured fodder and pasture rentals, faced an increased prices of commodities in response to the heightened demand because of the market mechanisms (Table 5). This surge significantly magnified herding costs, and the concomitant rise in fodder demand and prices substantially escalated the cash requirements for herders (Table 6, herder MJ). In this context, loans become herders' only solution, resulting in a notable increase in both the numbers and amount of loans taken by Qilian during the lockdown (Figure 4,a). In the pastoral context, loans not only fail to alleviate risks but also introduced the burden of interest and repayment obligations, exacerbating the financial strain on herders

(Table 6, Herder Z). Consequently, when the sale in Qilian were impeded, herders whose predominant revenue stream is livestock sale, confronted escalating production costs, particularly for fodder.

Moreover, an increase in livestock numbers necessitates additional labour input for feeding and care. Any shortfall in fodder supply or animal care can lead to heightened risks of livestock mortality or reduced reproductive rate among female animals, as demonstrated in the case of herder Q (Table 6). Without adequate funds to procure sufficient fodder to sustain livestock through the winter, there is an elevated risk of increased mortality rate (Table 6, herder Q and Z) and malnutrition among female animals, which, in turn, adversely impact reproductive performance (Figure 5,b).

In contrast, Maqu herders exhibit a lower cash outlay expenses in livestock production. With no market for herding rights and limited fodder usage, Maqu's production costs are much lower than in Qilian, resulting in fewer loans. Therefore, when faced with impediments to livestock sale, Maqu herders incur no additional financial losses beyond basic living expenses. Additionally, since the Maqu herders share grazing land within small groups and do not engage in market-based leasing or quota trading, an increase in herding demand by certain herders due to sale disruptions does not lead to intense competition over pasture resources. Instead, they mitigate herding costs through multiple relocations within the group, thereby externalizing herding costs and avoiding the risk of increased expenses from rising pasture prices. Consequently, after the pandemic lockdown, Maqu herders, with their lower degree of marketization encounter less production costs and production losses in comparison to Qilian herders.

5.3 Exclusion of Competing Explanations

Beyond the sufficiency of fodder supply, livestock mortality and reproductive rate are also contingent upon natural disasters and the state of livestock production infrastructure. Meteorological data indicate that neither of the areas exhibited anomalous temperature or precipitation patterns in 2022 (Figures 7, a and b), and herders surveyed reported no occurrences of droughts, snow disasters, or other climate-related events during the lockdown. This excludes any correlation between production losses in the two areas with climatic anomalies or natural disasters. In the sampled populations of the two areas, all herders in Qilian County possessed at least one modern warm shelter and sheep pen, in contrast to none of the sampled herders in Maqu. The slightly elevated livestock mortality rate in Maqu, relative to Qilian, is partly ascribed to less supplemental feeding and inadequate livestock infrastructure. Although the post-pandemic increase in livestock mortality rate was not significant in either area, mortality rate alone does not comprehensively represent production losses in livestock farming. Reproductive rate explicitly indicate that Qilian witnessed a marked decline in production following the pandemic lockdown, while Maqu's reproductive rate not only remained stable but actually increased by 1% (Figure 5,b).

In conclusion, the research findings substantiate the initial hypothesis of this study: the primary reason for the more serious impacts of the pandemic lockdown on Qilian compared to Maqu is associated with the level of marketization. The closer the market ties, the more severe the lockdown's impacts.

Discussion and Conclusion

This study illustrates the divergent impacts of a uniform pandemic lockdown on two case study areas with varying marketization level. The research findings underscore that Maqu, characterized by a lower degree of marketization, experienced muted effects from the lockdown. Qilian, however, with a higher degree of marketization, encountered more substantial repercussions. Maqu exhibited enhanced stability and sustainability when facing the pandemic lockdown's abrupt external shock. However, the market-integrated Qilian endured severe outcomes, with numerous herders encumbered by significant loan debt, and some even confronting insolvency, such as herder Z (Table 6). Hence, the inquiry into the root cause of this divergence arises.

Marketization is a pivotal avenue for economic growth and modernization; however, it can engender risks concurrently. The extant mainstream research on credit and fodder markets for pastoral socio-ecological systems, particularly in the context of extreme climatic events, has predominantly posited that market mechanisms facilitate herders' resilience to disasters (Agrawal, 2010; Addison and Brown, 2014; Carter et al., 2007; Ouma et al., 2011; Turner and Williams, 2002; World Bank, 1994; Horn et al., 2003; Müller et al., 2015; Schulze et al., 2016). Nevertheless, some case-based studies have unveiled that while market mechanisms might offer short-term alleviation for herders confronting disaster-induced impacts, over the long term, they may result in a severe deterioration of natural rangeland ecosystems, potentially generating the collapse of the pastoral economic system (Li and Li, 2021; Lu et al., 2022; Briske et al., 2015). This phenomenon arises from the dependency on external loans to procure fodder, which can disrupt the negative feedback loop between the pastoral economic system and the local ecosystem, culminating in an imbalance within the local socio-ecological system (Lu et al., 2021; Zhang et al., 2018).

The advent of the COVID-19 and its attendant control measures bear resemblances to the meteorological calamities commonly encountered in pastoral regions, given their inherent unpredictability and catastrophic nature. However, diverging from prior research that highlighted the potential long-term perils associated with market forces, this study discerns that in the context of abrupt occurrences, such as the pandemic, the risks intrinsic to market integration materialize swiftly, manifesting even within the short term.

In pastoral areas with high climate variability, pastoralists have historically employed strategies such as livestock mobility, livelihood diversification, communal herding, and storage to navigate such fluctuations (Scoones 1994; Xie and Li 2008), thereby sustaining a resilient socio-economic system (Fernández-Giménez and Swift 2003). However, the advent of land privatization (Fernández-Giménez 2001; Li et al. 2007; Li and Huntsinger 2011) and shifts in policy direction (Gongbuzeren et al. 2015) have encumbered the sustainability of these traditional practices. Consequently, pastoralists have sequentially gravitated toward market-oriented tactics. Through market mechanisms, they have amplified their socio-economic systems by integrating external resources, including fodder, feed, and credit facilities. Nevertheless, in the face of sudden incidents akin to pandemic lockdowns, these market-reliant pastoralists are exposed to associated risks, culminating in a surge of production costs and economic losses. This mode of livestock production, heavily contingent upon external resources, has transcended local ecological thresholds, with the socio-economic system effectively expanding outward and progressively diss-embedded from the indigenous ecosystem, leading to deleterious environmental impacts (Table 6, herder Q). The elevated stocking rates, sustained by substantial external fodder inputs, have intensified the overgrazing of indigenous pastures, further depleting natural forage reserves. This, in turn, fosters an increased dependency on external market inputs, establishing a vicious cycle that jeopardizes the stability of the pastoral economic system and potentially precipitating its collapse.

The incursion of market mechanisms does not inexorably signify the obsolescence of traditional strategies designed to navigate uncertainty. A crucial factor that attenuated the pandemic lockdown's impact on Maqu herders, relative to Qilian, is the preservation of a communal pasture management approach. Despite some households confronting heightened herding demands consequent to impeded livestock sale, they effectively internalized financial burdens by employing community-based practices, such as rotational herding. This traditional strategy showcased a more robust resilience to abrupt shock compared to the scenario in Qilian, where herders, who wholly dependent on market mechanisms, were severely affected by the COVID-19 lockdown.

In the process of transitioning from traditional subsistence-based pastoralism to commercialized livestock production, pastoral areas on the Tibetan Plateau have yet to establish effective mechanisms for managing market risks. This study reveals that herders lack direct channels for livestock sale and depend on intermediaries to access the market, highlighting the vulnerabilities and risks inherent in pastoral markets. To enhance the stability and sustainability of rangeland pastoralism amid market-oriented development, this study offers the following recommendations: 1. Enhance herders' participation in market design: strengthen herders' involvement in various market stages, from purchasing fodder to selling livestock, by developing a market chain that centers on herders. This approach would mitigate the risks associated with market fluctuations. 2. Support traditional pastoral strategies: recognize and support traditional pastoral strategies and knowledge, such as community-based reciprocal herding and resource-sharing systems, which are crucial for coping with uncertainties and sudden disasters. Policy measures should encourage the preservation of these traditional practices, allowing local experience to play a more significant role in sustainable development.

Acknowledgements
Firstly, we are thankful to our friends gDugdkar, rDorje Lhungrub, Macig Skyabs, gCodpa Dongrub, and others who provided convenience and assistance during the field investigations, as well as to all the herders who participated in interviews and shared valuable information. Last but not least, we extend our gratitude to all members of our research group for their guidance and assistance in data organization, mapping, and the revision processes of this thesis.

Abstract

The supply of nitrogen (N) to plants limits primary productivity in numerous ecosystems and these limitations in N concentrations in plants also limit herbivores, by limiting their productivity in relation to both plant nutritional quantity and quality. Carbon isotope ratio can provide insight about the photosynthetic pathways utilized by different plant species. Plant C and N isotope ratios were studied for different species growing in old arable lands in Kubedlana communal area, located at 32◦11′53 S and 28◦14′1 E and at 1020.8 m altitude in the Eastern Cape, South Africa. The vegetation type of the study area is the Foothill Moist Grassland. The area receives an annual rainfall between 600 mm and 750 mm. The study was aimed at testing whether there was seasonal shift amongst different plant species in relation to δ13C and δ15N isotopes. Leaf samples of *L. cuneata* (legume), forbs (weeds) and native grasses from the area were sampled to determine carbon and nitrogen isotope ratios. Plant samples were dried for 48 h at 70 °C and ground with a ball mill. All sampling was done once in spring (November) 2022, summer (February) 2023 and autumn (March) 2023 and winter (May 2023) seasons, respectively. Permutational multivariate analysis of variance (PERMANOVA) was used to test the effect of plant type (forbs, grass and legume) on $\delta^{13}C$ and $\delta^{15}N$ isotopes. There was a significant difference (P = 0.001) between the three plant species and seasonal change regarding $\delta^{15}N$ ratios. $\delta^{13}C$ ratios, plant type also significantly (P = 0.001) affected plant carbon ratios. These findings emphasize the importance of

legume inclusion into old lands which is crucial in promoting nutrient cycling in pastures and ultimately nutritive value which is critical for improved animal performance.

Introduction

Nitrogen (N) is a significant limiting resource in numerous terrestrial ecosystems and N cycling influences most aspects of ecosystem function (Thomas *et al*., 2013). The supply of N to plants limits primary productivity in a myriad of ecosystems (Oberson *et al*., 2013). The limitations in N concentrations in plants also result in limitations to herbivores, by constraining the productivity of herbivores in relation to both nutritional quantity and quality of plants (Craine et al. 2015b; Zavala *et al*., 2013).It is therefore crucial to understand how patterns in terrestrial N cycling occur within and across ecosystems in order to predict patterns of plant productivity, ecosystem carbon sequestration, nutrient fluxes and trace gas losses to the atmosphere (Goll *et al*.,2012; Hudman *et al*., 2012). Photosynthesis is also strongly affected by nitrogen availability because the photosynthetic machinery accounts for more than half of the N in the leaves (Pinder *et al*., 2012). Typically, plant leaves are used as an index of δ^{15}N of the whole plant. Although there may be differences that exist among leaves, roots, and stems (Unkovich, 2013), the N isotope ratios generally correlate among plant fractions and any average differences are generally minor. For example, a study that was done, across 90 grass species collected from 67 sites in four grassland regions worldwide for the determination of δ^{15}N, the δ^{15}N of leaves averaged just 0.3‰ less than those of roots compared to a range of 18 ‰ for leaves and 14 ‰ for roots (Craine *et al*., 2015b). Although the N cycle is consisting of numerous processes that are difficult to measure, the ratios of δ^{15}N in plants or soils provide an indication on patterns of crucial aspects of the N cycle. These aspects comprise of the following: N supply rates to ecosystems and plants, N availability to plants, the N pathways by which N is lost from ecosystems, and the quantity of N lost. There is evidence that plant species differ in their capacity to assimilate inorganic and organic N however, there is limited known information and how interactions with companion plants affect the use of different N sources (Unkovich, 2012).

Therefore field (farm) research was carried with the aim to conduct a full investigation into the plant carbon (δ^{13}C) and nitrogen (δ^{15}N) nutrition of *L. cuneata*, a leguminous plant species, and its companion plants growing in old arable lands at Kubedlana communal area near Tsolo, Eastern Cape, South Africa. The study of *L. cuneata* and its companion plants' carbon and nitrogen nutrition is particularly relevant for understanding the long-term effects of land-use changes and the potential for ecological restoration. By examining the δ^{13}C and δ^{15}N signatures of *L. cuneata* and its companion plants, researchers can clarify the plant-soil-microbe interactions, nutrient cycling, and the potential for these abandoned lands to support diverse and resilient plant communities. Additionally, this analysis can contribute to an in-depth understanding of the nitrogen cycling dynamics within the old arable lands' ecosystem. Furthermore, the insights gained from this research can inform sustainable land management practices, such as the integration of *L. cuneata* and other leguminous species into agroecosystems, to enhance soil fertility, improve nutrient cycling, and promote the overall ecological health of these agricultural landscapes. This research was also aimed at elucidating the complex interplay between the carbon and nitrogen dynamics within this plant community, with a particular focus on understanding the adaptive strategies and resource partitioning mechanisms employed by *L. cuneata* and its associated plant species in the context of the old arable land ecosystem as influenced by seasonal change.

Study Area

The research was conducted in old arable lands at Kubedlana communal area near Tsolo under OR Tambo district municipality in the Eastern Cape Province, South Africa. Kubedlana is located at 32◦11′53 S and 28◦14′1 E and at 1020.8 m altitude. The vegetation type in the study area is classified as Foothill Moist

Grassland (Mucina and Rutherford, 2006). The annual rainfall of the area is estimated to range between 600 mm and 750 mm, while temperatures range between 3 ◦C in winter and 28 ◦C in summer. The soil chemical properties are as follows: P (5.99 mg/kg), K (0.20 mg/kg), Ca (4.26 mg/kg), Mg (1.16 mg/kg), and Zn (6.28 mg/kg).

Plant sampling and preparation

Samples of the uppermost fully expanded leaves of legumes, forbs (weeds) and native grasses from the legume and control (grass only) plots were sampled to determine dry matter production and other biochemical contents. Leaf samples were dried for 48 h at 70 °C and ground with a ball mill. Leaf nitrogen and carbon isotope ratios (i.e. foliar $\delta^{15}N$ and $\delta^{13}C$) and N were determined from approximately 3 mg with an isotope-ratio mass spectrometer (IRMS; Deltaplus XP and Delta C prototype Finnigan MAT, respectively, Finnigan MAT, Bremen, Germany; 0.1‰ precision). The $\delta^{15}N$ values represent nitrogen isotopic composition of the sample relative to that of atmospheric dinitrogen in ‰: δ 15N = (Rsample Rstandard − 1) × 1000 (1), where R = sample is the sample isotope ratio (15N/14N) and Rstandard is the $\delta^{15}N$ ratio for atmospheric N_2.

Data analysis

R vegan package statistical package was used to analyse all data, utilising a permutational multivariate analysis of variance (PERMANOVA) (Anderson, 2001; McArdle & Anderson, 2001). PERMANOVA was used to test the effect of the season (summer, winter, spring, and autumn) and plant type (forbs, grass and legume /*L. cuneata*) on foliar nutrient content. To graphically ordinate variation in plant isotope composition among the plant types and seasons, nonmetric multidimensional scaling (NMDS) was applied. Then a Non-Metric Multidimensional Scaling (NMDS) using Manhattan distance to assess the compositional dissimilarity among samples based on plant nutrient and isotope data was also used. The NMDS analysis was performed in R using the vegan package, with the dimensionality reduced to two axes to facilitate visualization. In addition, the generalised linear mixed model (GLMM) for each variable, with season as a random effect was also used to analyse data.

Results

There is a difference in the $\delta^{13}C$ isotope composition, and the shift is clear and inclined to plant type. Grasses had high ^{13}C content in comparison to forbs and legumes (Figure 3). In contrast, forbs and legumes usually utilising the C3 photosynthetic pathway, have a different carbon-concentrating mechanism as C4 plants, and they tend to have a higher discrimination against the ^{13}C isotope during carbon fixation. Consequently, C3 plants, including forbs and legumes, typically have lower ^{13}C content (more negative $\delta^{13}C$ values) compared to C4 plants. There was also a distinct observed differences in the ^{15}N isotope composition among the plant types in the old arable lands and this can be related to the fact that legumes, such as *L. cuneata*, can fix atmospheric nitrogen (N_2) through a symbiotic relationship with nitrogen-fixing bacteria called *Rhizobium*. The biological nitrogen fixation process preferentially incorporates the lighter ^{14}N isotope into the plant biomass, resulting in the lower (more negative) $\delta^{15}N$ values observed in legumes in current study. Grasses and forbs primarily obtain their nitrogen from the soil, and soils often have higher $\delta^{15}N$ signature due to various soil nitrogen transformation processes such as mineralization, nitrification, denitrification. Therefore, the non-leguminous plants tend to have higher $\delta^{15}N$ values as they assimilate the heavier ^{15}N isotope from the soil. When the data were classified seasonally according to drier (Winter and Autumn) and rainy seasons (Spring and Summer), there was a notable response ($p = 0.001$) in $\delta^{15}N$ values to variations in precipitation. Higher ($p = 0.001$) $\delta^{15}N$ values were observed during the dry and lower during rainy seasons, respectively. This seasonal tendency was observed throughout sampling seasons, but a variation in the scale on $\delta^{15}N$ values was noted, both for legume and non-legume species. (Table 1; Figure 2).

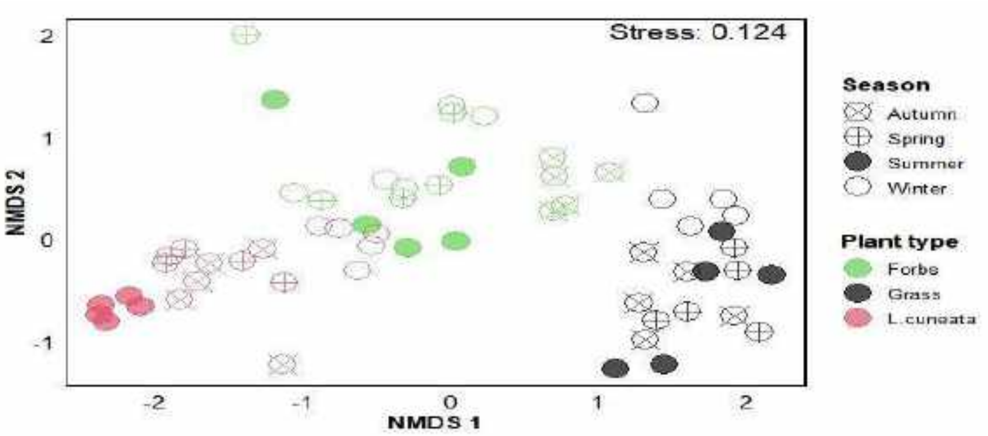

Figure 1: NMDS ordination of samples based on species plant nutrition and isotope data using Manhattan distance. Sites that are closer together in the plot have more similar plant nutrition and isotope compositions, as determined by Manhattan distance. Plant nutrients and isotope variables showed distinct spatial separation between the three plant types.

Table 1: Seasonal and plant type effect and their interaction on $\delta^{15}N$ content

Group variable	**df**	**R^2**	**F**	**P**
Season	**3**	0.072	10.399	0.001
Plant type	**2**	0.691	148.398	0.001
Season*Plant type	**6**	0.124	8.918	0.001
Residual	**48**	0.111		
Total	**59**	1.000		

There are significant differences in season ($r^2 = 0.072$ and $P = 0.001$), plant type ($r^2 = 0.691$ and $P = 0.001$), and in their interaction ($r^2 = 0.124$ and $P = 0.001$).

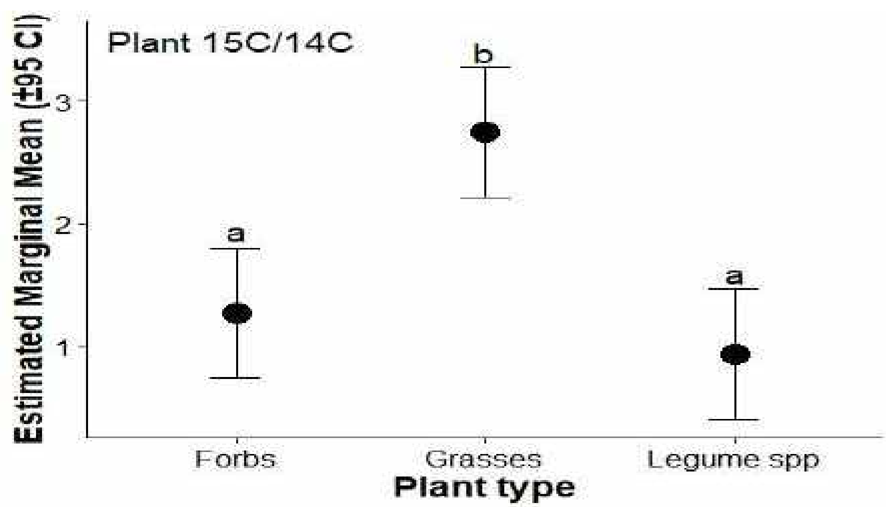

Figure 3: Carbon isotope ($\delta^{13}C$) nutrition of legume *(L. cuneata*) and different companion plant species growing in Kubedlana communal area.

Discussion

The $\delta^{13}C$ signature of grasses was significantly higher (less negative) than that of forbs and legumes. The type of pasture had a significant effect on $\delta^{13}C$. Grasses typically have higher $\delta^{13}C$, whereas legumes typically lower $\delta^{13}C$ than both forbs and grasses due to differences in C isotopic fractionation during CO_2 assimilation. The basis of the use of $\delta^{13}C$ procedure is that legumes (C3) species discriminate against ^{13}C during photosynthesis to a greater extent than do grasses (C4) species. Due to this fractionation during photosynthesis, C3 plants typically contain approximately 14 parts per thousand less carbon-13 than C4 plants. There was a notably clustering of plant functional groups where legumes and grasses separated along NMDS 1. The observed range of foliar $\delta^{15}N$ values for the legumes was notably smaller in comparison to grasses and forbs; respectively. This finding is consistent with the findings made by (Gerschlauer *et al*.,2019); who argued that $\delta^{15}N$ values of plants that mainly rely on N_2 fixation are usually - 0 ‰, reflecting atmospheric isotopic N values (Enriquez-Hidalgo *et al*.,2015). Craine *et al*.,2015b), also alluded that most N_2-fixing plants show significant departures from 0 ‰ due to differences in reliance on fixed N. The strong depletion of $\delta^{15}N$ in legumes compared to the forbs and grasses is an indication that legumes largely relied on atmospheric N. Foliar N concentration ranging at (-3.14 ‰ and -7.02 ‰) for legumes, which was lower than (4.65 ‰ and 7.91 ‰) for grasses and (-0.88‰ and 4.35 ‰) for forbs, respectively were found in the current study. Unkovich (2013); also argued that variations in $\delta^{15}N$ of symbiotic N_2 fixation were not necessarily the product of N_2-fixation, but rather a combination of measurement errors, intra-plant fractionation events resulting in tissue differences and possible preferential losses of ^{15}N-depleted NH_3. Higher values of $\delta^{15}N$ depicted by grasses are an indication that grasses depend, to some extent, on N from non-symbiotic N_2 fixation or from the soil.The $\delta^{15}N$ value, is a widely used indicator of nitrogen cycling and sources within ecosystems. The observed pattern in the current study, where grasses and forbs exhibit higher $\delta^{15}N$ values compared to legumes, can be ascribed to numerous underlying mechanisms such as nitrogen fixation, nitrogen cycling and fractionation, nitrogen acquisition strategies and environmental conditions. Legumes have the unique ability to fix atmospheric nitrogen (N_2) through a symbiotic relationship with nitrogen-fixing bacteria (e.g., *Rhizobium*). Consequently, legumes typically exhibit lower $\delta^{15}N$ values compared to plants that rely on soil-derived nitrogen sources, such as grasses and forbs.

Conclusion

In conclusion, the observed differences in the ^{13}C isotope composition among the plant types (grasses, forbs, and legumes) growing in the old arable lands of the Eastern Cape, South Africa, are primarily driven by their distinct photosynthetic pathways and carbon acquisition strategies. The observed shift in ^{13}C content, where grasses exhibited higher ^{13}C content compared to forbs and legumes, can be attributed to the distinct photosynthetic pathways employed by these plant types. Grasses, which primarily utilize the C4 photosynthetic pathway, usually possess higher ^{13}C content due to the efficient carbon-concentrating mechanisms involved in this pathway. In contrast, forbs and legumes, which predominantly utilize the C3 photosynthetic pathway, exhibit lower ^{13}C content. This difference in ^{13}C content reflects the distinct carbon isotope discrimination patterns associated with the C3 and C4 photosynthetic pathways. Therefore, the observed differences in the ^{15}N isotope composition among the plant types (grasses, forbs, and legumes) in the old arable lands of the Eastern Cape, South Africa, can be attributed to the distinct nitrogen acquisition and cycling processes associated with each plant functional group. The higher $\delta^{15}N$ values in grasses and forbs reflect their reliance on soil-derived nitrogen, while the lower $\delta^{15}N$ values in legumes are a result of their ability to fix atmospheric nitrogen. The observed higher δ15N values during the dry season and lower values during the rainy season can be attributed to the variations in water availability and its impact on nitrogen cycling processes. Several studies have shown that water availability is a key driver of $\delta^{15}N$ values in ecosystems, regardless of other factors such as soil nitrogen stock. During drier periods, reduced water availability can lead to increased soil nitrogen mineralization, nitrification, and volatilization, which preferentially remove the lighter 14N isotope and enrich the remaining soil nitrogen with the heavier 15N isotope.

Key words: Temperate grassland; GPP; Grassland-use system; Trans-boundary research

Abstract
Global climate change and divergent grassland use systems may lead to divergence and degradation of grassland systems in arid and semi-arid regions. However, the effects of grazing intensity on the gross primary productivity (GPP) of grasslands under climate change and the nomadic versus sedentary grazing systems are still unclear. Here, we investigate the grazing effects on different steppe ecosystems by comparing a ratio index change of nomadic GPP to sedentary GPP (NS) under different grazing intensities. The grassland GPP increased significantly between 2001-2023 across three grazing intensities under nomadic and sedentary grazing systems. The NS index in desert and meadow grasslands increased and then decreased across grazing intensities, with 2012 being the turning point. Surprisingly, the typical grasslands exhibited the opposite characteristics. The impact of differences in grazing systems did not exceed the regulatory role of climatic factors. Random forest analysis revealed that the minimum temperature ratio of the coldest month of nomadic to sedentary sites was the dominant factor influencing the NS index in desert and meadow grasslands. In typical grassland, the precipitation ratio of the warmest quarter of nomadic to sedentary sites is predominantly the NS index. Our study highlights the impact of changing climatic environments on the grassland GPP in the semi-arid region.

Introduction
Grazing reshapes vegetation communities' structure, composition, and function through feeding, urination, trampling, and seed dispersal (Ren *et al.*, 2024). The protection of semi-natural grasslands has relied on the maintenance of traditional nomadic systems for hundreds or even thousands of years (Deng *et al.*, 2023).

The traditional nomadic system is an inheritance that simulates the migratory behavior of wild herbivores. With the development of society and economy, some traditional nomadic grazing methods on common grasslands have gradually been transformed into fenced sedentary grazing on private pastures (Parra *et al.*, 2025). However, to our knowledge, the differences in the impacts of different grazing systems and intensity changes on grassland vegetation communities under the context of climate change remain unclear.

The grasslands of the Mongolian Plateau (MP), a significant portion of the Eurasian continent's temperate grasslands, are primarily found in Mongolia (UM) and China's Inner Mongolia Autonomous Region (IM). They are vital for regional ecological security and the livestock economy. However, the interaction of grazing and climate change has led to severe grassland degradation, posing an urgent challenge for sustainable grassland management in the region. The MP is a complete physical geographical unit. The parts of IM in China and UM have the same climate, biological evolution history, and similar modern climates, soil, and vegetation types. However, human activities driven by changes in land use policies show significant differences in the two countries. In the IM, an extensive sedentary grazing utilization mode has been formed, while in UM, traditional grassland nomadism is still practiced. Although many studies have focused on the impact of the combination of grazing methods, intensities, and climate change on the UM grassland ecosystem, most of them are limited to a single region within IM or UM and focus on the grassland conditions under different land uses. There is a need for comprehensive, cross-border studies to assess the impact of varying grassland utilization systems on vegetation productivity. Understanding these impacts and mechanisms is crucial for restoring degraded grasslands and developing sustainable management practices, ensuring regional ecological security.

Methods

The study area, situated in the central MP, encompasses desert, typical, and meadow grasslands in the IM and UM regions. July–August 2023, we identified 18 paired fenced experimental areas, which have been enclosed for 10 to 60 years, across these grassland types. Within a 30 km radius of each fenced plot, we established 36 additional paired experimental areas with varying grazing intensities, including light and heavy grazing under different methods (traditional nomadic grazing in UM and free grazing within fenced paddocks in IM). These 54 experimental areas served as the basis for a 4 km^2 buffer zone, which was used to analyze MODIS GPP data for each site in 2001-2023 (Fig. 1). The RFM method was used to analyze the driving mechanisms of the differences in GPP under different climatic conditions and grassland utilization patterns.

Results

Moderate grazing promotes the increase of vegetation GPP

From 2001 to 2023, the vegetation GPP in the fenced, lightly grazed, and heavily grazed experimental areas all showed a significant increasing trend (Fig. 2(a-c)). Under both the traditional nomadic grazing and fenced grazing systems, the typical grasslands and meadow grasslands are both applicable to the "Intermediate Disturbance Hypothesis" (IDH). The average value of vegetation GPP from 2001 to 2023 was the highest under light grazing, followed by the fenced and ungrazed grasslands, and finally the heavily grazed plots. Regardless of the grazing system, the vegetation GPP of the desert was more suitable for the Dynamic Disequilibrium Hypothesis (DDH).

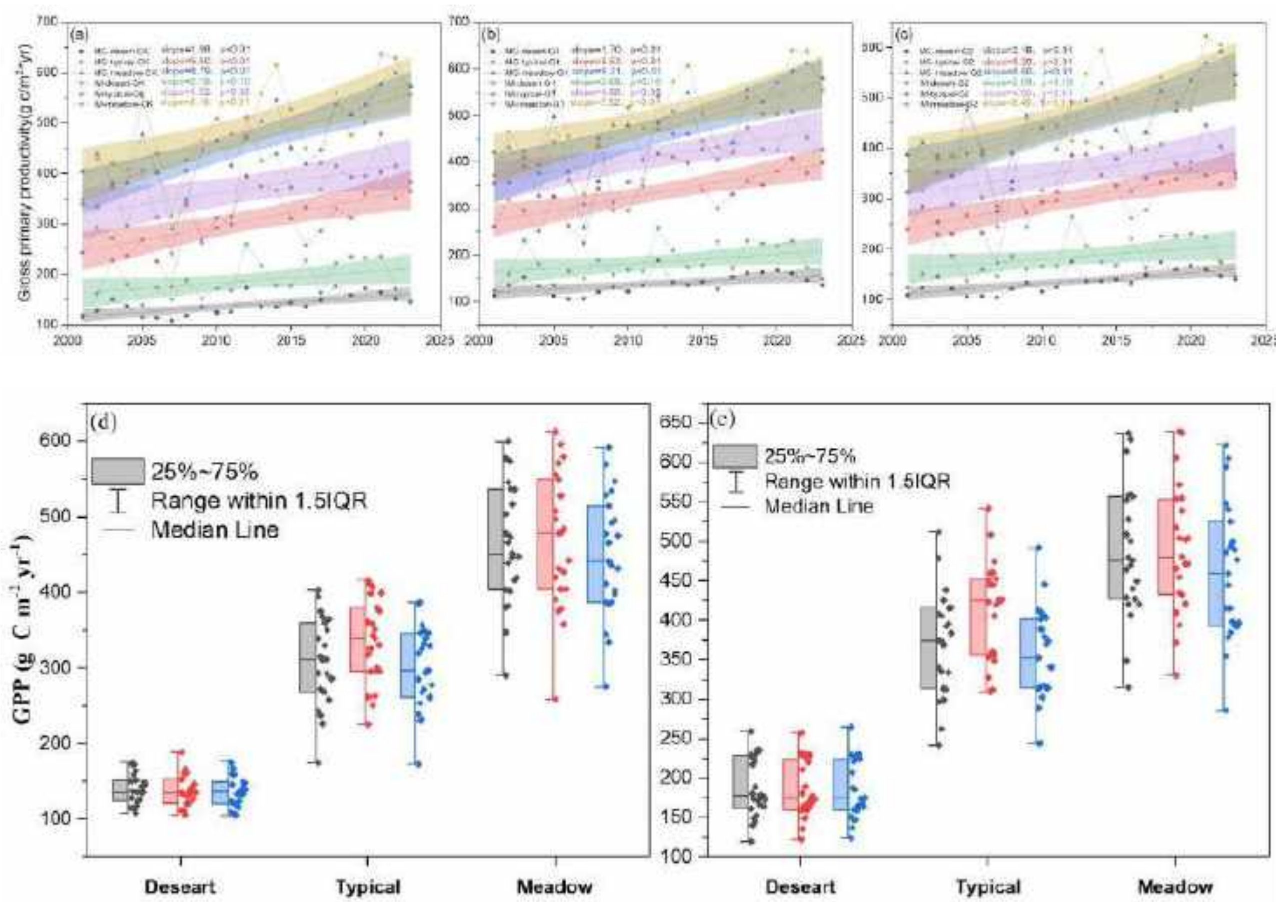

Fig. 2 Vegetation GPP changes along the grazing gradient under different grazing systems in 2001-2023.

Climate Impacts on Vegetation Surpass the Effects of Grazing Regimes

In 2001-2023, the ratio changes of vegetation GPP in the nomadic vs sedentary grazing systems in the enclosed and grazed experimental zones across desert grasslands and meadow grasslands both exhibited a pattern of initial decline followed by an increase, predominantly driven by the minimum temperatures during the coldest months. However, the ratio changes of vegetation GPP in the fenced experimental areas of typical grasslands showed a trend of increasing and then decreasing, which was mainly regulated by the average temperature in the warm season. The impact of differences in grazing systems did not exceed the regulatory role of climatic factors. Under the traditional nomadic system, the trend of the ratio change of

GPP of vegetation under light and heavy grazing to that under free grazing within fenced paddocks was consistent with the trend under the fenced state. However, under the influence of grazing factors, the regulatory factors became the variability of temperature (for desert and meadow grasslands) and the rainfall in the warm season (for typical grasslands)

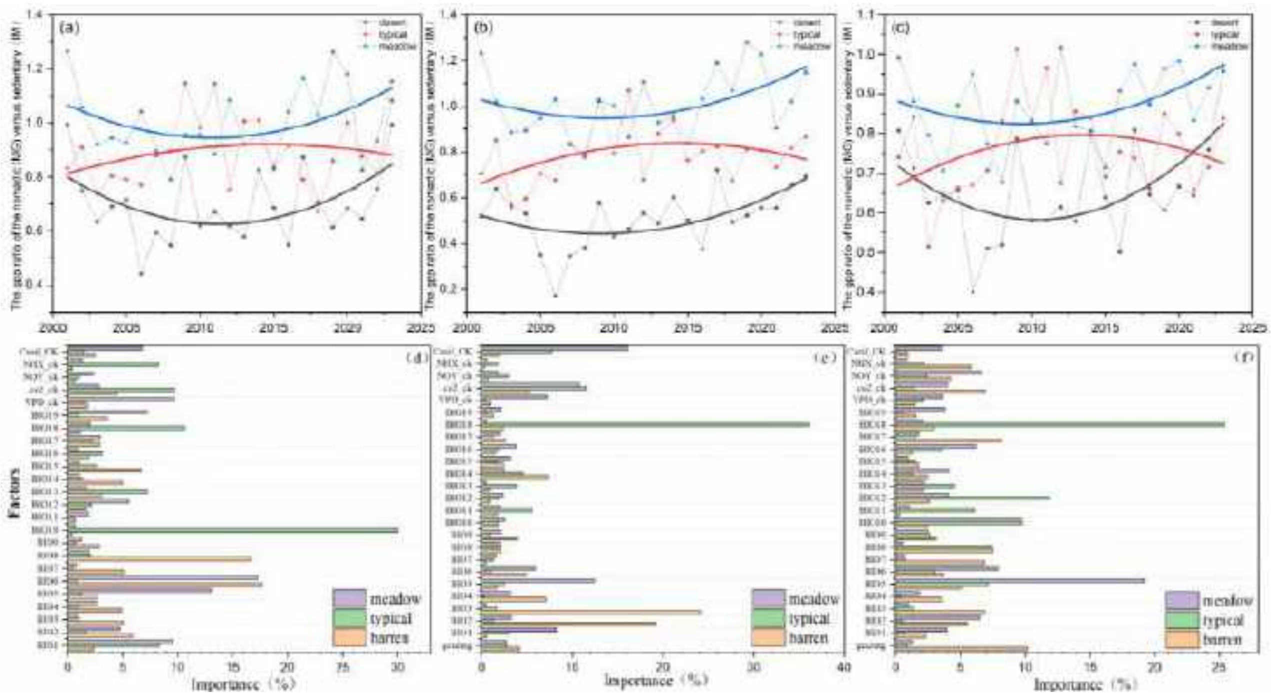

Fig.3 The differential changes in vegetation GPP under different grazing systems in 2001-2023 and their driving factors. (a), (b), (c) and (d), (e), (f) represent the grazing gradients of CK, G1, and G2 respectively.

Discussion

Grazing practices and climate change influence vegetation community productivity, with temperature variability being a key driver of GPP changes across different grazing systems. The IDH applies to the vegetation in the typical grassland areas and meadow areas that are semi-arid and semi-humid (Vidaller *et al.*, 2022). Whether under the traditional nomadic system or the sedentary grazing system, medium grazing will promote the vegetation productivity of the typical grasslands and meadow grasslands; while heavy grazing will reduce the vegetation productivity of the typical and meadow grasslands (Parra *et al.*, 2025). Desert vegetation GPP is highly unstable under any grazing system (Deng *et al.*, 2023; Palmer *et al.*, 2016). In fenced areas, the productivity difference between nomadic and sedentary grazing systems is primarily controlled by the annual minimum temperature, whereas under grazing conditions, it is influenced by temperature variability. Thus, controlling grazing intensity in desert areas and implementing moderate grazing in typical and meadow grasslands is crucial to restoring productivity. Additionally, strict policies to reduce greenhouse gas emissions and temperature variability are essential for mitigating extreme climate events and enhancing regional vegetation productivity.

Key words: arid rangelands; degradation; rehabilitation; paradigm shift.

Abstract

Libya, spanning 1.75 million km², has rangelands covering 7.7% of its area, supporting approximately six million sheep, goats, and camels. Historically, pastoralism has been the primary land use, deeply intertwined with the socio-economic fabric for millennia. Despite significant government investments in agricultural and rangeland development, these ecosystems have suffered extensive degradation in terms of declining vegetation cover, biodiversity loss, reduced soil fertility, and diminished productivity reflect a broader pattern seen across North Africa. The degradation of Libyan rangelands is rooted in decades of mismanagement, exacerbated by the government's frequent disregard for scientific recommendations and reliance on external consultants unfamiliar with local ecological and socio-economic contexts. Additionally, socio-economic changes, particularly following the oil boom of the 1960s, disrupted traditional grazing systems, while the limited involvement of local communities hindered effective conservation efforts. A significant challenge lies in balancing conservation initiatives with the livelihoods of pastoralists and local communities, often leading to conflicts of interest. This overview work underscores the urgent need for a paradigm shift toward holistic and adaptive strategies that integrate ecological, socio-cultural, and governance dimensions to address the challenges facing Libya's rangelands. Reforming rangeland survey methodologies, adopting sustainable rehabilitation techniques, and implementing controlled grazing regimes are critical steps in this process. Equally important is fostering active community participation to align conservation goals with local needs and interests. By pursuing locally informed and inclusive approaches, Libya can restore the resilience of its rangelands, ensure ecological sustainability, and support the livelihoods of local communities.

Introduction

North Africa is dominated by extensive steppe and Saharan landscapes, where pastoralism has been a cornerstone of human activity since ancient times. Traditionally, pastoralism was nomadic, relying on herding and animal husbandry under an open communal grazing system. Over the past century, profound societal transformations have significantly impacted the region's rangelands (Dutilly-Diane, 2007). Harsh environmental conditions, a history of mismanagement, population growth, and increasing demand for livestock products have collectively disrupted ecological processes in these semi-arid and arid regions.

Libya's landscapes in particular, are distinguished by diverse terrains, geological formations, and significant climatic variations across its regions. Rangelands form a considerable part of the country's territory, covering approximately 13.2 million hectares. These rangelands primarily consist of arid ecosystems, stretching across the northern regions, around oases, and in mountainous areas within the desert interior. They are characterized by sparse vegetation, with limited perennial grasses and a dominance of drought-resistant shrubs (Shaghlan et al., 2023).

Pastoralism has been the predominant land use across Libya for countless generations, with rangelands serving as a vital resource for indigenous communities (El-Barasi and Saaed, 2013). These ecosystems have historically provided resources for animal fodder and ethnobotanical services. They have also been essential as hunting grounds for wild birds and animals (Saaed et al., 2022). Furthermore, they act as a critical barrier against desert encroachment from the south. However, extensive research (e.g., El-Barasi et al., 2013; Saaed et al., 2019; Habib et al., 2022; Saaed et al., 2022) reveals that Libyan rangelands face escalating threats from unsustainable anthropogenic activities and climate change. These ecosystems are particularly fragile due to limited and unpredictable rainfall (Al-Bukhari et al., 2018), low soil organic matter and nutrient levels, sparse vegetation cover, and a non-equilibrium ecological system (El-Barasi and Saaed, 2013; Habib et al., 2022).

This overview work aims to shed light on Libya's rangeland experience, detailing its historical context, current condition, and outlining a future vision for sustainable rehabilitation and management. It emphasizes the critical, yet often overlooked, factors that have contributed to the persistent failure of past efforts to improve Libya’s rangelands over recent decades.

Environmental settings

With its vast area (1.75 million km²), Libya is the second-largest country in North Africa, lying along the southern Mediterranean coast and heavily influenced by the arid Sahara Desert (Fig. 1). Over 90% of its land is desert, except for a narrow coastal strip up to 150 km wide (El-Barasi & Saaed, 2013). The country has a 1,900 km Mediterranean coastline, with a predominantly flat topography broken by the Jabal Nafusa in the west, El-Jabal El-Akhdar in the east, and southern mountain ranges (Jansen, 1988). Libya is divided into two main phytogeographical regions: the Sahara, characterized by extreme aridity and sparse vegetation, and the Mediterranean coastal belt, which receives higher rainfall and supports richer vegetation (Saaed et al., 2019).

Situated between 19° and 33° north latitude, Libya is one of North Africa's driest regions, dominated by subtropical high-pressure systems that create pervasive aridity. Rainfall is limited to winter, with high variability and localized "thunderstorm cells," making it the primary surface water resource in the absence of perennial water sources (Saaed et al., 2022). About 91% of Libya is hyper-arid desert with under 50 mm of annual rainfall, 8% is rangeland receiving 50–200 mm, and only 0.7% is agricultural land receiving 200–400 mm. Forests make up 0.3% of the land in areas with over 400 mm of rainfall. Annual plants flourish briefly in the rainy season, while perennials form the main vegetation framework, varying with soil, water, and climate conditions. Temperatures range from 5°C to 35°C in the north and from below freezing to over 45°C in the southern desert. The harsh climate and sandy soils dominate much of Libya, with clay and loam soils found in localized northern areas, red soils in highlands, and saline soils along coastal regions and interior oases.

Fig. 1. The distribution of rangeland and forest areas in Libya

Rangelands current state

Archaeological evidence shows that human populations in Libya have been herding sheep and goats for over 7,000 years (Barker et al., 2012). Land use historically included grazing, grain cultivation, firewood collection, charcoal production, and harvesting plants for food, medicine, and construction and handicraft raw materials. Valleys and mountains provided habitats for birds and wildlife, essential for food and traditional medicine as well (Saaed et al., 2019). Pastoralism has long been privately managed, with nomadic households once comprising >5% of the population (Le Houerou, 1975). However, nomadism has nearly vanished, and most rural people now live-in cities. Livestock ownership has shifted from small subsistence flocks to larger commercial herds exceeding a thousand animals. Mechanized water transport and supplemental feeding allow year-round grazing in the same range, disrupting ecological balance and exacerbating rangeland degradation (Sidahmed, 1996).

Since 1960, Libya's livestock population has grown 3.5 times, surpassing the rangelands' carrying capacity, estimated at 2.8 million mature sheep (Le Houerou and Aly, 1982). Currently, livestock numbers are approximately 190% of this capacity, with rangelands contributing about 25% of livestock forage (Dutilly-Diane, 2007) in good years. This limited production is attributed to reduced reliance on rangelands, driven by sedentary production systems and complementary feeding practices. Degradation is evident in declining vegetation cover, biodiversity loss, and the spread of invasive species. In many areas, perennial vegetation has fallen below 25%, while soil erosion and fertility loss have rendered the landscape increasingly dysfunctional, jeopardizing ecosystem stability and wildlife survival (El-Barasi et al., 2013; Shaghlan et al., 2023).

Challenges and limitations in rangeland rehabilitation

Since Libya's independence in 1951, agriculture, livestock, and rangelands were prioritized as key economic sectors before the discovery of oil. Early efforts included studies and rehabilitation initiatives in collaboration with international organizations, like the FAO, involving numerous experts in rangeland management. However, despite these efforts, limited progress has been achieved in improving rangelands. Key obstacles include inadequate understanding of ecosystems, ineffective resource management, and insufficient awareness of the long-term consequences of degradation (Saaed et al., 2019). Management practices often conflicted with regional ecology, such as large-scale tree planting in areas naturally dominated by sparse shrubs, disrupting ecological balance. Additionally, rangeland projects have largely excluded local communities, whose involvement in protection and rehabilitation remains minimal despite recent acknowledgment of its importance. Political instability and weak legal protections have further hindered progress, leaving rangelands vulnerable to degradation and overexploitation. Foreign-led conservation efforts often overlooked local cultural, historical, and tribal dynamics, while unregulated communal grazing continues to exacerbate degradation. The population surge, from 1.089 million in 1954 to 6.931 million in 2020, has added further strain on natural resources. Balancing the economic, cultural, and social needs of rangeland residents with conservation objectives remains a significant challenge, particularly as these fragile landscapes, dominated by xerophytic shrubs, are highly vulnerable and challenging to rehabilitate.

Looking forward

Rehabilitation in arid and semi-arid regions, such as those in Libya, is inherently complex and challenging due to their unique biodiversity, limited rainfall, and the intricate spatial and biological dynamics driven by stochastic events (Carrick et al., 2015). Additionally, these areas are often subject to significant anthropogenic pressures due to the scarcity of natural resources (Saaed et al., 2022). To enhance biodiversity, maintain ecological processes such as clean air and water, and achieve sustainable management and rehabilitation of Libya's degraded rangelands, several strategies are proposed. First, comprehensive ecological studies should be conducted to better understand the drivers of rangeland degradation, ecological thresholds, and potential recovery opportunities, with an emphasis on soil studies, vegetation mapping, and climate impact assessments. Second, protected areas should be established, aiming to safeguard at least 5% of the rangelands within the next decade, accompanied by clear management plans focused on conservation and sustainable use. Third, a reform of the pastoralism system is necessary, transitioning from communal grazing to a controlled, closed, rotational grazing system that enhances vegetation recovery and soil stability. This could be supported by education programs for local communities and infrastructure like fenced enclosures and designated grazing zones, while also reducing the number of domestic grazing animals to under three million head. Fourth, enforcing a ban on rainfed agriculture in arid zones with less than 250 mm/year of rainfall is critical, with incentives for alternative practices like greenhouse farming or agroforestry. Fifth, anthropogenic activities such as wood gathering, medicinal plant collection, overhunting, and pollution need to be regulated through strict laws and monitoring systems, promoting sustainable alternatives like regulated harvesting and waste management. Sixth, providing alternative livelihoods for local communities can mitigate dependence on unsustainable practices, through programs such as ecotourism, solar energy jobs, and small-scale industries like beekeeping and craft production. Special attention must be paid to local populations; their activities should not be banned but adapted to the area's potential, with a focus on altering behaviour to maximize economic gain while minimizing environmental costs (El-Barasi and Saaed, 2013). Seventh, long-term rehabilitation programs should focus on landscape functionality, prioritizing soil health, water retention, and the recovery of native vegetation, supported by large-scale seeding programs and the use of modern techniques like hydrological interventions and remote sensing. Eighth, the promotion of renewable energy, particularly solar power, should be encouraged through community-based solar projects and subsidies for solar panel installation to reduce reliance on traditional fuels. Ninth, local communities must be educated and empowered through workshops, awareness campaigns, and training programs on sustainable practices and the importance of preserving rangeland ecosystems. Lastly, strong policy frameworks are essential for supporting sustainable rangeland management. This entails updating national policies to prioritize rangeland conservation, enforcing anti-degradation laws, and securing funding for rehabilitation and research. Implementing these strategies can transform Libya's rangelands from degradation to a sustainable and productive system that supports both the environment and local communities.

Conclusion

The sustainable management and rehabilitation of Libya's rangelands require a multifaceted approach that integrates ecological understanding, community engagement, and effective policy frameworks. The proposed strategies—ranging from ecological studies and the establishment of protected areas to the promotion of renewable energy and alternative livelihoods—aim to address the root causes of degradation while ensuring the resilience and profitability of rangeland systems. By prioritizing both environmental conservation and the socioeconomic needs of local communities, Libya can foster a balanced and sustainable future for its rangelands, securing their ecological integrity and long-term viability for generations to come.

Modeling the distribution of *Vachellia tortilis* (forssk.) in Tunisian drylands under climate change scenarios

Msadek, J[1]; Tarhouni, M[1]

[1] Laboratory of Pastoral Ecosystems, Spontaneous Plants and Associated Microorganisms. Arid Regions Institute - Medenine 4100. University of Gabes, Tunisia.

Key words: Climate change; habitat; modeling; drylands.

Abstract

Biodiversity conservation, through the creation of national parks, is generally helping to maintain a greater level of resilience within ecosystems and to protect the natural plant cover and threatened plant species. This research was conducted in Bou Hedma national park, a UNESCO-MAB biosphere reserve containing the unique *Vachellia tortilis* (Forssk.) Gallaso & Banfi steppe with trees in Tunisia. The focus is to explore how the distribution of suitable habitat for *V. tortilis*, might shift under climate change scenarios using Maxent modeling algorithm. The Canadian Earth System Model version 5 (CanESM5) was used for projecting the future distribution. The model was run under two Shared Socioeconomic Pathways (SSP245, SSP585) during four time periods (2021-2040, 2041-2060, 2061-2080 and 2081-2100). The tested climate change scenarios seem affecting the specie's suitable habitat in the park. Three soil variables (Clay, Coarse, WRB Classes) are significant factors in determining *V. tortilis*'s suitable habitat. Distribution modeling provides valuable information for managers to implement suitable strategies to conserve this endemic, rare and threatened plant tree and the overall ecosystem.

Introduction

Dryland ecosystems are threatened both by climate variations and human disturbance (Millennium Ecosystem Assessment (MEA) 2005). Increased temperature, variability in rainfall and severe droughts are the main climatic conditions threatening the ability of these ecosystems to produce (Yao et al. 2020) and represent significant problems to biodiversity conservation both by altering habitats and affecting species distributions (Hilbert et al. 2007). Active management is recently considered as the major challenge for maintaining biodiversity and reducing natural resource degradation and combat desertification (Gamoun and Louhaichi 2021). The establishment of national parks is one of the main strategies to achieve biodiversity conservation (Ouled Belgacem et al. 2019) and to preserve the natural plant cover as well as the threatened plant species in arid and desert area of Tunisia and all around the world (Ouled Belgacem et al. 2008).

Vachellia tortilis (Forssk.) Gallaso & Banfi (Fabaceae) is a "Keystone species", widely distributed in arid and semi-arid ecosystems of North, East and Southern Africa, the Middle East and the Arabian Peninsula

(Taha et al. 2022). It is well adapted to disturbances (drought, fire and browsing) (Noumi and Chaieb 2012). It is also known by the ability to improve the soil fertility and to increase biodiversity (Abdallah et al. 2008). This study focuses on modeling the distribution of *V. tortilis* in Bou Hedma national park under both optimistic and pessimistic climate change scenarios. By examining the shifts in suitable and unsuitable habitats, we aim to understand the potential impact of climate change on this vital species and inform conservation strategies to optimize its future safeguarding.

Methods

Study area

Bou Hedma national park (34.476102 N, 9.649239 E; Figure 1), created in 1980, plays a key role in the conservation of flora and fauna biodiversity and contains the unique *V. tortilis* steppe with trees in Tunisia (Tarhouni 2003). It is characterized by an arid Mediterranean bioclimate (Le Houérou 1969). The average annual rainfall varies between 100 and 200 mm. The average annual temperature is about 17.2°C.

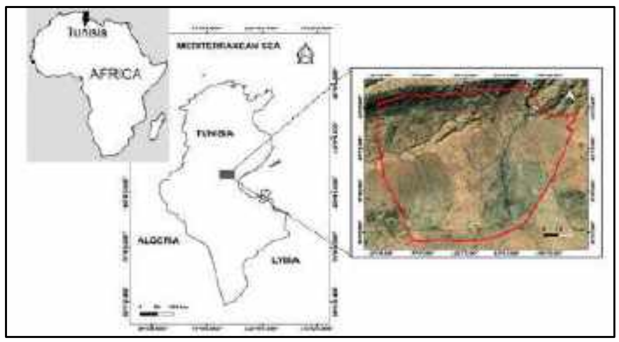

Fig. 1 Geographical location of Bou Hedma national park

Environmental variables & species distribution modeling

The undertaken environmental data is downloaded from the "WorldClim" database (www.worldclim.org) (19 bio-climatic variables from each time-period (2021-2040, 2041-2060, 2061-2080 and 2081-2100) in addition to three topographical ones) and from the soil grids database (www.soilgrids.org) (12 soil variables). All these variables are used to model the current and future distribution of *V. tortilis* according to the Canadian Earth System Model version 5 (CanESM5) predictions under two Shared Socioeconomic Pathways (SSP245, SSP585).

Results

Model validation and influencing variables

It is clear from table 1 that the Maxent model showed good predictive ability with an Area Under Curve (AUC) ranging from 0.854 to 0.894.

Table 1 Area Under Curve (AUC) of the distribution of Vachellia tortilis under current (2018) and future climate scenarios (SSP245, SSP585) according to the Canadian Earth System Model version 5 (CanESM5) in Bou Hedma national park.

	Current	**SSP245**				**SSP585**			
	2018	**2021-2040**	**2041-2060**	**2061-2080**	**2081-2100**	**2021-2040**	**2041-2060**	**2061-2080**	**2081-2100**
AUC	0.855	0.866	0.871	0.888	0.862	0.854	0.877	0.894	0.855

Under both scenarios, it seems that coarse and soil classes-WRB are the strongest predictors of *V. tortilis* distribution with respectively 42.15% and 14.87%, under SSP245, and 31.92% and 27.6% under SSP585 (Figure 2). Bio17 and clay are also important but with lesser contributions (respectively 6.47% and 7.92% under SSP245; 5.9% and 6.05% under SSP585).

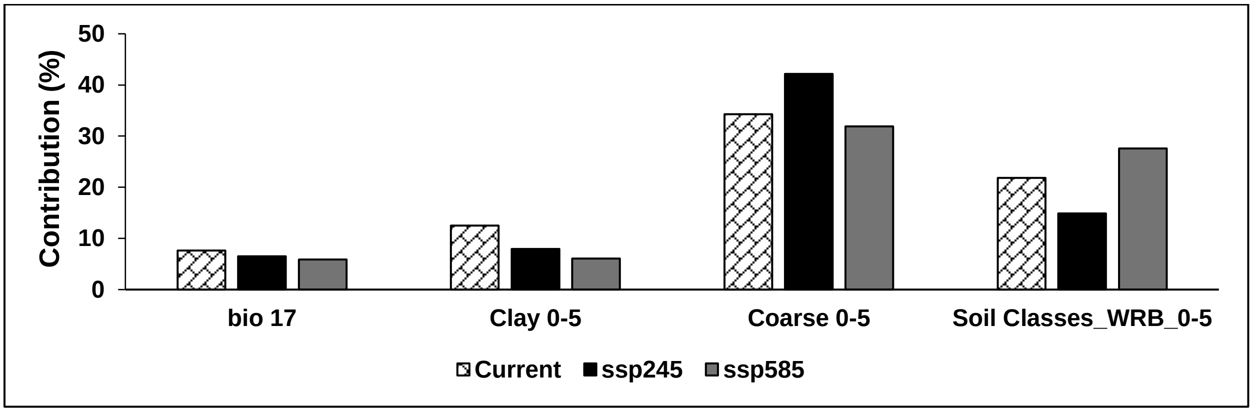

Fig. 2 Contribution (%) of bio-climatic and soil variables when predicting the distribution of Vachellia tortilis in Bou hedma national park using MaxEnt model.

Habitat suitability for Vachellia tortilis

The results of Maxent are represented in table 2 and figure 3. Under current climate condition, Maxent indicated that 214.30ha are suitable (very high potential, VHP) for *V. tortilis* to grow (table 2). The species is covering some hectares in the south-western and the south east parts of the park (figure 3). In the center, it occurs over a large area of Moderate (MP) to high (HP) potential (911.24ha and 650.41ha respectively) (table 2). In the North parts, the habitat of the species seems to be completely unsuitable (low potential, LP) (1386.23ha).

Table 2 Changes in suitability of Vachellia tortilis habitat (ha, %) from the current situation to 2100 according to SSP245 and SSP585 scenarios from the Canadian Earth System Model version 5 (CanESM5).

		Area (ha)				**Changes (%)**			
		LP	**MP**	**HP**	**VHP**	**LP**	**MP**	**HP**	**VHP**
2018	**Current**	1386.23	911.24	650.41	214.30	-	-	-	-
2021-2040	**SSP245**	1438.74	877.33	604.44	241.66	3.79	-3.72	-7.07	12.77
	SSP585	1483.95	776.50	620.90	280.82	7.05	-14.79	-4.54	31.04
2041-2060	**SSP245**	1563.42	968.24	400.14	230.38	12.78	6.25	-38.48	7.50
	SSP585	1532.24	836.02	529.69	264.23	10.53	-8.25	-18.56	23.30
2061-2080	**SSP245**	1770.51	765.44	385.30	240.92	27.72	-15.10	-40.76	12.42
	SSP585	1579.14	890.07	470.93	222.04	13.92	-2.32	-27.60	3.61
2080-2100	**SSP245**	1350.39	986.24	620.32	205.23	-2.58	8.23	-4.63	-4.23
	SSP585	1579.47	967.20	386.48	229.04	13.94	6.14	-40.58	6.88

Under SSP245, climate change could increase the most suitable habitat (very high potential) with 12.77%, 7.50% and 12.42% in 2040, 2060 and 2080 respectively, and a decrease of 4.23% in 2100. SSP585 showed also a great increase of very high potential that reached 31.04% by 2040 (table 2). Using the future MaxEnt layers, the predicted distribution map (figure 3) indicates a decrease in areas of moderate and high potentials in the center of the park, where the unsuitable areas (low potential) will dominate.

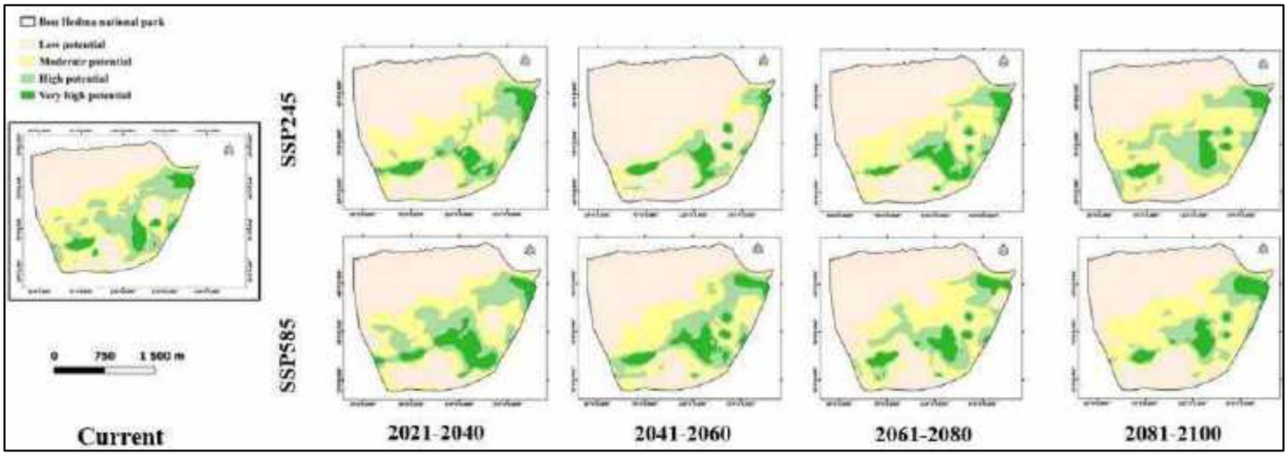

Fig. 3 Changes in suitability of Vachellia tortilis habitat under SSP245 and SSP585 climate change scenarios of the CanESM5 model.

Discussion

To guide conservation priorities and management planning, predictive vegetation models could help to identify hotspots of environmental change or plant habitat suitability (Bedair et al. 2023). Species distribution and predictive vegetation models represent excellent tools to mitigate the impact of climate change (Capera et al. 2023), especially the MaxEnt model, which requires datasets of actual presence called "Occurrences", and will be helpful in identifying suitable area for future habitats. *Vachellia tortilis*, in Bou Hedma national park, seems to follow a kind of regressive dynamic proved by the replacement of suitable area by the unsuitable ones. Similar results are showed by Anthelme and Michalet (2009) who demonstrated the absence of regeneration of *V. tortilis* in the Air-Tenere Nature Reserve (Sahara, Niger) under climate change. The low regeneration of *V. tortilis* in Bou Hedma could be explained by the dominance of large and aged individuals in one hand (Noumi and Chaieb 2012) and by the negative interaction between *V. tortilis* and other plant species in the other hand (Noumi et al. 2023).

The obtained results indicate that the distribution of *V. tortilis* is significally influenced by soil texture, especially the presence of clay and coarse particles. Several studies emphasized the crucial role of edaphic factors in enhancing the accuracy of projection (Buri et al. 2017). Clay soils, known for their water retention capabilities (Romero et al. 2011), may provide necessary moisture during dry periods, while Coarse particles enhance soil aeration and drainage (Bigelow et al. 2001). This combination of soil properties creates an optimal environment for the establishment of *V. tortilis* in arid and semi-arid ecosystems (Ludwing et al. 2003; Yadeta et al. 2018).

Conclusion

Distribution of *Vachellia tortilis* is modeled under optimistic and pessimistic climate change scenarios. In the future of Bou Hedma national park, unsuitable habitats of *V. tortilis* will increase and take place of suitable area. This regressive dynamic indicates that the species is situated under greater danger and highly sensitive to climate change. Such results can be very useful to conserve habitats of this threatened species. Recommendations are given to protect and to enhance the current *Vachellia* suitable area.

Key words. C_3/C_4 plants, halophytes, aridity index, salinization, pasture restoration, Aral Sea basin

Abstract:
The cold winter rangelands of the Aral Sea basin are among the world's biodiversity hotspots, providing unique habitats, breeding grounds, migration corridors, and flyways for rare and endangered species of plants, animals, and birds. Situated along the historic "Silk Road," the Central Asian Cold Desert Rangelands (CACDR) are also the origin of many cultivated crops, including wheat, rye, barley, legumes,

roots, tubers, and fruit trees. However, the increasing frequency of droughts due to climate and human affected changes is expected to exacerbate and further reduce the productivity of already degraded rangelands. Additionally, soil salinization, one of the major issues affecting agriculture, significantly decreases vegetation cover, botanical diversity, and the palatability of key species.

This study introduces a novel assessment of isotope screening for salinity and drought tolerance in key C_3 and C_4 halophytes. These halophytes, cultivated on various arid and semi-arid rangelands, are evaluated based on their life forms, root depths, and biomass yield production. The Circular Halophytic Mixed Farming (CHMF) system is explored as a strategy to improve the productivity of rangelands impacted by salinization and drought. This system involves intercropping halophytes with salt-tolerant non-conventional crops (NCCs) such as wild succulents, amaranthus, foxtail, pearl millet, licorice, artichoke, sesame, and sorghum. Within a single growing season, the CHMF system can remove approximately 1.8 kg of NaCl equivalent per kilogram of dry soil.The harvested biomass from halophytes serves as a bioenergy source and as livestock feed when mixed with traditional crops in specific proportions. Re-seeding and 'seed isles' techniques—utilizing species such as *Haloxylon ammodendron, Xylosalsola paletzkiana, X. richteri, Halothamnus subaphyllus, Artemisia halophylla, Caroxylon orientale*, and *Bassia prostrata*—are employed to establish pastoral agrophytocenoses, shelters, windbreaks, and to enhance the productivity of salt-affected pasturelands. These innovative rangeland restoration technologies aim to address the ongoing degradation of indigenous knowledge systems and promote sustainable management of arid and semi-arid ecosystems.

Introduction

The deserts of Central Asia represent the northernmost and coldest edge of native C_4 plant growth, showcasing a globally unique taxonomic composition alongside diverse and unusual biochemical, physiological, and structural features (Gintzburger et al., 2003; Matsuo et al., 2013). However, the ongoing desiccation of the Aral Sea has caused detrimental changes in the vegetation composition of rangelands with perennial valuable forage species being replaced by less palatable and invasive annual plants. Severe soil salinization in the Aralkum desert rangelands (former seabed of the Aral Sea) is a major driver of land degradation, threatening the crop-livestock ecosystem services essential for food security and rural livelihoods in the region. Recurrent cycles of drought and high soil salinity further exacerbate these challenges, limiting food and fodder production and necessitating large-scale imports of both. Overcoming the winter feed bottleneck remains one of the most pressing challenges for livestock development across Central Asia. Halophytes have shown promising potential in rangeland restoration programs (Toderich et al., 2024) under limited water availability and land salinization. Despite extensive evidence of the benefits desert rangelands offer for livestock grazing and ecosystem services, there is an urgent need to incorporate native forage halophytes and underutilized crops into rangeland restoration schemes. Currently, the salinity and drought tolerance indices, as well as water use characteristics of wild halophytes in the Central Asian Cold Desert Rangelands, remain poorly documented, along with road map cultivation techniques for these species. This study aims to evaluate the adaptation potential of halophytes and the benefits of their domestication to enhance the productivity and economic value of CACDR rangelands degraded by salinization.

Methods

Plant material for stable isotope analysis had been gathered at natural halophytic vegetation of typical desert plant communities. The carbon and oxygen isotope ratios were expressed in standard delta notation (&) relative to the VPDB (Vienna Pee Dee belemnite) and VSMOW (Vienna Standard Mean Ocean Water) standards, respectively: d 13C or d 18O = $(R_{sample} / R_{standard}) - 1$, where R_{sample} and $R_{standard}$ represent the

$^{13}C/^{12}C$ or $^{18}O/^{16}O$ of the samples and the standard, respectively. The d ^{18}O in the stem water were analysed using an isotope ratio mass spectrometer (MAT252; Thermo Fisher Scientific, Rockford, IL, USA) at the Mie University, Japan. R v.3.6.1 software was used for principal component analysis (PCA) with multiple factors. The package “factoextra” was used for multiple correlations between parameters.

Research target area

Uzbekistan, a double-landlocked country in central Eurasia within the Aral Sea basin, is particularly vulnerable to environmental degradation and drought. The majority of its land cover consists of herbaceous vegetation in deserts and semi-deserts, along with piedmont mountainous regions (Fig. 1). The total desert area in the region is estimated at approximately 150 million hectares, accounting for 37% of the total land area. Rangeland soils in these areas have lost 30–50% of their soil organic carbon pool, leading to a significant decline in soil quality due to widespread salinization. The region's climate variability, characterized by an aridity index of 0.065–0.18 and low annual precipitation (80–150 mm), drives successive droughts and extreme temperatures, further exacerbating rangeland degradation. Additionally, changes in land use—such as the conversion of desert and steppe vegetation into new croplands—are accelerating desertification. Agricultural expansion and concentrated livestock grazing near settlements have become the primary drivers of these new land-use practices, intensifying pressure on already fragile ecosystems.

Buchhorn et al. 2020 (modified by Timur

Results

Screening of Halophytes and Non-Conventional Crops. The analysis of stable isotope ratios (d^{13}C and d^{18}O) in 53 wild rangeland halophytes across diverse pasture types, characterized by varying climatic conditions (precipitation, elevation), groundwater levels, reproduction strategies, and biomass yield, highlighted the dominance of C_4 species within the *Amaranthaceae* family (>53.2%). Among ten neglected non-conventional, but already naturalized crops, C_4 species (*Amaranthus*, *Setaria*, *Sorghum*, and *Pennisetum*) and C_3 species (licorice, artichoke, sesame, rhubarb, safflower, and alfalfa) were nearly equally represented. Notably, C_4 halophytes and neglected crops exhibited significantly higher $\delta^{13}C$ values in their leaves compared to C_3 plants, indicating higher water-use efficiency under arid conditions. Perennial C_4 plants further displayed elevated d^{18}O values, suggesting deeper root systems and enhanced drought tolerance (Fig. 2a). When categorized by plant types—annual herbs, perennial herbs, and woody species—significant differences in d^{13}C were observed, while perennial herbs had notably lower d^{18}O values in leaves. Additionally, a strong positive correlation was established between d^{18}O and root system depth among the studied species, underlining the adaptive strategies of deeper-rooted plants in accessing water under saline and arid conditions (Fig. 2b).

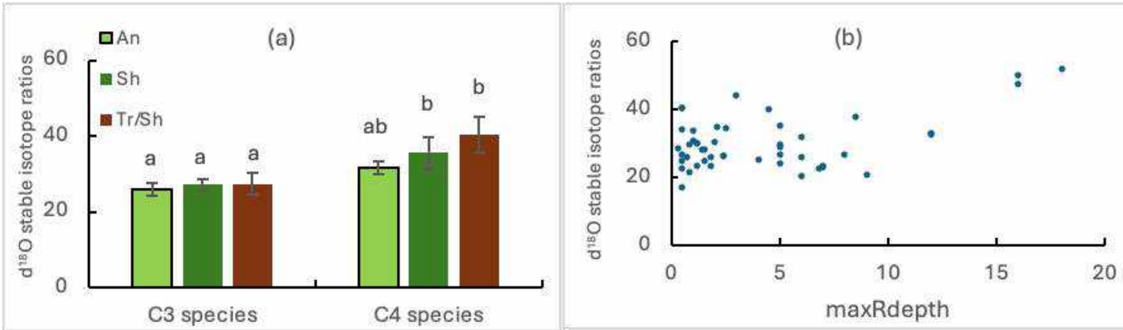

Fig. 2 The oxygen isotope ratio (d ^{18}O) in leaves of annual plants (An), shrubs (Sh) and tree-like shrubs (Tr/Sh) of C_3 and C_4 species (Fig. 2a) in relation to its maximum root depth (Fig. 2b).

Agroforestry and Afforestation technologies for Rangeland Restoration. These techniques revealed significant potential for restoring desert rangelands, severely affected by salinity and drought. Deeply transplanted seedlings of C_3 and C_4 trees, shrubs, and plants during early spring or late fall performed well on both loamy and sandy soils with shallow to moderately saline groundwater. Species such as *Elaeagnus angustifolia*, *Robinia pseudoacacia*, *Populus*, *Tamarix* and *Ulmus*, when intercropped with annual succulent halophytes, legumes, and annual grasses, demonstrated the fastest growth rates and highest water-use efficiency. Optimal agroforestry systems designed for traditional farming practices included 12% tree cover, 20% wild succulents' halophytes, 30% alfalfa, and 38% annual forage crops. This configuration effectively reduced salt accumulation in the root zone, enhanced soil drainage, and provided year-round feed resources for livestock. In addition, these systems contributed by reducing wind erosion and stabilizing soils mitigating the effects of climate variability (Yamanaka et al., 2020).

Circular Halophytic Mixed Farming (CHMF) Technology. The CHMF system was developed by utilizing over 45 economically valuable halophyte species selected from the 760 identified in Central Asia. Following 3.5 to 6 years of continuous cultivation, severely degraded saline rangelands were converted into fertile soils capable of supporting diverse crops, including saltbush, *Karelinia, Suaeda, Amaranthus, Bassia*, cereals (*Agropyron*, foxtail millet, sorghum, pearl millet), sesame, sunflower, and melon (Fig. 3). This system achieved a 1.5–1.8-fold reduction in soil salinity due to the efficient salt uptake and removal by halophytes and reduction of using irrigation water, main source of salts. Additionally, the harvested biomass served as a dual-purpose resource, providing high-quality animal feed and raw materials for bioenergy production. The implementation of CHMF also yielded broader ecological and socioeconomic benefits. Improved soil organic carbon stocks, soil health, and vegetation cover contributed to ecosystem restoration, while promoting biodiversity by supporting rare, endangered, and climate-vulnerable species. The system's capacity for year-round biomass production stabilized fodder availability for livestock through the production of organic products such as honey and high-value fodder. Moreover, CHMF facilitated community engagement, sustainable land-use practices, and integrating indigenous knowledge systems required for rangeland management and conservation.

Fig. 3 Multi-stage salts remediation effect of CHMF technology (Karabuga Site),

Community-based Landscape Restoration actions. Community engagement played a critical role in restoring degraded rangelands through the implementation of "seed isles technique." Pastoral communities were trained to utilize this low-cost approach, which involves spreading mixed seeds of halophytes in uncovered areas. This technique relies on anemochory (wind dispersal) to propagate seeds, achieving significant rehabilitation of degraded *Artemisia* foothill rangelands within three to five years. Without disturbing the topsoil, such approach facilitated vegetation cover and self-regeneration of native species, drastically reducing labour and costs associated with traditional restoration methods.

The results demonstrated remarkable success: in the first year, shrubs yielded approximately 150 kg of dry mass per hectare, increasing to 220 kg/ha of dry mass and 40 kg/ha of seeds in the second year. By the third year, dry yield reached 800 kg/ha, with 100 kg/ha of seeds. Once established, these mixed perennial shrub plantations can sustain grazing forage production for over 20 years. The CHMF approach highlights the importance of integrating indigenous knowledge and community participation work in achieving long-term sustainability for rangeland restoration.

Synergies Between Technologies. The integration of agroforestry and CHMF technologies offers a synergistic approach to combating rangelands degradation in Central Asia. While agroforestry systems provide immediate benefits in soil stabilization, microclimate regulation and resource diversification, CHMF contributes long-term soil recovery and sustainable biomass production. Together, these technologies hold immense potential for reversing land degradation trends, enhancing rural livelihoods, and building climate resilience in arid and semi-arid regions. Although, it is important to address policy regulations and overgrazing practices that are widely spread across the area.

Fig. 4. Foothill improved pastures (seed island techniques) by seeding mixed *Ceratoides*, *Camphorosma*, and *Bassia* (C4 forage halophytes), better known as desert "alfalfa", a high-calorie, year-round small ruminant feed. (Mugol village (Jizzakh region,2022).

Discussion and conclusion

Our study highlights the critical role of abiotic factors (temperature, precipitation, and groundwater) variations in shaping the distribution and abundance of C_3 and C_4 plants in the halophytic flora of desert and semi-desert rangelands, while biotic interactions play a secondary role. As shown in Fig. 5, the distribution of C_3 succulent halophytes is largely influenced by life form and root depth, with a higher prevalence of succulents among perennial species than annuals.

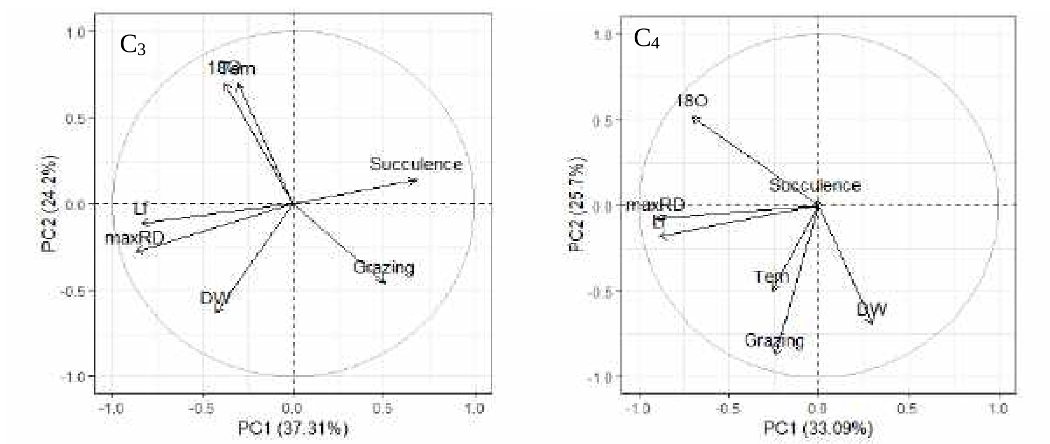

Fig. 5 The multiple correlations between life form (Lf), root depth (maxRD), dry biomass (DW), succulence (Succulence), type of grazing (Grazing), $d^{18}O$ (18O) in leaves of C_3 and C_4 species and mean temperature (Tem).

These findings align with previous studies emphasizing the adaptive strategies of perennial halophytes, which utilize deep root systems to access water from subsurface aquifers. Groundwater-dependent C_3/ C_4 rangeland ecosystems, as noted by Ronde et al. (2024), provide essential drought protection. In cold winter desert rangelands, shallow groundwater aquifers act as "water savings accounts," sustaining ecosystems during periods of low or absent precipitations, particularly during hot summer months. This dependency is evident for C_3 species, where oxygen isotope discrimination ($d^{18}O$) is positively correlated with temperature, reflecting the role of groundwater in supporting physiological functions under temperature stress. Conversely, no such relationship exists for C_4 species, which are more reliant on their inherent water-use efficiency and less dependent on groundwater availability.

Biomass production in these ecosystems is influenced by both abiotic and physiological factors. For C_3 species, biomass is strongly correlated with life form, while for C_4 species, other factors such as water-use efficiency and salinity tolerance appear to play a more prominent role. The study also revealed that the optimal spatial combination of C_3 and C_4 halophytes—considering life form, aridity index, physiological traits, water uptake depth, and adaptation mechanisms to soil salinization—can maximize biomass yield on rangelands. This highlights the potential for leveraging complementary ecological strategies of C_3 and C_4 plants to improve rangeland productivity in short-and long-term use.

A particularly promising approach is the integration of wild native and naturalized rangeland fodder species into the Circular Halophytic Mixed Farming system. Our results suggest that combining C_3 halophytes in open grazing areas with non-conventional crops (NCCs) in cultivated grazing systems creates a synergistic effect, enhancing biomass yield and improving the resilience of rangelands to climate stress. Annual precipitation and grazing type were positively correlated with fodder biomass yield, underscoring the importance of tailoring rangeland restoration strategies to specific climatic conditions and animal grazing schemes. Furthermore, this study reaffirms the ecological niches occupied by C_3 and C_4 halophytes in degraded rangelands. C_3 species tend to colonize nutrient-rich microsites, where their physiological adaptations allow them to thrive, while C4 species are better suited to nutrient-poor microsites due to their efficiency in photosynthesis and resilience to arid conditions (Shuyskaya et al., 2012). By strategically utilizing these species, restoration efforts can optimize both spatial and functional diversity, contributing to sustainable rangeland management and conservation.

In conclusion, the integration of wild native halophytes, naturalized species, and non-conventional crops within the CHMF framework offers a scalable solution for addressing rehabilitation of rangelands affected by soil salinity. The coexistence of C_3/C_4 species under a wide range of soil salinities is essential for developing optimal rangelands rehabilitation technique. This approach not only reduces salinization and enhances climate resilience but also supports biodiversity conservation and the sustainable use of ecosystem services. The findings of this study provide valuable insights for the design and implementation of rangeland restoration programs in arid and semi-arid regions globally.

Predicting forage production into the future

Becchetti, TA[1]; Taylor, A[2]; Feirer, S[3]; Kelly, M[2]; James, JJ[4]

[1]Livestock and Natural Resource Advisor, University of California Cooperative Extension, Modesto, CA, USA; [2]University of California, Berkeley, CA, USA; [3]University of California Cooperative Extension, Hopland, CA, USA; [4]California Polytechnic State University, San Luis Obispo, CA, USA

Key words: forage; production; climate

Abstract
Patterns of forage production on California annual rangelands influences an array of critical ecosystem services and functions across almost 50% of the land area in California, including livestock production, soil carbon sequestration, and wildlife habitat, among others. Growth of annual grasses and forbs that make up this forage base are particularly sensitivity to changes in amount and timing of precipitation and seasonal variation in temperature. Thus, forage production on California rangelands is expected to change significantly with future changes in climate. We created a model to quantify how climate changes might impact timing and amount of forage production in the mid-century, as well as spatial differences across the state.

The broad objectives of this project are to quantify how future changes in temperature and precipitation may alter the timing and amount of forage production on California annual rangelands and evaluate how the changes may vary either spatially (e.g. by major land resource area or ecoregion) or vary as a function of historical climatic conditions (e.g. to sites with lower historical precipitation vs. higher historical precipitation). We have integrated three main sources of data, historical weather data for California, a 30m data product that takes a partitioned 16-day Net Primary Productivity (NPP) dataset and uses an equation based on mean annual temperature to separate belowground from aboveground NPP and is available through the Rangeland Analysis Platform, and projections of future climate. The model was created using back-casting to obtain a statistically significant model. Model(s) will be used to predict future changes in NPP in both timing and amount. Models can then be used by land managers to make decisions on how to best prepare for future scenarios under different Representative Concentration Pathways (RCPs) to determine impacts to forage production, wildlife, and carbon sequestration.

Introduction
Climate change and the impacts to NPP have been a concern for many. In California, with predominately annual rangelands relying on annual precipitation to determine NPP, and therefore a forage base for livestock production as well as wildlife habitat and ecosystem services, predictions of an overall warmer

and drier climate as we approach 2100 has many concerned. Researchers are attempting to quantify the impact climate changes will have on NPP, and then extrapolate impacts to managing resources to maintain many ecosystem services. The assumption is that as the temperatures warm and precipitation reduces, NPP will also decrease, resulting in reduction of livestock grazing. We took our teams expertise in forage production (NPP), modelling and GIS to create a model to predict NPP through the end of this century and into the beginning of the next.

Methods

Before we could start to predict forage production, we first needed to define out study area, focusing on grasslands in California. We used freely available data sources for all our efforts. Grassland cover as defined by the California Department of Forestry and Fire Protection's Fire and Resource Assessment Program (FRAP) (CalFire, 2024) was the basis of our data, with the exception of irrigated pastures (Liu et al,. 2021) and unvegetated areas (Felton et al., 2021). Pixels with more than 50% grassland cover were included. Climate data utilized included daily precipitation, daily soil moisture (within the top 10cm layer), minimum temperature, and maximum temperature from the CalAdapt python package for the historical climate period (1950 to 2005). We then converted annual datasets to water years (October 1 to September 30). We defined the start of the growing season based on accumulated precipitation exceeds 25mm (Chaplin-Kramer and George 2013). For the annual rangelands, we also needed to determine the end of the growing season. To do this, we defined the end of the growing season for each pixel using the maximum separation method applied to the top-level soil moisture curve during the water year. This is a phenological algorithm that identifies the two points of greatest change in a given seasonal curve. We utilized only the second point of change to indicate the point in the water year in which soil moisture was depleting. The algorithm is described in Descals et al. (2021). The primary predictor input into our model is the total sum of heat units during our defined growing season for each pixel and each year in the historical period (1950-2005) that we calculated. We were then able to back cast with actual forage production data to ensure a good fit of the model before forecasting. To improve results, the state was broken into fifteen ecoregions: Central California Coast, Central Valley Coast Ranges, Northern Great Valley, Southern Great Valley, Klamath Mountains, Modoc Plateau, Mojave Desert, Northern California Coast, Norther California Coast Ranges, Northern California Interior Coast Ranges, Sierra Nevada, Sierra Nevada Foothills, Southern California Coast, Southern California Mountains and Valleys, and the Southern Cascades. These ecoregions captured seasonal variations in precipitation and temperature and improved the model's ability to predict NPP.

Results

Back casting proved the model's fit in predicting NPP (Figure 1) when predicted NPP was plotted against actual NPP (R^2 equals 0.724). It should be noted that outliers in production at either end did not produce a perfect fit model, and why our R^2 is not higher. The model tends to overpredict NPP at the lower end, and underpredict NPP at the upper end with the strongest correlation from 1,000 kg/ha to 4,000 kg/ha. Extremes on either end did not have enough sample size to provide enough data to accurately predict with the model. We then examined all the variables that were potentially available for the model and looked at the Random Forest Feature Importance of each to see what was driving the overall model. Distance to the ocean and elevation were the two most important features in the model, accounting for approximately 40% of the model (Figure 2).

As the distance from the ocean increased, NPP dropped, as expected. Looking at forecasting NPP by ecoregion, the model's prediction varies across ecoregions, with the southern California Coast predicted to decrease in NPP while the Northern Great Valley as well as other ecoregions will increase in NPP.

Discussion [Conclusions/Implications]

If our current trajectory for climate does not change, the current Representative Concentration Pathway (RCP 8.5) will result in a mix of decreased NPP especially in the southern coastal area of California, but also increases in NPP, in both north and south Great Valley and the adjoining Central Valley Coast Range. The predicted variation in NPP across the state will require managers to shift their management practices. For part of the state, that means increasing management potentially through grazing, to manage NPP. Also of note, the model is not predicting any large swings in NPP across the state between now and 2100, but there are predicted swings at 30-year intervals that could impact management over the next 75 years. Managers will need to continue to implement all drought management tools they have developed over the years and be prepared for the next downward trend in NPP.

Abstract

The late January/early February 2019 north-west Queensland flood and associated wind chill event had a devastating impact on the grazing industry and local communities, causing high stock mortality, infrastructure damage, and business disruption. Rangeland condition was also severely impacted by the flood. In some areas, severe erosion stripped away soil, including nutrients and seed bank, while in other areas, soil deposition smothered pasture. Prolonged floodwater inundation (up to two weeks) in low-lying areas also contributed to pasture death. The impacts of the flood were exacerbated by a prolonged drought which impacted the region in the six years prior to the flood, and in the three years following the flood. This project sought to assess land condition recovery on Mitchell Grass Downs rangelands five years on from the flood. In late February and early March 2019 (soon after the floodwaters receded), on-ground land condition assessments were completed at 130 sites across the region. In September 2024, land condition assessments were repeated at 62 of the original sites. In 2024, land condition: improved at least one condition score at 30 sites (48%); remained the same at 29 sites (47%); and declined at least one condition score at 3 sites (5%). Results indicate that land that is maintained in good condition is more resilient to the impacts of extreme weather events (both drought and flood) and recovers more quickly after the event. The observed improvement in land condition at many sites was supported by strategic grazing land management and above average rainfall in recent years. In this region, droughts and floods are likely to increase in frequency and severity. It is critical that we improve understanding of the linkages among drought, floods, grazing land management and land condition to assist producers to build greater resilience in their production systems.

Introduction

High interannual rainfall variability and extreme climate events (e.g., droughts and floods) naturally occur across northern Australia's rangelands (McKeon et al. 2004). In this region, it is common for periods of drought to be immediately followed by periods of intense rain and flooding. During drought, the landscape is most vulnerable to severe impacts associated with flooding, due to reduced surface cover and biomass. The interrelationship between drought and flood impacts on land condition are conceptually understood, but rarely quantified (Barendrecht et al. 2024).

The 2019 north-west Queensland flood, caused by a monsoonal depression, was a particularly significant event. In late January and early February 2019, the Flinders River catchment had 10 consecutive days of widespread heavy rainfall. Julia Creek Airport (Bureau Station 29058), for example, recorded 571 mm over the event, with a maximum daily total of 229 mm. The rainfall event, unprecedented since records started (in the early 1900s), triggered widespread flooding, estimated to cover over 13 million ha (AgForce Queensland 2019). The flood affected area had been in drought for the six years prior to the flood. The flood event, coupled with an extreme wind chill, resulted in the death of over 0.5 million livestock, and caused significant infrastructure damage (Phelps 2019). The flood event also had severe impacts on land condition with widespread soil erosion, soil deposition and pasture death (Hall 2020a,b). Anecdotal evidence from this and other events suggests that land that is maintained in good condition is less susceptible to severe impacts associated with extreme climatic events, and these landscapes recover faster (D. Phelps, pers. Comms). However, this is rarely quantified. In Northern Australia, predicted changes in climate include an increased frequency and severity of extreme climate events (State of Queensland 2019a). Such changes may exacerbate existing pastoral management challenges such as declines in pasture productivity, reduced forage quality, and additional livestock heat stress. An improved understanding of the interrelationships among grazing land management, climatic conditions and pasture responses are needed to help recommend management strategies that build landscape resilience to climate extremes and ensure long-term rangeland productivity.

Methods

The study is focused on Mitchell Grass Downs land types in the Richmond and Julia Creek areas, within the Flinders River catchment of north-west Queensland, Australia (Fig. 1). The study area has a hot semi-arid climate, with high rainfall seasonality. On average, the catchment receives 492 mm of rain per year, 88% of which falls during the wet season (December – March). The topography is relatively flat, intersected by multiple anabranching and ephemeral channels and creeks draining to the Flinders River. In late February and early March 2019, staff from the Queensland Department of Agriculture and Fisheries completed field land condition assessments at 130 sites across the region (Hall 2020a). The land condition assessment utilised the A, B, C, D framework (Karfs et al. 2009). In this framework, A represents the best condition, with good soil condition, high coverage of 3P (perennial, productive, palatable) grasses, and few weeds, while D represents the poorest condition. Sites were limited to land alongside a selection of major highways or secondary roads that could be accessed after the flood. All 3P grasses and seedlings were recorded, as well as annual grasses, legumes and weeds. In August 2020, the land condition assessment was repeated at most of the sites surveyed in 2019 (Hall 2020b). In September 2024, 62 of the original 130 sites were reassessed (Fig. 1).

Results

Out the 62 sites initially surveyed in 2019 and re-assessed in 2024, land condition: improved at least one condition score at 30 sites (48%); remained at the same condition score at 29 sites (47%); and declined at least one condition score at 3 sites (5%) (Table 1, Figure 1). Overall, where the pastures had been well managed during the six-year drought prior to the flood and the Mitchell grass tussocks retained at least 15 cm of basal stem, there was a higher proportion of plants surviving and regrowing within a month of the floodwaters receding. These plants are still surviving. Several sites that were assessed to be in C or D condition in 2019, have improved to a B condition in 2024 (Fig. 2A, B). Despite considerable soil loss during the flood event, enough seed bank remained at these sites to stimulate pasture re-establishment. Anecdotal evidence suggests such re-establishment has been supported by strategic grazing land management and above average rainfall in recent years. Conversely, despite receiving good wet season rainfall over the past two years, some sites have remained in C- or D condition (Fig. 2C), while nearby other properties have A and B condition Mitchell grass pastures. After the flood, tussock rhizomes were exposed at many sites due to severe wash, resulting in tussock death. In 2024, evidence of exposed tussocks still remains at most sites, but the surviving tussocks seem to be in relatively good health (Fig. 2D). The impact of the flood appeared to be more severe in lower parts of the undulating landscape where flow depths, velocities and periods of inundation are likely to have been higher than on the more elevated parts. The flood impact also appeared to be more severe closer to the main drainage channels, creeks and the Flinders River.

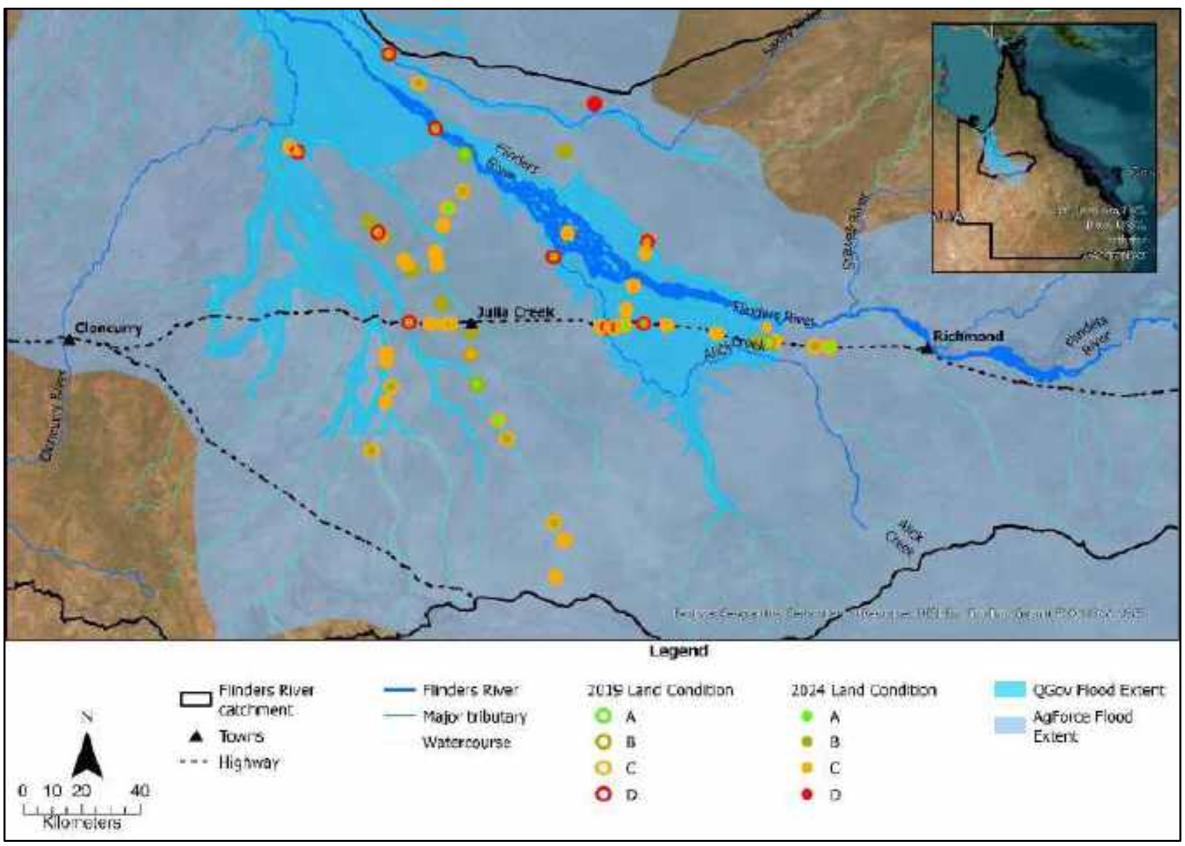

Figure 1. Map showing the change in land condition rating of sites surveyed in both 2019 and 2024, as well as extent of the flood zone as mapped by the State of Queensland (2019b) and AgForce Queensland (2019).

Rainfall across the study areas was average to below average in the six years prior to the late January/February 2019 flood and in the three years following the flood (Fig. 3). Well-above average rainfall occurred in 2022/23 and average rainfall occurred in 2023/24.

Table 1. Matrix showing the change in land condition rating of 62 sites assessed in 2019 and 2024.

	2024					
	Rating	**D**	**C**	**B**	**A**	**Total**
2019	**D**	1	3	7	0	11
	C	1	21	10	6	38
	B	0	2	7	4	13
	A	0	0	0	0	0
Total		2	26	24	10	62

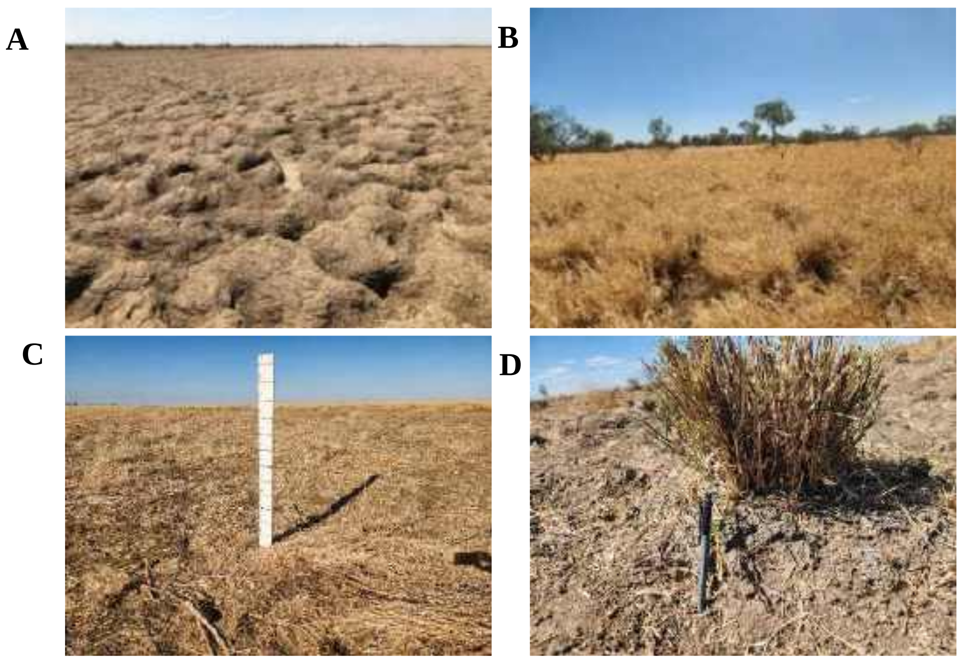

Figure 2. (A) Photo of a site that was in D condition in early March 2019 with complete loss of pasture cover and serious scouring. (B) Photo of the same site in September 2024. The site has recovered to B condition with high coverage of Mitchell grass. Note, the 2024 was taken closer to the treeline, visible in the 2019 photo. (C) Photo of a different site in 2024 that has remained in C- condition. (D) Photo of an exposed Mitchell Grass tussock in 2024.

Discussion

Across the Mitchell Grass Downs, a wide range of flood impact and recovery responses on land condition are evident. The variation in response can be linked to interactions among: (i) historical grazing management; (ii) the impact of the preceding long-term drought, combined with the grazing management imposed during this drought; (iii) the hydrodynamics (depth, velocity and duration of inundation) during the flood; (iv) grazing management following the flood; and (v) climate conditions following the flood. Overall, it is clear that land managed to remain in good condition (A or B), is much more resilient to severe impacts associated with extreme climate events (both drought and floods) and recovers more quickly. Continued monitoring at the assessed sites will enable long-term quantification of pasture recovery while accounting for seasonal climatic fluctuations. Further work is needed to better understand the role that soil type has in influencing flood impact and recovery. Further work is also needed to better model the hydrodynamics of floodwater in this low-gradient, multi-channel landscape.

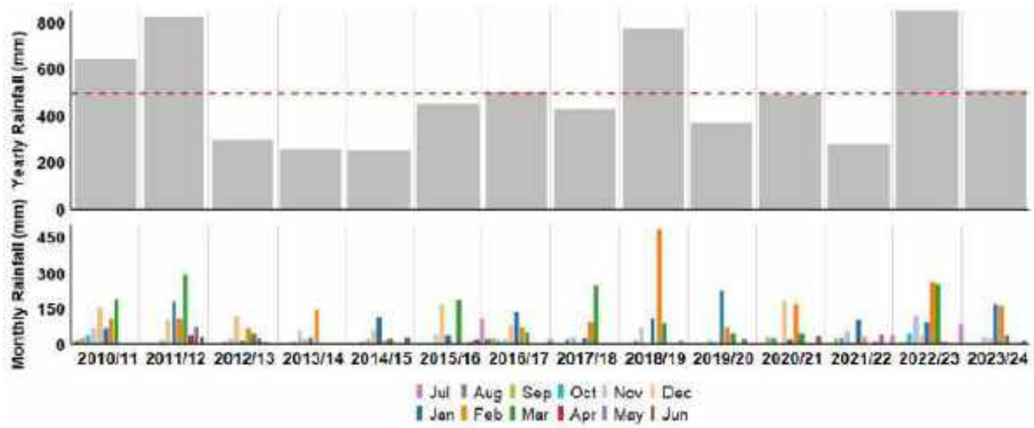

Figure 3. Monthly and yearly rainfall at Julia Creek. Annual rainfall is calculated as commencing on 1 July and ending on 30 June the following year to encapsulate a full wet season. The red dotted line shows the long-term (1888/89 – 2023/24) mean annual rainfall. Data source: State of Queensland (2024).

Key words: Bison; grazing; greenhouse gas; soil carbon

Abstract

The bison is a highly held species in the United States (U.S.) due to its historic and cultural significance along with its distinction as the national mammal. Despite a drastic decline in the 1800s, the U.S. bison population is rebounding with nearly 250,000 existing within private operations, federal, state and public herds, and public lands (U.S. Department of Agriculture 2024). A majority of this population is owned and raised privately as livestock. However, several herds also exist as conservation or Indigenous herds. As the bison production sector continues to grow, its impact on the climate is coming into question. Similar to other grazing ruminant livestock, bison emit greenhouse gases (GHG), which are often publicly associated with negative environmental impacts. However, bison can also positively impact the environment by contributing to healthy grasslands and carbon sequestration through grazing action. South Dakota State University (SDSU) was recently awarded a commodity development grant focused on grazing livestock producers, including bison producers. A primary goal of this project is to assess the environmental impacts of bison grazing systems and to encourage sustainable land management practices by providing producers with practice incentives and creating novel market opportunities. To accomplish this, SDSU is partnering with bison producers in the Northern Great Plains to implement sustainable grazing and land management practices and subsequently measure, monitor and verify associated GHG and carbon impacts. Measurements include soil carbon and GHG, along with estimates of bison GHG emissions measured using GreenFeed (C-Lock, Inc., Rapid City, SD, USA) technology. Data generated from this project will help establish baseline environmental impact estimates for grazing bison, which are needed to help inform producer management decisions and guide future market development opportunities.

Introduction

While tens of millions of Plains bison (*Bison bison bison*) once roamed the plains of North America, a sharp decline in bison numbers occurred in the 1800s, driven by a number of factors including commercial hunting, disease introduction, environmental conditions (e.g., drought), and division of the plains by railroad expansion (Boyd and Gates 2006). This drastic decline ultimately led to one of the first major conservation movements in North America, with numbers dwindling to a few hundred in the late 1880s. Conservation efforts were first led by private citizens, with government efforts later gaining momentum to reestablish the Plains bison population (Freese et al. 2007).

The Plains bison is unique in its multi-faceted significance as a production, conservation, and cultural species. Greater than 90% of today's bison are managed for commodity production purposes. However, bison are publicly recognized as culturally important because of their Indigenous culture status and their designation as the U.S. national mammal. As the commodity production sector continues to grow, the impact of bison production on the climate is being scrutinized. Bison are ruminants that generate and emit greenhouse gases (GHG) similarly to beef cattle (Stoy et al. 2021), and these GHG are frequently associated with negative impacts on the environment. However, these grazing ruminants also have potential to positively influence carbon sequestration and soil health in grasslands through changes in plant species composition and carbon distribution (Reeder and Schuman 2002). Additionally, intentional grazing management can result in more carbon sequestration than GHG emissions (Teague et al. 2016) and improved nitrogen cycling (Vega Anguiano et al. 2024), indicating that grazing livestock systems can support ecologically healthy grasslands and ecosystems and promote greater biodiversity (Ratajczak et al. 2022; Tielkes and Altmann 2021).

While bison reintroduction has been successful in growing the Plains bison population, the GHG impacts of such reintroductions are unknown. There have been limited attempts at understanding GHG emissions from bison, including using eddy covariance (Stoy et al. 2021) and gas chambers (Galbraith et al. 1998) to estimate GHG on enclosed bison along with employing known energy requirements to estimate historical herd emissions (Kelliher and Clark 2009). However, numerous factors can influence methanogenesis and subsequent measures of GHG, including (but not limited to) host genetics, age and diet along with seasonality and type of production system. The recent development of GreenFeed technology (C-Lock Inc., Rapid City, SD) has enabled GHG sampling on individual grazing livestock. This technology has been used to successfully collect GHG emissions data on both grazing (Husmann et al. 2024; Waghorn et al. 2016) and confined (Ryan et al. 2022) cattle. Use of GreenFeed technology to collect GHG measurements on grazing bison will help inform the environmental impact of bison production and reintroduction. Our objective is to collect GHG measurements on grazing bison along with relevant soil carbon, forage and climatic data to provide baseline knowledge for bison grazing systems in the Northern Great Plains of the U.S.

Methods

We are currently engaged in a large-scale, five-year study focused on bison and beef calves produced on operations in the Northern Great Plains that implement approved conservation practices, such as cover crop grazing, conservation cover and range plantings, and prescribed grazing. A critical component of this project is determination of GHG emissions and carbon sequestration associated with grazing bison and beef cattle. To accomplish this, we have established cooperative partnerships with three bison operations and four beef cattle operations located in South Dakota and Wyoming. GreenFeed units are deployed at each operation to collect GHG measures from grazing animals. Additionally, soil samples are actively being collected from each operation for determination of soil organic carbon and bulk density along with microbial community size and composition, which can be earlier indicators of changes in carbon sequestration potential. The goal of this initial report is to share preliminary results from the first year of GHG data collection on grazing bison.

Study Sites - Bison

South Dakota State University established cooperative partnerships with three bison operations to measure GHG emissions of grazing bison. These operations were selected because they are located in different geographic gradients across Wyoming and South Dakota and ultimately represent the greater study area of the Northern Great Plains. Historical grazing activity information is being collected for each site, but all sites have been grazed by bison in recent years. Site 1 is located near Custer, South Dakota, and consists of approximately 650 hectares at a mean elevation of 1,320 m. The dominant vegetation consists of western wheatgrass and green needlegrass, along with big bluestem and sideoats grama. The predominant soil type is silty clay loam. Ambient temperatures range annually from 2.2-13.3 °C and average precipitation is 551 mm. Site 2 is located near Gillette, Wyoming, and consists of approximately 20,900 hectares at a mean elevation of 1,524 meters. The dominant vegetation is Wyoming big sagebrush along with shrub needle and thread, western wheatgrass, crested wheatgrass and blue grama. The predominant soil type is loamy. Ambient temperatures range annually from 0.3-14.7 °C and average precipitation is 337 mm. Site 3 is located near Fort Pierre, South Dakota, and consists of >59,000 hectares at a mean elevation of 750 meters. The dominant vegetation is from the Western wheatgrass community. The predominant soil type is dense clay. Ambient temperatures range annually from 2.0-16.3 °C and average precipitation is 477 mm.

GreenFeeds

The GreenFeed pasture system from C-Lock (c-lockinc.com) collects gas flux measures of primarily methane (CH_4) and carbon dioxide (CO_2), with oxygen (O_2) and hydrogen (H_2) as additional options. The system reads the animal's electronic identification tag upon entry and dispenses a small amount of pelleted feed as an attractant. As the animal consumes the bait, a fan draws air at a continuous rate past the animal's mouth to enable the capture of eructation events. The animal must be within an approved head proximity for a minimum of 2 minutes with adequate airflow (> 29 L/s) for a measurement to be recorded. Animals can be measured multiple times each day and settings regarding the number of visits, number of bait drops per visit and timing of allowed visits can all be modified in the machine interface.

There is no standard adaptation procedure for bison on GreenFeed units. Therefore, the procedure for GreenFeed introduction and use varied by site due to differences in pasture size and herd management. At Site 1, a subset of bison heifers (n = 12) was initially adapted to the GreenFeed units during the Fall of 2023 before being combined with the main herd (n = 115) in 2024. At Site 2, the GreenFeed units were rotated alongside the yearling and 2-year-old bison (n = 618) as part of the rotational grazing plan. At Site 3, bison (n = 3,133) were placed into relatively smaller pastures of < 567 hectares to encourage initial use; however, average pasture size at Site 3 at the time of GreenFeed unit introduction was considerably larger than at Sites 1 and 2, ranging from 2,740-4,474 hectares.

Results

GreenFeed Use and GHG Emissions

GreenFeed adoption was unsuccessful at Site 3 with only two observations recorded. This was likely due, in part, to the substantially larger pasture size, machine movement restrictions and limited labour resources. The herd at Site 3 is also enrolled in a grass-fed program, restricting the type of bait used in the machine to alfalfa pellets. Site 1 also used alfalfa pellets but Site 2 used a textured sweet feed as bait. GreenFeed adoption success was much greater at Sites 1 and 2. The number of monthly GreenFeed observations at Sites 1 and 2 are shown in Table 1, along with monthly means for the two greenhouse gases of primary interest, CO_2 and CH_4. In total, 1,696 observations were recorded across Sites 1 and 2 in 2024 (to-date). No observations were recorded at Site 2 in April due to temporary bison relocation to another grazing allotment.

GHG Emissions

Averages and standard deviations for CO_2 (g/d) and CH_4 (g/d) for Sites 1 and 2 are also presented in Table 1; results from Site 3 are not shown due to the limited data collection from that herd. A simple t-test indicated no difference ($P > 0.10$) in either CO_2 or CH_4 across the two sites.

Table 1. GreenFeed observations and CO_2 and CH_4 emissions collected from grazing bison at Sites 1 and 2 in 2024.

Site	Month	GreenFeed Observations	[1] CO_2, g/d	[2] CH_4, g/d
1	January	243	6,047.37 (1,106.5)	146.34 (52.3)
1	February	159	5,791.64 (1,150.3)	127.45 (50.7)
1	March	238	5,809.51 (1,085.9)	134.91 (46.3)
1	April	306	5,410.92 (1,285.8)	120.64 (41.3)
1	May	87	6,931.43 (1,624.2)	196.69 (71.2)
1	June	52	7,687.42 (1,611.5)	194.80 (84.3)
1	July	70	8,421.40 (1,615.7)	222.98 (80.4)
1	August	59	6,654.10 (1,129.5)	190.7 (62.8)
2	March	9	6,125.75 (1,023.9)	144.89 (44.3)
2	May	9	5,754.40 (647.4)	153.96 (35.9)
2	June	140	6,623.39 (1,266.5)	157.66 (70.0)
2	July	183	6,887.39 (1,167.3)	165.98 (65.7)
2	August	122	6,469.23 (1,266.5)	157.96 (76.4)
2	September	19	6,217.32 (1658.8)	145.35 (74.3)

[2] CH_4 mean (CH_4 standard deviation), g/d

Discussion

Grazing lands account for 25% of the global sequestration potential of carbon storage (Follett and Reed 2010) and the role of grazing animals – including bison - is critical in the control of the carbon cycle (Schmitz et al 2023). There is limited GHG data on grazing bison, and data captured from this study over the next five years will be fundamental in documenting GHG emissions in foraging bison and furthermore understanding the role of bison grazing systems in net carbon sequestration on grasslands.

We have demonstrated that GreenFeed units can be successfully adapted for bison use. It does appear, however, that limiting pasture size may be critical for successful adoption by bison. A smaller pasture size may help to ensure closer proximity to a GreenFeed unit, which could be an important factor considering differences in grazing behaviour between bison and cattle. However, it is also worth considering that limiting pasture size may influence other effects associated with bison grazing and carbon cycling. Finally, limiting other supplement availability and/or choosing a more enticing bait may be critical in persuading bison to use the GreenFeed with only a small amount of pelleted feed bait.

While GHG estimates did not differ across the two bison sites included here, further analysis and data collection are needed to determine differences associated with season and forage type and availability. Forage samples were collected routinely at each site across the grazing seasons, and associated climate data has been archived. Additionally, soil samples were collected at each site and will be analysed for soil organic carbon and bulk density along with soil microbial communities. These data collectively will help establish the baselines for bison grazing systems in the Northern Great Plains.

Testing virtual fencing for the sustainable management of north Australian rangelands: Impacts on beef cattle grazing behaviour, pasture resource, and cattle production.

Muller, J[1,2]; Spiegel, NB[1].

[1]Department of Primary Industries, Queensland. PO Box 976, Charters Towers, Qld, Australia 4820

Key words: Adaptive grazing; grazing distributions; perennial pastures

Abstract

The selective grazing behaviours of cattle frequently lead to degradation of selected areas. Virtual fencing (VF) will be tested to control cattle spatial grazing distributions in extensively managed herds in northern Australia. If VF can successfully be used to change spatial grazing pressure, this would allow for increased rest for preferred areas and improved utilisation of less preferred areas that would otherwise have limited productive value. This will likely improve land condition, carrying capacity, and drought resilience. If successful, VF could be an important tool for management of grazing impacts to increase production and achieve a variety of environmental goals in the extensive systems of northern Australia.

Introduction

Cattle are highly selective grazers at the patch and landscape scale (e.g., Mott 1987; Senft et al. 1987), preferring specific areas, especially those close to water and on flatlands, while under-utilising other, less preferred areas within a paddock (Andrew 1988). This uneven spatial use is particularly problematic in the large heterogenous paddocks of northern Australia, even when stocking rates are appropriate (Hunt et al. 2007). Overutilisation of selected areas leads to negative changes in pasture and land condition such as loss of palatable perennial grasses, increased bare ground and risk of soil erosion, and weed invasion. Increased utilisation and thus productive use of previously underutilised areas may provide opportunity to incorporate rest in preferred areas.

While physical fencing may be implemented to increase the evenness of spatial grazing pressure (Bailey 2004), it is often cost prohibitive in the extensive rangelands of northern Australia. Virtual fencing (VF) has been demonstrated to be highly successful in managing cattle grazing distributions across pastures in intensively managed systems (e.g., Lomax et al. 2019). However, the use of VF in extensively managed north Australian herds, and the associated impacts on pasture and cattle production, are yet to be studied in detail.

In this four-year experiment, a virtual fencing system will be tested to investigate the following in extensively managed beef herds: 1) Can VF technology successfully be used to overcome preferential grazing and increase evenness of cattle grazing distribution across large, spatially variable paddocks? 2) Do VF-enabled changes in spatial grazing pressure result in improvements in pasture species composition and dry matter production? and 3) Do VF-enabled changes in spatial grazing distribution influence cattle production? In preparation for the experiment, initial work has been completed investigating cattle learning of the VF system and grazing preferences. This paper covers the experimental methods and preliminary results on cattle learning and grazing preferences.

Methods

The four-year grazing experiment will be conducted at the Spyglass Beef Research Facility (110 km north of Charters Towers, Queensland; 19°29'24.6"S 145°41'30.3"E), with an average rainfall of ~610 mm. Two treatments are to be compared: VF and Control. In the VF groups, VF collars will be used to control utilisation of different land types, allowing resting of areas as needed while excluding cattle from any scalded areas. The control herds will be managed conventionally, with free access to the whole of their paddocks. The VF and control herds will be managed in separate paddocks matched for similar watering circles, soil types, and topography. The VF and control paddocks will be replicated twice, with replicate 1 paddocks being approximately 790 ha each and replicate 2 paddocks being approximately 390 ha each. Paddocks will be stocked primarily with young cows (approx. 60 and 16 per paddock for replicates 1 and 2 respectively), with a small number of growing non-reproductive cattle (10 per paddock) for the monitoring of weight change without the confounding effects of lactation. Stocking rates will be adjusted mid-year annually based on forage availability (Department of Primary Industries 2018). Cattle movement planning will be done in consultation with the project's producer advisory group. All groups of cattle will be managed to meet their nutritional and welfare needs.

Pre-experimental work, including training cattle to use VF, investigation of grazing distributions and baseline pasture monitoring was conducted as follows.

Heifers (n=50) were trained to use VF in small paddocks. Several changes in the location of the VFs were made to investigate cattle behavioural responses, as seen in Figure 1B. Training began in a 24 ha paddock, with the VF first activated on the morning 17 November 2023. The VF was then shifted out approximately 50 m to allow an additional grazing area on the morning of the 20 November 2023. A week later, the gate into an adjacent 57 ha paddock was opened and the VF was moved to allow cattle into the adjacent paddock. On 30 November 2023, the VF shape in the new paddock was shifted to confine grazing to the north/northwestern side of the paddock. To investigate baseline grazing distributions, freely grazing heifers (n=227), including those in the initial training program, were allowed to graze across all replicate 2 paddocks during the month of August 2024. GPS co-ordinates were recorded at 10-minute intervals using the virtual fencing collars.

Animal behaviour data analysis was conducted as follows. The success of VF group cattle responding to the VF within the groups during and after training was quantified by a success ratio, i.e., the ratio of audio cues to electric pulses (Hamidi et al. 2024). GPS data for baseline grazing distributions were used to quantify cattle preference for topography types using Ivlev's index, where a value of -1, 0, and 1, respectively, indicate that a land class is never used, is used in proportion to its availability, or is exclusively used (Ivlev 1961). Topographical position class was mapped and analysed using Ivlev's index. Topographical position class is an index based on differences in elevation between different points at different scales and local slopes (Weiss et al. 2001).

Baseline measurements of land condition were taken at evenly spaced grid points at intervals of 325 m across the paddocks and will be resurveyed at the end of the grazing trial. A detailed soil survey conducted previously for Spyglass (Bryant and Harms 2016) was utilised to map the soil types in each paddock. Land condition was assessed using the ABCD framework (see Quirk and McIvor 2003; Karfs et al. 2009; State of Queensland 2015) which includes rating both pasture and soil condition. Other measures taken included the top three species contributing to yield, total standing dry matter, level of defoliation and tree basal area. Indian couch grass (*Bothriochloa pertusa*) occurrence is also being monitored as a proxy for disturbance (Spiegel 2023). Baseline mapping of degraded areas (scalds and gullies) will be conducted. Cover metrics (organic cover, green cover, biomass) will be collected annually. Preliminary findings reported herein are focussed on one replicate only, with a closer to complete data set.

Measurements

Live weight production of cattle will be calculated based on yarding weights collected at annual weaning musters (Fordyce 2023) with weekly weight change monitored using Optiweigh portable weighing platforms.

Seasonal pasture monitoring will use the BOTANAL methodology (Tothill et al. 1992) at the end of the wet and dry seasons. Average yields and defoliation scores will be used to develop pasture species selection indices (Andrew 1986; Hunt et al. 2013). Paddock site data will be pooled for soil type and related to animal distribution data. Pasture biomass and green cover will also be assessed at a paddock level using a combination of remote sensing methods, including CiboLabs remote sensing (Guerschman et al. 2023) and LongPaddock MyFORAGE (https://www.longpaddock.qld.gov.au/forage/myforage/).

Preliminary results

During the initial training of cattle to use the VF system, there were high incidences of both audio cues and electric pulses delivered on day one, which rapidly decreased by day two (Figure 1A). There was a rapid increase in success ratio from day one to day three (Figure 1A). The activation of a virtual fence in the second paddock (30 November, Figure 1B) was associated with a rapid increase in incidence of audio cues delivered with minimal electric pulses delivered.

Cattle preference, land condition and proportion of 3Ps (perennial, palatable, productive pasture species) are shown by topographical position class in Table 1. The only topography class with a positive Ivlev index value was the flat plains . The lowest proportion of 3P species also occurred on the flat plains (46% c.f. 62% for highlands). Overall mean land condition ratings ranged from B class (fair) for the open slopes and highlands, to C class (poor) for the flat plains and lowlands. The overall mean land condition across all topographies was a high C (C^{+}). The naturalised stoloniferous grass *Bothriochloa pertusa* was found across all topography classes with the exception of lowlands, with the highest occurrences on the flat plains and open slopes, and to a lesser extent on the highlands (data not shown).

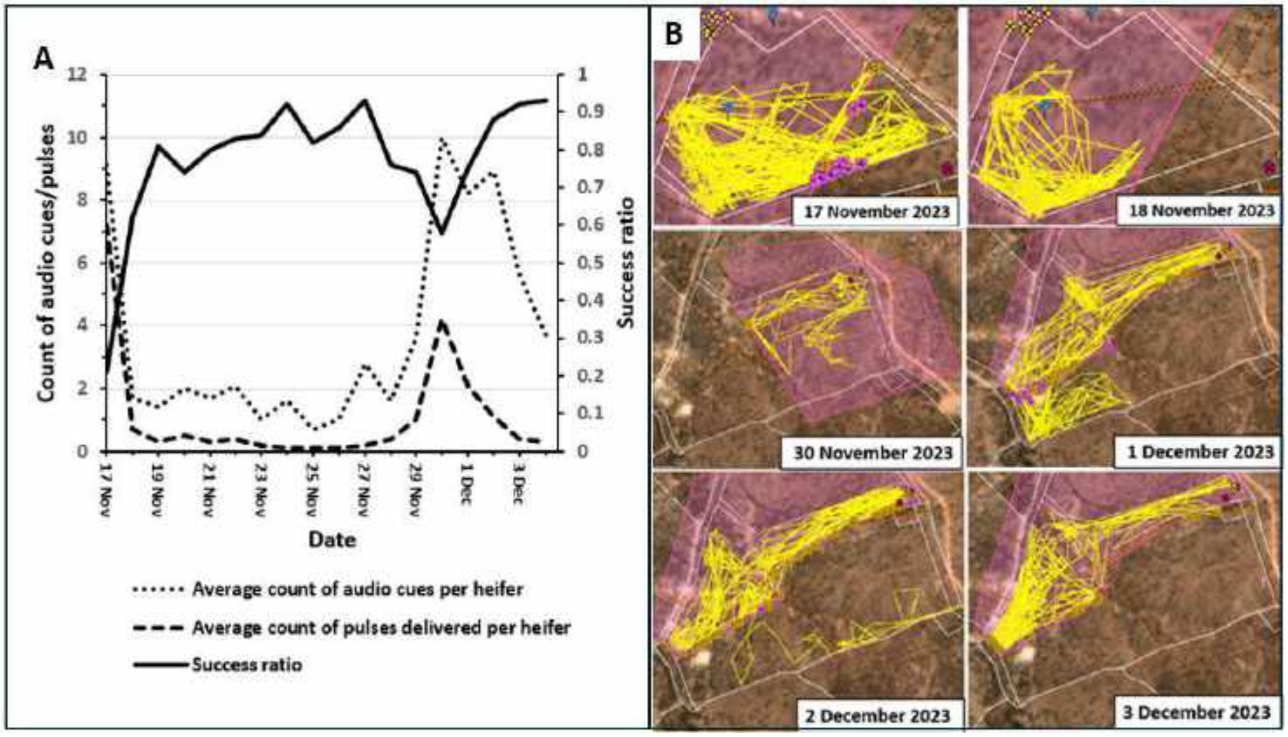

Figure 1. Audio and pulse cues delivered to heifers and success ratio throughout the training program from 17 November to 3 December 2023 (A), and cattle movement 'tracks' for 10 randomly selected heifers during the first 16 days of the training program. White line=physical fence, pink shaded area=virtual fencing inclusion zone, yellow= 'tracks' walked by cattle (B).

Table 1. Preliminary results for cattle preference, the contribution of 3P species to yield and average land condition by topography type for paddocks within replicate 2.

Topographical position class[A]	Ivlev's index value[B]	Proportion 3P species[C] (±SEM)	Average land condition[D]
Flat plains	0.13	46% (±5%)	C^+
Lowlands	-0.29	52% (±10%)	C
Open Slopes	-0.33	60% (±7%)	B^-
Highlands	-0.44	62% (±12%)	B^-
Other	-0.85	no data	no data

[A]The topographical position class is an index based on differences in elevation between different points at different scales and local slopes (Weiss et al. 2001).
[B]Ivlev's index is a common measure of food selection based on both the extent of selection and the relative abundances of the food types in the environment, in this case the relative abundance of land areas by topographical position class.
[C]3P stands for preferred grass species that are Perennial, Palatable and Productive. The proportion of 3P species was calculated from the top three pasture species contributing to yield.
[D]Land condition classes include A (good), B (fair), C (poor), D (very poor), with the possible range within each class including variants from high (plus), neutral, to low (negative).

Discussion

This study demonstrates that naive cattle can learn to respond to the VF audio cues within a day, as indicated by a rapid increase in success ratio after day one of training. When the animals were shifted to a second paddock and restricted to a portion of the paddock, they were able to be contained to the VF inclusion zone largely by responding to the audio cue with a minimal incidence of electric pulses. The success of cattle learning to respond to VF cues in this study is consistent with other studies investigating the learning of a VF system by dairy cattle (Lomax et al. 2019) and moving small herds of beef cattle (<13 cattle) short distances of <400 m (Campbell et al. 2021). While the functionality of VF does show promise on a small scale, no published studies to date have evaluated its capacity to hold and shift cattle in the extensive, variable landscapes of northern Australia.

The large paddocks and variable terrain in north Australian production systems present additional challenges for VF systems. These include obstacles (e.g., hills, gullies, and trees) for radio transmission between VF base stations and collars, the large proportion of herds that are predominately breeding females and the challenges associated with cow-calf movement patterns, predators, and multiple widely spaced watering points. Potential challenges to achieving full use of VF technology, yet to be investigated in this study, are likely to be associated with shifting cattle from one watering point to another and shifting cows during the calving period.

Preliminary results indicate that the topography type with the highest preference and therefore highest risk of overgrazing is the flat plains, with all other topography types being avoided by cattle. However, this result is based on cattle GPS data for the month of August 2024 only, and grazing distributions will likely change at other times and with varying seasonal conditions. The preference of cattle for flat plains (e.g. Raynor et al 2021) is consistent with the lower 3P abundance in the flat plains compared to other topography types.

Conclusion

This experiment aims to test the VF system for high level control over grazing distributions in extensively managed herds, while also monitoring impacts on land condition and cattle production. Our preliminary results show that it can be used at least on a small scale and provide data on cattle grazing behaviour and land type selection. Whether VF can be used to implement increased rest of pastures within large heterogenous paddocks and ultimately produce positive biological and economic outcomes in a northern production systems context is yet to be established.

Key words: animal behavior; herd instinct; migratory grazing;

Abstract

On expansive rangelands, a major alteration to the historic grazing patterns is the lack of herd instinct that increased animal density and supported nomadic behavior. It is thought that re-instilling herd instinct into domestic livestock may mitigate the overuse of specific areas on rangelands and improve profit per acre, while supporting more diverse plant communities and wildlife habitat. A new technology is the Herd Instinct Tag (HIT) that utilizes audio and electrical stimuli to maintain animals at a defined herd density. HIT does not define borders, but rather tags communicate with each other to maintain herd density based on animal proximity. To test the HIT, 41 Hereford-cross animals were divided into two groups, HIT and control (CON), and evaluated for 5 weeks on the Mimms Division of the Dixon Water Foundation in Marfa, TX. Animals were maintained in separate pastures and recorded weekly to evaluate behavioral changes over time. There were no significant differences between treatments for any animal behaviors. Spatial distribution differed between treatments with the average distance between HIT individuals being 18.3 m, whereas the CON averaged 258.4 m between individuals. Ultimately, there were no indications that HIT affected animal stress levels following the use of HIT for 5 weeks. Animals with HIT successfully maintained a higher herd density but the long-term impacts on animal and rangeland health and production still need to be evaluated.

Introduction

Over the last 100 years increased attention has been placed on the state and revival of rangeland health, resulting in significant emphasis on extensive grazing systems and sustainable grazing practices (Kothmann 1974). During the mid-1900s, the management of livestock and rangelands became particularly centered on the creation of grazing systems that relied on the idea of rest-rotations, as opposed to traditional continuous grazing. These grazing rotation systems have various forms, including deferred rotation, short duration grazing, high intensity-low frequency, and adaptive multi-paddock grazing, which involve different approaches to the timing and duration of rest periods (Teague et al. 2013). Nevertheless, these systems commonly aim to mimic, to some degree, historic, migratory grazing patterns of native grazers (Teague et al. 2013; Bamforth 1987; Guy et al. 1981) that consisted of resource use followed by a non-grazing period, generally supporting landscape heterogeneity and co-existence of livestock and wildlife on rangelands (Behnke 2021; Chen and Shi 2018).

Within extensive rangeland scenarios there is a market for livestock management systems that producers can maintain use to desired stock density and support migratory grazing patterns where animals move as a unified herd. Because of this, a new technology coined the Herd Instinct Tag (HIT; RanchCheck, Inc., Marfa, Texas, USA) has been developed that focuses on re-instilling herd instinct into domestic livestock to support migratory grazing. HIT is a solar powered ear tag that utilizes audio and electrical cues to maintain animals at a user defined proximity that translates to herd density, but it does not define borders. Instead, the tags communicate with each other to determine and maintain herd density based on animal proximity relative to the center of the group. The goal of HIT is to promote innate herd instinct and promote animal grazing as a unified herd with minimal human intervention. As with any new technology, evaluating its influence on animal behavior and performance is crucial for successful implementation and widespread adoption. Therefore, our study objective was to assess the impact of HIT on animal behavior and evaluate its ability to maintain herd formation relative to "free ranging" animals.

Methods

The animals used in this experiment were registered and cared for according to guidelines approved by the Institutional Animal Care and Use Committee (AUP 2022-1163) at Texas Tech University.

On the Mimms Division of the Dixon Water Foundation in Marfa, TX (30.3929 ° N, 104.0622 ° W: elevation 1,432 m), a total of 41 yearling Hereford heifers and steers (318 ± 23 kg) were used to evaluate HIT. A total of 19 HIT were placed on animals. However, during the first week of observation, two animals in the HIT group lost their tags, resulting in 17 total tags for the full observation period. Animals were divided into two groups, HIT (17 operational HIT (65 g; n = 17) and control (CON, conventional ID tag (10 g; n = 24), and evaluated over a four-week period (February 24 – March 24, 2024). Animals were stratified by sex, nine heifers and ten steers initially received HIT, with random tag assignment within groups being performed by alternating between HIT and CON tags for every animal that entered the chute. Tag placement was performed by removing the current ID tags and fitting the assigned tag (i.e., HIT or CON) by securing it through the pre-existing hole in the ear. Following tag application, HIT devices were activated and each group was released into separate pastures (HIT 55 ha; CON 457 ha) out of the eyesight of each other. The HIT device was set to maintain a maximum distance of approximately 30 m between individuals. Although not optimal, the CON group was placed in a larger pasture due to a lack of similar-sized paddocks not out of eyesight of the HIT group, as well as grounding issues with electric fences. Data logged by the HIT included the continuous periodical relative proximity between the devices and all audio or electric cues.

Animals were maintained in their separate pastures and monitored weekly to evaluate behavioral changes over time using a modified ethogram of behaviors (Ranches et al. 2021). Individual animal behaviors were recorded using focal-animal sampling (Altmann 1984) for five minutes using a spotting scope with a mounted GoPro camera (GoPro Hero10 Inc. San Mateo, California, USA). Animal behavior monitoring was performed two days per week over a four-week period on the following dates: February 24 and 25, March 3, 4, 10, 11, 17, and 18 of 2023. All videos were taken at the same relative time each week, between the times of 8:00 AM to 6:00 PM Central Standard Time (CST), alternating between the two focal groups to ensure equal time sets for both morning and afternoon evaluations (e.g., HIT monitored during the morning on day 1 and afternoon for day 2). Behavioral analyses were performed by evaluating every 30 seconds of the recording. All recordings of individual animals were analyzed into observations by recording the primary behavior during the 30 second period. Observations were removed from the dataset if the animal being evaluated was out of view at any point. To evaluate spatial distribution, drone aerial images were taken between 11:00 AM and 2:00 PM CST for both groups. GPS positions of the cattle were obtained by georeferencing (Syetiawan et al. 2020) aerial pictures taken with a drone at a height of 200 meters in ArcGIS pro (ESRI, California, USA) and proximal distance between all animals within a group were determined by calculating the distances between their GPS positions.

All statistical procedures were performed using the MIXED procedure of SAS software version 9.4 (SAS Institute Inc., Cary, NC). Behavioral data were evaluated for the 2×2 factorial arrangement, considering treatment and week as fixed factors, with animal within group considered a random intercept. Distance data was evaluated to assess the effect of treatment and week using a completely randomized model. Normality and homogeneous variances were checked using Kolmogorov-Smirnov and Levene's tests, respectively. Mean comparisons were performed using Least Square Means for all significant effects ($P \leq 0.05$) and tendencies assumed at ($0.05 < P \leq 0.10$).

Results

There was no difference in post-tagging behavioral scores between the CON and HIT ($P > 0.05$). There was no interaction or main effect differences for any animal behaviors, with both CON and HIT spending similar proportions of time within each behavior category ($P > 0.05$). However, the spatial distribution assessment indicated a significant interaction between treatment and week ($P < 0.001$). Because the interaction appeared to be a result of social and environmental stressors, we compared treatments by week. The control treatment demonstrated significantly greater spatial distribution for all weeks ($P < 0.01$)

Discussion

Overall, time spent in all behavioral groups was similar between treatments. Feeding comprised >60% of behaviors, followed by locomotion and cohesive behaviors. Agonistic and agitation behaviors were <1% for both groups, indicating animal discomfort due to HIT was not present. According to Kilgour 2012, animals exhibiting <5% of these behaviors are considered to be in a state of comfort. Confirming the previous observation, both groups demonstrated high levels of cohesive behavior, with 10 and 15% for CON and HIT, respectively. We found that the CON group had numerically greater locomotion than the HIT group, which was surprising initially; however, this was likely due to individual animal movement within HIT group being constrained by the herd relative to the CON group and the greater pasture size of CON. Generally, our results follow the same trend found in virtual fence studies where no negative behaviors are noted following use of the technology (Lee and Campbell 2021; Verdon et al. 2021; Campbell et al. 2019).

The assessment of spatial distribution indicated a significant interaction between treatment and week, but this interaction can be largely attributed to CON in response to social and environmental stressors. There was no difference in distribution over time for HIT, with the average distance between HIT individuals being 18.3 m. In contrast, CON averaged 258.4 m between individuals with large weekly variations. The greatest distance between individuals was observed in week three for CON group (550.3 m), while the greatest distance for HIT herd was in week 4 (23.9 m). The HIT group in week two had the least distance between individuals (8.4 m), whereas the least distances for CON were in weeks one and four, 125 and 105 m, respectively. Overall, the HIT group maintained a single herd within a radius of no greater than 30 m, while the CON group divided into subgroups spaced up to 920 m apart.

Throughout the trial the HIT herd remained clustered, demonstrating the HIT's potential to maintain group density. In contrast, the CON group's proximity varied with their activity. For example, the CON herd would form a single group near water or supplement but disperse into subgroups during grazing events. The HIT group, however, maintained close proximity during all activities, including grazing, watering, and resting. When most of the herd wanted to rest, HIT individuals who wanted to graze stayed adjacent to the herd to maintain formation. Although anecdotal, evidence that suggests herd instinct was improved is that animals #2 and #6 lost their HITs midway through week one but did not stray from the herd even though they were no longer receiving cues. Although receiving only a brief period of exposure to the tags, these animals demonstrated strong herding behaviors and had to be moved to another paddock by ranch personnel.

There were no differences in animal behavior between animals that received CON vs HIT. The primary stressors observed in this study were associated with altered herd dynamics from splitting one herd into two and environmental stressors (i.e., freezing temperature, snow, and high winds). Animals with HIT maintained a close cluster formation which translates to a higher herd density. The HIT appears to adequately maintain herd dynamics without compromising animal welfare, but tag weight likely needs to be reduced to mitigate ear damage. Greater evaluation of tag weights is a prerequisite for future technology applications. Next steps for HIT require longer term evaluation of the technology and how it influences animal performance and ecosystem health.

How rural Mongolians understand climate change: knowledge, attitude and practice survey

Bayarmaa Enkhbayar, EBA[1]

[1]Global Green Growth Institute

Key words: climate change, resiliency, herders, knowledge, readiness

Abstract

Over the last 80 years, Mongolia's average annual temperature increased by 2.36°C. The population groups, in particular herder groups are likely to be disproportionately affected due to not only their exposure to shocks and stresses but also their limited capacity to withstand and respond to climate induced disasters and risks. Mongolia's Climate change mitigation and adaptation policy goals can succeed and can be sustainable if the public, key stakeholders and policymakers support effective action. The priorities of protecting vulnerable groups to climate change, empowering the public to respond to climate induced risks were also mentioned in the Nationally Determined Contributions. However, no studies have been conducted to identify what opportunities exist to increase knowledge and promote positive attitudes and practice among the rural population and vulnerable groups. This 'Climate Change Knowledge, Attitude and Practice Survey in Mongolia' was commissioned by the Global Green Growth Institute and the Ministry of Environment and Tourism. The purpose of the Survey was to assess awareness, knowledge, attitudes, practice and media consumption related to climate change among the population including the herder communities. The results of the study inform the development of a national awareness-raising campaign strategy to improve public awareness and capacity-building activities to mainstream climate change in national policies. The survey covers awareness, knowledge and attitudes of entire communities, namely their observations about weather, environmental and climate changes, understanding of causes and effects. The survey reveals capacity needs of stakeholders and priorities needed for mitigation and adaptation strategies at community and national levels. It focuses on rural community's access to information about CC and strategies for effective awareness campaigns.

Introduction

The Mongolian climate is harsh and continental due to its unique geographical location in the center of the Eurasian continent. It is at a high altitude above sea level, is surrounded by tall mountains, and is in a remote location far from the sea. Mongolia faces some of the most pronounced climate change risks of any country in the world. This includes rapid desertification, water scarcity, changing precipitation patterns, and seasonal intensification of extreme weather events[i]. The country has extreme weather conditions, fragile ecosystems, and prominent pastoral livestock and rain-fed agriculture sectors, making Mongolia vulnerable to climate change risks that affect the economy, livelihoods and traditional cultures.

High temperatures are likely to increase the frequency and severity of heatwaves and droughts, while *dzud* (extreme cold, harsh winter natural phenomenon unique to Mongolia) will become more frequent and fiercer. Extreme events such as landslides, flash floods and land erosion are highly likely to occur due to the increased intensity of extreme rainfall. More frequent and intense drought conditions will accelerate the rate of desertification of previously productive pasture and grazing land. The number of extreme weather events, including drought, *dzud* and flooding has doubled in the last 20 years and the devastating socio-economic impact caused across the country is well documented. In addition to these extreme events, the impacts of climate change affect public health and livelihoods – both directly and indirectly. The increase in respiratory illnesses (12%) and cardiovascular disease (8%) is highly common among the population depending on the regions and is expected to rise due to climate impacts.

Animal husbandry continues to play a vital role in Mongolia's economy, employment, and export earnings. However, with increasing livestock density and the impacts of climate change, approximately 70% of the country’s pastureland is now degraded. This degradation has led to a decline in the quality of livestock products, such as meat, dairy, wool, and cashmere, which are essential to the economy and account for over 80% of the food sector. Mongolia`s agriculture sector stakeholders claimed that agriculture is the most vulnerable to climate change impacts. They pointed out the need for sufficient regulation to balance the livestock population and better controls over meat, cashmere and dairy production. Moreover, the technical capacity of the sector, particularly at the academic and university levels, was considered sufficient by the availability of a large amount of research linking climate change to agriculture and livestock. However, on the overall issue of climate change, the national data reports about the lack of qualified and competent personnel or experts at the sectoral and organizational levels.

Methods

The survey assessed the general awareness, knowledge, and attitudes of rural Mongolians regarding climate change. It explored their observations of weather, environmental, and climate changes, their understanding of the causes and effects of climate change, and their concerns about its impacts.

The survey employed a mixed-method, non-experimental, and cross-sectional approach, with a sampling design aimed at capturing results at the national level and across all regions. Data collection took place between September and November 2022 through face-to-face interviews conducted in 13 *aimags* and Ulaanbaatar city. A total of 2,804 respondents participated, of whom 51.9% were female, 48.1% male, and 36% (1,009) from rural areas. The survey employed a stratified, multi-stage cluster sampling method to select sites and respondents. Additionally, 49 key informants were purposefully chosen from national and local government, non-governmental organizations (NGOs), academia, media, and the private sector. Among the respondents were 402 herders (14.3%) and 20 farmers (0.7%), alongside government officials, civil society organization (CSO) members, business representatives, and others.

The majority (89.8%) of 402 herders lived in rural areas, particularly in the steppe zone (42.5%). Regarding gender, 55.2% of herders were male, compared to 46.9% among non-herders. Over half (52.0%) of the herders were aged 35–59 years, and educational attainment among herders was significantly lower; 84.6% had completed secondary education. Furthermore, only one-third (34.1%) of herders had purchased private livestock insurance. The rural population includes herders and farmers and other groups whose lives are vulnerable to climate change impacts. Those that had lower levels of completed secondary education were more likely to live in rural areas. Within the rural population, a distinction should also be made by age as well as it has been found that knowledge, attitude and practice levels differ with age.

During the interviews, questions on climate change mainstreaming capacity factors were asked, including demand, leadership, resources, technical capacity and institutional arrangements. A total of nine focus group discussions were conducted which included community representatives - men and women, youth, older people, herders, farmers, ethnic minorities, communities in *ger* areas, mining-affected areas, and remote border areas. The Survey examined how socio-economic status can influence climate change awareness, information needs, and the processing of climate-related information. In doing so, the team constructed and used a simple vulnerability index that measured different characteristics of a person that places them at higher risk of economic deprivation, health issues and social isolation in relation to climate change. A total of 13 characteristics were used to construct the index including age, disability, chronic illness, income, levels of education, internal migration status, and those who engaged in livelihoods vulnerable to climate change impacts. Using the index, the respondents were divided into two groups - 'less vulnerable' and 'vulnerable' - to allow for disaggregated analyses by vulnerability status. The survey did not include a "not vulnerable" category in the vulnerability index because the primary focus was on assessing varying levels of vulnerability among respondents. By concentrating on the "vulnerable" and "less vulnerable" groups, the analysis could more effectively identify and compare disparities in climate change awareness, information needs, and information processing.

Results

Awareness, knowledge, attitudes and practices

Those that participated in the Survey possessed relatively good awareness about climate change. Over two-thirds of respondents (67.3%) said they had heard about climate change and nearly half of respondents (46.6%) stated that climate change had affected their lives and livelihoods in the last 10 years. Moreover, the majority of respondents (84.0%) agreed that human activity is the main cause of climate change. However, citizens in both rural and urban areas demonstrated poor knowledge, attitude and practice regarding climate change.

Rural respondents' (36% of the total survey participants) knowledge about the causes and effects of climate change was low; therefore, they are unlikely to believe that climate change is occurring globally and affects Mongolia. While they noticed more environmental changes and experienced natural disasters, they thought it frequently occurs in ten-year cycles and is natural. They were, however, more concerned with the negative effects of environmental changes, including seasonal changes, because it has the potential to affect their livelihoods. A high number of rural respondents were also willing to receive more information about climate change from the media.

The fact that many respondents thought they had a low understanding of climate change and awareness of the ways to cope with the effects of climate change should be taken as an opportunity for raising awareness. The Survey found that there was high demand for reliable and consistent information related to climate change. The majority of the respondents (85.4%) said they would like to receive more information related to the topic from the media. Key stakeholders - including local government officials, civil servants, journalists and others in the media sector - will play a crucial role in improving the public's understanding of climate change and their demand for climate change information. However, those who were in the position to inform and engage the public also had a low understanding of climate change and lacked resources.

Media consumption and communication

Television, or TV, (73.6%) and the internet (63.7%) were the primary sources respondents used to obtain information on important topics - such as politics, the economy, health, education and the environment. The mobile phone was the most accessible device to reach people from all segments. More than 99.1% of the respondents who used mobile phones said they use their mobile phone, or someone else's, 'everyday' or 'occasionally.' In terms of trustworthiness in sources of information, TV was the fourth most trusted source of information (67.5%) after trainings and meetings (87.3%), local authorities (83.6%), and family and friends (73.9%). Trust in internet was the lowest (29.8%)

Discussion, Conclusions, Implications

The research revealed that most Mongolians surveyed had observed changes in weather patterns during their lifetimes, such as an increase in extreme temperatures and weather events. However, public understanding of climate change was generally limited, particularly in rural areas, including among local government representatives. While 84% of respondents agreed that human activity is a cause of climate change, rural respondents—such as herders and farmers—primarily attributed climate change to common environmental issues like mining and livestock overgrazing. The survey also highlighted a strong demand for reliable and consistent information on climate change. Science-based, consistent awareness of climate change and its impacts can empower herders and farmers to strengthen their resilience, enhance their adaptation capacity, and better prepare for potential climate events.

One of the most significant barriers to improving the public's understanding of climate change has been a lack of leadership in communicating information about climate change in Mongolia. Although multiple government and non-governmental agencies could potentially take a leadership role on climate change awareness, they lack the resources to do so. They also have not prioritized information and communication as a response to climate change. There have been efforts to raise awareness on the topic through the media and press in the past. However, these efforts did not reach a broader audience and have not made an impact due to a lack of synergy and coordination. Capacity-building, raising awareness, information dissemination and coordination of responsibilities are mandated to government organizations. However, due to inconsistency and instability, the activities have been largely ineffective. The multi-stakeholder engagement approach in decision-making, policy development and implementation are currently insufficient and needs to be improved. Therefore, establishing a mechanism, and promoting leadership in communicating information about climate change, are the most crucial steps for effective awareness-raising in Mongolia. A pool of financial resources that donors can contribute to (and is specifically dedicated to climate change awareness) could be created. This would help the sustainability of the awareness-raising campaign, support future climate change and communication efforts, and improve coordination between stakeholders working in the field.

Given the limited finances allocated from the state budget, it will be crucial to utilize other available financial resources – such as foreign investments and donor support – that can help with climate change awareness-raising and capacity-building. Communication, information, and awareness-raising initiatives in particular, will be central to Mongolia's response to climate change.

Acknowledgements

I would like to express its gratitude to the Global Green Growth Institute, the Ministry of Environment and Tourism, Tselmegsaikhan Lkhagva (Executive Director, IRIM, Batsugar Tsedendamba (Consultant, IRIM) and Yanjinpagma Nyamsuren (Consultant, IRIM) for providing their overall guidance, conducting consultations to define the scope of the Survey, and for their invaluable support throughout the Survey.

Attentive maintenance models of social-ecological pastoral systems

Burnett, T.J

[1] University of California, Berkeley

Key words: Resilience; Social-Ecological; Adaptive; Sustainability; Complex

Abstract

Pastoral societies have developed sophisticated institutions for managing persistent, sustainable social-ecological systems in nonequilibrium environments. These institutions operate at different geographic scales in different years, depending on the climate. This paper generalizes a methodology for modelling groups of related pastoral institutions as complex adaptive systems. The methodology then draws on hierarchy theory to detect inter-system relationships that are characteristic of social-ecological panarchies. I applied this methodology in southeast Amdo, Tibet (part of western China), an area with highly differentiated cultural and linguistic pastoral institutions. The methodology generated three interdependent models, which I termed "Attentive Maintenance Models" and which each describes complex adaptive systems at a distinct social-ecological scale: livestock herd composition, livestock herd movements, and dairy product flows. Each attentive maintenance model further reveals 1) degrees of freedom for influencing pastoral systems at that scale and 2) which institutions play similar roles to one another in enabling systems at that scale to persist. Historical qualitative data, sourced through semi-structured interviews, supports my theory that completely removing any one type of institution in an attentive maintenance model (e.g. those linked to ecological cycles, stochastic social events, or personal sentiments) precipitates system collapse across all scales. Since attentive maintenance models reveal the degrees of freedom for helping a system adapt as well as which of its types of institutions are most vulnerable for a lack of redundancy, I recommend using this methodology to assess the adaptive capacity, resilience, and vulnerability of pastoral social-ecological systems prior to forecasted types of political and climatic change. This framework reveals opportunities to reinforce resilience, adaptive capacity, sustainability, and risk management in existing pastoral systems through the development of educational resources about pastoral system function and the protection of functionally redundant institutions.

Introduction

In southeast Amdo, Tibet in western China, overlapping southern Gansu Province and northern Sichuan Province and at an elevation between roughly 3000 and 4000 meters, nomads historically managed the compositions of herds and flocks, the locations of herds and flocks, and the production and distribution of dairy products (Burnett, in press). They were attentive to ecological, social, and sentimental cues to manage these resources in particular ways: ecological cues such as physical, phenological, and physiological changes encouraged partial resource turnover; social cues such as ceremonies, celebrations, and chance meetings encouraged partial resource recombination; and sentimental cues stemming from gratitude or long-term habits and relationships encouraged partial resource persistence (Burnett, in press). The combination of these types of resource management guided nomads in adapting their pastoral resources to the ever-changing environment.

Ellis and Swift (1988) theorized that pastoral ecosystems are often non-equilibrial: “strongly controlled by external forces rather than, or in addition to, internal biotic factors” (Ellis and Swift 1988:453). Yet, despite pastoral systems’ sensitivity to external influences, Ellis and Swift observed in the region they studied—Ngisonyoka Turkana in northern Kenya—that “[the] ecosystem and its pastoral inhabitants are relatively stable” (Ellis and Swift 1988:453). Fernandez-Gimenez and Le Febre (2006) described how pastoral institutions—"the formal and informal rules, norms, and repeated patterns of interaction among people that guide individuals’ behaviour with respect to the environment and other people” (Fernandez-Gimenez and Le Febre 2006:342)—support strategies of “flexibility, mobility, diversity, reserves and reciprocity” (Fernandez-Gimenez and Le Febre 2006:342) that enable pastoralists to persist in “patchy and unpredictable low-productivity environments” (Fernandez-Gimenez and Le Febre 2006:341). Burnett (2024a) demonstrated that such pastoral institutions in southeast Amdo, Tibet in western China are interdependent in a highly structured way, and Burnett (in press) modelled the structure of the interrelationships between pastoral institutions there, then used the resulting model to trace historical disturbances’ effects on social-ecological resources—the resources that pastoralists traditionally had managed in response to ecological, social, and sentimental cues.

This paper generalizes Burnett’s methodology of i) identifying social-ecological resources in a pastoral system, ii) identifying the pastoral institutions responsible for maintaining those social-ecological resources, iii) modelling the management of social-ecological resources using Attentive Maintenance Models (AMMs), and iv) embedding those AMMs into a Panarchical Model comprising nested sets of complex adaptive systems (Holling 2001; Gunderson and Holling 2002; Burnett 2024a; Burnett, in press). It then demonstrates that using Panarchical Models and AMMs can help people manage risk by predicting the combined effects of different policies and environmental changes on the resilience, adaptive capacity, and sustainability of a pastoral system.

Methodology for Modelling Pastoral Systems Using Attentive Maintenance Models

The first step in developing AMMs to include in a Panarchical Model of a pastoral system is to identify the system’s social-ecological resources, as follows (Burnett 2024a; Burnett, in press):

1. Record, then translate into a written language, semi-structured interviews with people in their native dialects talking about the natural resources they depend on.
2. With each successive interview, adapt the topics/questions to better align with what past interviewees seemed excited or enthusiastic to talk about, talked about at greater length, or chose to talk about (especially when their responses did not directly answer the questions you had thought you were asking). If there is a strong division of labour in the management of natural resources between the different demographics of people that you interview, then the topics and questions you focus on will need to be fine-tuned independently for each demographic.
3. From the transcripts, compile a list of all the actions that people described having taken alongside whatever particular observations they had made that precipitated those actions. Some examples from southeast Amdo include: “winter → slaughter yaks and sheep for food,” “livestock not happy → move the livestock,” “meet somebody with a good yak → try to exchange livestock for it,” “livestock fare poorly somewhere → avoid that location during that season in the future,” and “feel for your past livestock and have excess butter → offer religious butter lamps” (Burnett, in press).

4. Divide the resulting list into three separate parts, one each for observations related to: physical, physiological, and phenological cycles; social happenings or events; and internal personal sentiments.
5. Identify things, concrete or abstract, that are directly affected by actions taken in all three parts of the list. The things will likely be describable in two parts: i) an ecological resource and ii) what is being managed about that ecological resource (e.g. "livestock" and "herd composition," "livestock herds" and "location," and "dairy products" and "flows of production and distribution"). These things are likely to be critical social-ecological resources within the system that you are studying.

For each social-ecological resource identified, an AMM can then be constructed that describes important ways that pastoralists manage the related ecological resource. An AMM is constructed using the following steps:

1. Subset the list that you compiled of sequences of observations and actions to include only those that directly affect the social-ecological resource for which you are making the current model.
2. Place the three parts of the subsetted list side-by-side: place the sequences associated with ecological observations in the left-hand column, sequences triggered by social events or observations in the middle column, and sequences related to sentiment, accrual, or persistence in the right-hand column.
3. Rephrase each sequence's action component as a decision that affects the available set of a single ecological resource (e.g. livestock in a herd or flock, pastures to move to, or dairy product recipients).
4. Use arrows to represent observations and draw boxes to represent consequent decisions that are made.
5. To simplify the diagram, multiple arrows may be pointed to a single box wherever different observations can lead to the same decision state. The final AMM should resemble Figures 1 and 2.

In Figure 1, observations (arrows) lead to decisions (boxes) about Set A of an ecological resource. Observation-decision sequences in the left column are triggered regularly by ecological observations. Sequences in the middle column are triggered stochastically by social observations. Sequences in the right column are triggered by sentiment. An emergent attribute of Set A becomes a social-ecological resource that adapts based on the interplay of decisions being made at these three different frequencies.

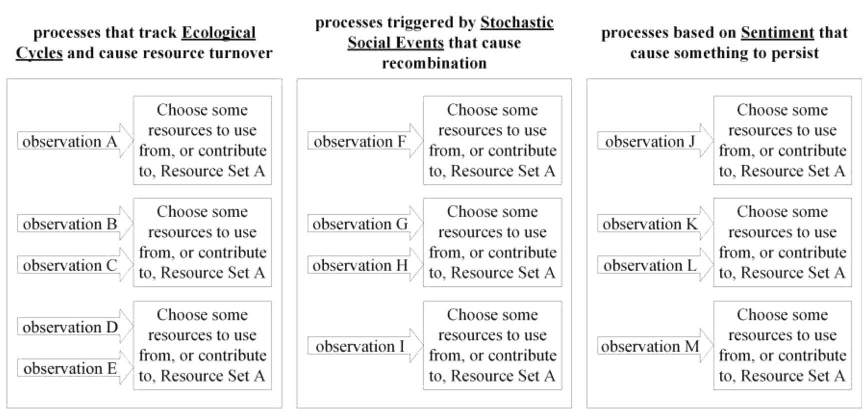

Figure 1: Schema of an Attentive Maintenance Model (Burnett 2024b)

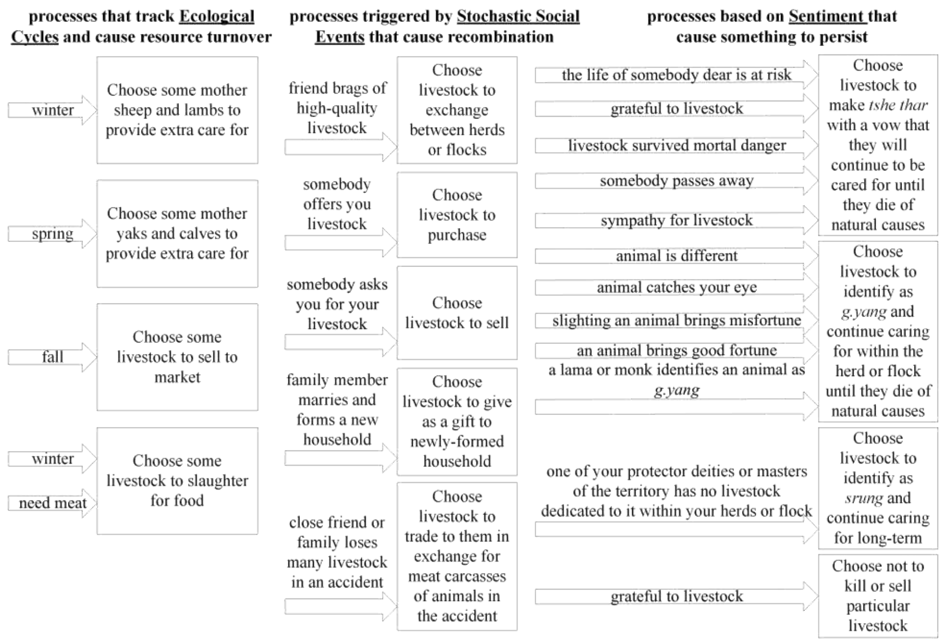
Figure 2: Livestock Herd Composition Attentive Maintenance Model (Burnett 2024b)

Ecological, social, and sentimental observations prompt nomads to make decisions affecting the fates of individual livestock in southeast Amdo. These three different types of observations occur at different frequencies, and they prompt different types of decisions. Collectively, they cause livestock herd compositions to adapt to the ever-changing environment.

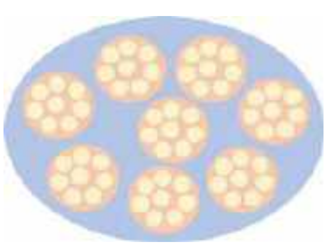


Modelling the Interdependence of Different Social-Ecological Resources in a Pastoral System

Different social-ecological resources in a pastoral system are managed in accordance with different AMMs, but they are also hierarchically interdependent (Burnett 2024a; Burnett, in press; cf. Holling 2001, Gunderson and Holling 2002). For example, in southeast Amdo, each household can manage its own herd's composition, but then to feed that herd the household must begin to move through rangeland. As households meet each other while moving through the common rangeland, they pool their labour to increase dairy production (Burnett, in press). These relationships are hierarchical because many herds must exist before they will develop patterns of sharing forage with one another, and many families must be keeping their herds and tents close to other families before noticeable increases in dairy production and distribution will arise due to shared labour. Each larger social-ecological resource management pattern is therefore sustained by many functionally redundant management patterns of a smaller-scale social-ecological resource: large regional flows of dairy are sustained by many sets of households internally sharing milking labour, and cooperation within each of those sets of households is sustained by the movement patterns of the many households' yak herds (see Figure 3).

The more types of hierarchically interdependent social-ecological resources exist in a pastoral system, the more resilient that pastoral system will be (Burnett 2024a). As different households exchange labour,

Figure 3: Hierarchical Structure of Panarchy (Burnett 2024b)



In Figure 3, using the example of southeast Amdo, each innermost yellow oval represents a herd of yaks maintained by one household, each intermediate orange oval represents the patterned movements of many herds of yaks, and the outermost blue oval represents the production and distribution of dairy products coming from the many sets of many households moving with their herds of yaks. Larger ovals are sustained by many functionally redundant smaller ovals and also provide a network of resource exchange for the smaller ovals that increases their adaptive capacity and resilience to disturbance.

livestock, and knowledge with one another in response to ecological, social, and sentimental cues (respectively), those exchanges enhance their guiding of the adaptation of their social-ecological resources, and they improve the odds that those social-ecological resources can recover from disturbances. Since the management of each different social-ecological resource generates a new social network, hierarchies that have more scales of social-ecological resources provide people with more social networks. The resultant increase in structured connectedness enhances pastoral system resilience (Walker and Salt 2012) by increasing in-network opportunities for people to share labour, livestock, and knowledge with one another. Figure 3 illustrates panarchy's nested hierarchical structure, which underlies the resilience in addition to the sustainability of pastoral systems.

Implications

The role that social-ecological resources play in structuring the social resource networks of pastoral systems has largely been overlooked in scientific literature. Studies of rangeland management and pastoral cultures usually measure ecological resources and social resources separately. Since ecological resources and social resources both fluctuate for pastoral societies, pastoralists create internal resource stability by developing dependable patterns of pastoral institution use that mediate their relationships with society and ecology. In this paper, I have shown how to detect those stabilizing patterns and communicate them using AMMs and a Panarchical Model, as in Figure 4. These models can be used for environmental education, to vet proposed policies, and to plan for climate change. They are useful because they clarify when seemingly irrelevant customs are critical to the resilience and sustainability of a pastoral system in practice and they reveal vulnerable institution types.

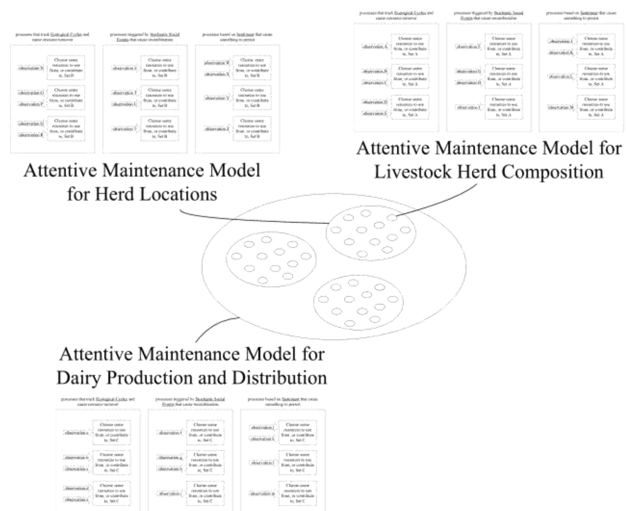


Figure 4: Scales of Panarchy and Attentive Maintenance (Burnett 2024b)

Attentive Maintenance Models can be used to describe the management of social-ecological resources at different scales within a panarchy. The three types of nested social-ecological resources in this sample Panarchical Model are managed in accordance with three respective Attentive Maintenance Models.

Every column in the AMMs of a pastoral panarchy is critical to pastoral resilience. Removing any one of them causes the loss of social networks at that scale and all larger scales of the pastoral panarchy, reducing the resilience of the pastoral system. In southeast Amdo, private leasing of rangelands once used in common now prevents pastoralists from moving their yak herds in response to social, ecological, or sentimental changes, amounting to the removal of three columns of attentive maintenance. Dairy production is no longer sustained by the social-ecological pattern of yak herd movements, which once led households to share milking labour. The larger two scales of social networks and resilience in the pastoral panarchy are thus fading, but assessment with a Panarchical Model reveals both the mechanisms underlying these changes and the potential to reverse them (Burnett, in press). Risk in a pastoral system can be mitigated by the restoration and support of all columns of attentive maintenance; in combination, the columns help a system adapt to its changing context, even when the columns' internal sequences change.

De-risking, inclusion and value enhancement of pastoral economies (drive) project in Kenya

Nenkari, H[1]; Ouma, M[1]; Mbaka, M[2]; Muimi, D[3]

[1] State Department for Livestock Development, Kenya.

[2] Zep-Re - PTA Reinsurance Company

[3]Kenya Development Corporation

Key words: De-risk; Rangelands; Pastoralists; Index-Based Livestock Insurance; Private sector.

Abstract

DRIVE is a regional financial intervention project being implemented in four Horn of Africa (HoA) countries as part of building resilience to climatic shocks, facilitating trade and supporting livestock value chains within the rangelands. The project objective is to protect pastoral economies against drought risk, increase financial inclusion of pastoralists and better connect them to markets and to facilitate livestock trade and upgrade livestock value chains by mobilizing private investments. The project has two components: one is to support the provision of an integrated package of financial services to build climate resilience including drought index insurance, savings incentives and manage digital payment, and the other is to better include pastoralists in the livestock value chains and facilitate trade and de-risk private investments in the livestock value chains. The project supports four priority areas including: pasture production and conservation, livestock breeding of cattle, sheep and goats, livestock finishing and value addition. To ensure sustainability, the project is private sector led, with regional implementation via local private sector players and international reinsurers, that are constituting pastoralist groups around economic activities to have access to products and services for ownership and alignment to the project objectives. Extensive lessons were learnt from current and previous drought schemes. So far, 186,903 small scale pastoralists have bought USD 4.08 million worth of insurance premiums covering 673,986 Tropical Livestock Units (TLUs), and fourteen private sector investments worth USD 8.9 million have been approved for financing. The project has made livestock insurance payouts of USD 4.94 million to the pastoralists via mobile money transfers.

Introduction

The Horn of Africa (HoA) includes the eight countries that are members of the Intergovernmental Authority on Development (IGAD) namely Djibouti, Eritrea, Ethiopia, Kenya, Somalia, South Sudan, Sudan and Uganda. Most of these countries are amongst the poorest and most fragile regions in the world, where one third of the population lives below 1.9 dollar a day (HOA REM, 2021). In the eight HoA countries, one fifth of the total population is made up of pastoralists or agro-pastoralists, i.e., around 50 million people. Their main source of livelihood is the rearing of livestock, mostly in open grazing rangelands in the semi-arid areas. Several countries have come together to strengthen regional cooperation and address global challenges within the "Horn of Africa Initiative". The region is exposed to disasters, amplified by climate change, and recurrent severe droughts are a key factor for poverty and conflicts in pastoral economies. Droughts degrade rangelands, deplete livestock, and lead to underinvestment. Underinvestment lowers pastoral productivity and holds pastoralists in a poverty trap. Pastoralists move across national and clan borders in search of greener pastures and the pressure on scarce resources exacerbates conflicts. About 29 percent of the total land area in Ethiopia and 40 percent in Kenya is classified as degraded. However, such degradation is caused by growing population numbers, land use for economic development, and climatic impacts.

The economies of countries in the HoA are highly dependent on pastoralism and livestock production as a source of livelihoods, income, and contribution to GDP. The impacts of the COVID-19 pandemic have been severe and compounded by other shocks. The regional livestock trade is significant but mainly unrecorded and focused on live animals. Livestock trade represents one of the few economic success stories in the Horn of Africa (Little, 2020).

The livestock value chains are dominated by traders, with limited benefits going to the pastoral producers. Livestock sales are often influenced by ethnic and family ties, due to the uncertain business environment, the absence of formal systems of credit enforcement, weak infrastructure, limited market support services and prevalent insecurity in pastoral areas (HoA REM, 2021). Women are highly engaged in the pastoral economy, as labourers, consumers, and producers, both for markets and their households. Access to formal financial services and credit for pastoral producers is limited

The project development objectives are to enhance pastoralists' access to financial services for drought risk mitigation, include them in the value chains, and facilitate the livestock trade in the Horn of Africa. Compagnie De Réassurance De La Zone Préférentielle (ZEP-RE), PTA Reinsurance Company and Kenya Development Corporation (KDC) are the project Implementing Partners for component 1 of De-risking pastoral production through a package of financial services and component 2 Part 1 of Promoting livestock value chains through trade facilitation and private sector support respectively while the State Department for Livestock Development is the Implementer of component 2 Part 2 which involves supporting management of the project and guiding day-to-day operations of DRIVE project. The project period is October 2022 to September 2027

Methods

In Kenya, the project targets 21 ASAL counties of Turkana, Marsabit, Isiolo, Laikipia Mandera, Wajir, Garissa, Tana River, Taita Taveta, Kilifi, Kwale, Lamu, Meru (Meru North sub county), Tharaka Nithi, Samburu, Baringo, West Pokot, Narok, Kajiado, Makueni and Kitui where pastoralism type of farming is done and drought Index based Livestock Insurance (IBLI) products are viable.

Training on the IBLI product has been conducted each season, equipping these stakeholders with essential knowledge on index-based insurance principles, premium structures, payout mechanisms. Specifically, promotional campaigns and outreach efforts are used to educate pastoralists how insurance could help them cope with drought by helping them purchase fodder, feed supplements, water, and vaccines during drought thus potentially keeping more animals alive and maintaining their livelihoods and leveraged community meetings, radio broadcasts, digital platforms, and printed materials to ensure that even

About 240,000 pastoralists from 21 project counties have been sensitised and registered in project financial digital inclusivity platform. Insurance companies assess livestock insurance payouts using Index-Based Livestock Insurance (IBLI) product that has been designed to protect against prolonged forage (pasture) scarcity. This index is typically derived from satellite data monitoring vegetation, and the pay-out is triggered when the index falls below 25th percentile of historical data indicating a potential livestock mortality risk due to drought.
