Trade facilitation and private sector support is done competitively by KDC and awarded to successful implementers after thorough assessment of their business plans

Results
The project has conducted livestock insurance sales to pastoral beneficiaries in the 21 project counties and cumulatively under Component 1 on pastoralist access to financial package for drought resilience the following milestones have been achieved in the 21 counties where livestock insurance has been implemented in the four livestock insurance sales seasons:

Out of the 240,000 pastoralists registered, 186,903 agreed to buy livestock insurance which is a good response. For sustainability, the subsidy reduces annually so that by the end of the project the pastoralists can buy the insurance on their own
Since the project's inception, the financial package under Component 1 has been successfully delivered to pastoralist communities in the 21 counties for five consecutive seasons of OND 2022, MAM 2023, OND 2023, MAM 2024 and OND 2024. This initiative has played a crucial role in enhancing the financial resilience of pastoralists by providing them with essential support mechanisms such as insurance, savings, and market access. Over this period, the project has sold 186,903 policies with 673,986 Tropical Livestock Unit (TLU) Insured (TLU= Cow equivalent) insured in the process which have positively impacted approximately one million pastoralists and their families, improving their ability to manage financial risks, sustain their livelihoods, and adapt to climate-related challenges. The project has subsidized livestock insurance premium at a rate of 70% - 80% where pastoralist have benefited from a total subsidy of USD 13.9 million and to this end the pastoralist have paid their 20%-30% of the livestock insurance premium totalling USD 4.08 million. The pastoralists who have procured livestock insurance for 3 TLUs and above have benefited from a one-off enrolment saving bonus (USD 50 per beneficiary) totalling to USD 7.3 million and the project has made livestock insurance pay-outs of USD 4.94 million to the pastoralist. The total benefits in terms of livestock insurance premium subsidy, enrolment saving bonus and livestock insurance pay-outs pastoralist in the 21 counties added up to USD 26.2 million

As at 31st January 2025, KDC had already disbursed loans worth USD 2,558,057 to successful investors, while 62 projects are pipeline Investment projects totals to USD 51,614,137

The Project Implementation Unit (PIU) carried out its coordination role as well as capacity building in collaboration with counties and relevant stakeholders. The project will subsidize insurance premiums up to the end of the project in the year 2027. The provision of index drought insurance products is been done commercially by roping in private sector insurance providers who will be able to cover their cost of operations and run profitable business. The project supports the creation of necessary awareness on insurance and the number of pastoralists buying livestock insurance and thus the using of other financial services like savings and credit is expected to increase. A strategy has been put in place where supported pastoral households under livestock insurance are linked to better livestock markets which will provide them with an opportunity to sale their livestock for better prices, thus increasing their income. As household income increases, they can contribute more for insurance premium payment reducing the fiscal burden from the government. The demand for formal financial services among the pastoralist is expected to go up with increased awareness on the DRIVE project interventions.

Key words: climate risk; last mile delivery; climate services; resilience, decision support.

Abstract

In the drylands of Africa, low and variable rainfall and the increasing incidence of extreme weather events, leave poor communities, dependent on pastoral and agropastoral livelihood systems, highly vulnerable. Building resilience must consider the immediate 'tactical' approaches for managing climate risk (e.g. de-risking measures such as the index-based livestock insurance (IBLI) bundled with credit, inputs, climate information services) and 'strategic' approaches, where communities work together to reimagine sustainable land-use and resilient livelihoods (e.g. participatory rangeland management (PRM) supported through bylaws). Enhanced mobile network penetration also offers unprecedented opportunities for the dissemination of information to pastoralists and farmers through digital channels. Further, digital technologies enable new methods of acquiring and sharing data, ground truthing, and obtaining user feedback especially in data sparse environments (e.g. KAZNET, a citizen science innovation that crowdsources information on rangelands animals, markets, food security, conflict). Data collected through such innovations can contribute to the monitoring of shocks, improving product design, informing policies and institutional decision making. This paper gives examples of several tactical and strategic approaches to building resilience in pastoral and crop-livestock systems in Africa.

Introduction

Climate variability is a major source of risk in livelihood systems of the drylands, that are home to almost 3 billion people and cover some 46% of the globe's land area (IPCC 2022). In the drylands, pastoral livelihoods take place on the rangeland areas (some 25% of the total land area), and in crop-based farming systems (some 12% of the total land area) (FAO 2019). Increasingly, these livestock-based livelihood systems are in flux and are threatened. Along with other biophysical, socio-economic and political factors, climate risk contributes enormously to food insecurity, economic losses, and multi-dimensional poverty (Shiferaw et al. 2014). Research has also identified potential options that can contribute to improved management of agricultural systems under variable climatic conditions, and the perceptions and coping strategies being adopted by farmers. Resilience, agricultural productivity and profitability under these high climate risk environments are therefore dependent on: (i) the inherent resilience of the livestock and farming enterprises which is a function of landscape and farm design within the context of the agricultural innovation system (strategic); and (ii) how well the livestock and farm management are planned and executed in the context of the risk (tactical). How this applies to agropastoral and pastoral systems in Africa is presented in a series of examples of on-going work that ILRI and its partners are undertaking in West, East and Southern Africa.

Tools and methodologies

Examples of strategic approaches to build agricultural system resilience include:

- Working with communities and government to co-design more sustainable land-use, for example the joint village level land use planning coupled with PRM and supported with bylaws (ICPALD 2024).
- Co-design climate information services with community of practice (CoP) for livestock farmers with digital technologies (mobile phones and radio program dissemination) (Houessionon et al. 2023, Diallo et al.2024).
- Influencing the decisions of pastoralists regarding routes and movements of livestock to access fodder and water (IGAD 2024).
- The use of model-based approaches to underpin the farm/landscape co-design process or to influence policymakers and development practitioners understand the farming systems' sensitivities and the potential benefits of climate change adaptation to current and future climate scenarios (AGMIP 2024; Whitbread et al. 2021)

Examples of tactical management of climate risk include:

- Innovative insurance schemes for livestock producers (i.e. IBLI) (Banerjee et al. 2019).
- The intelligent Systems Advisory Tool (iSAT) (Ramaraj et al. 2023)
- KAZNET as a data collection and dissemination approach based on citizen science principles to crowdsource data on rangeland condition, animal numbers, markets, conflict, household food security etc (Chalenga et al. 2022; Alulu et al. 2024).
- Web-based platforms like (WENDOU 2024) in Ferlo, Senegal for assessing water availability in ponds, thus facilitating stock drinking water management in arid areas.

Discussion

Strategic approaches for building resilient livelihood systems

The longer-term perspective, where an agricultural system is redesigned to be more resilient to the current and future climate patterns, can be termed 'strategic' planning. The design of the agricultural systems should consider what mix of management, enterprises and farming systems are most resilient to current and future climate also considering market and cultural factors. This requires analytics to understand the historical and projected climate scenarios, model-based scenario analysis, and co-design of farming systems that are more resilient to extreme events and reduce the damage of such events on the natural resource base. In some landscapes and environments, transformational changes in landscape design might be urgently needed (Whitbread et al. 2021).

In agropastoral systems, climate induced risk associated with season-to-season variability of rainfall is one of the major challenges to achieving food security across large parts of semi-arid Africa. Since season outcomes are uncertain, even with the best climate information, farmers have limited flexibility in applying management with confidence. In fact, in risky environments, farmers most often respond by adapting a risk averse strategy and are reluctant to invest in even risk reducing measures (Leathers and Quiggin 1991). In most agropastoral systems, there are a limited range of enterprise or crop options to consider. The options may be further restricted by cultural traditions, food preferences, market opportunities or simply a lack of access to inputs such as seed and fertiliser or knowledge. New thinking on crop-livestock integration is needed to bring the climate risk lens to the design and management of such systems. Examples include: Using diversification such as multi-species crop-tree-livestock (forage) farm systems (e.g. for the West African Sahel, millet-cowpea-ziziphus agroforestry-based systems show great promise according to Bado et al. (2021)); building soil fertility management and restoring soils to overcome nutrient limitations and avoid water stress (Bado et al. 2022); more broadly using crop breeding programs to enhance the use of multi-purpose traits in cereal germplasm (e.g. Blummel et al. 2020).

In pastoral systems, mobility has been the core adaptation mechanism in pastoral systems for generations. Restrictions on the mobility of pastoral communities and their livestock, conflicts and stricter cross-border control and defective tenure policies pose threats to the sustainability of pastoral livelihoods (IGAD 2024). While well managed rangelands may store carbon in soils and vegetation, and provide a range of ecosystem services, the management of rangeland systems in Africa are increasingly contested as populations grow, government policies tend to aim at settling pastoral populations, and the resource base becomes degraded (Nori and Scoones 2024). Recognizing that pastoral communities remain central to finding solutions, empowering communities to design and manage landscapes with good governance, resolving and preventing conflicts between land users, employing early warning systems (i.e. drought, extreme events) and other methods to manage livestock and rangeland resources are key. Methods such as participatory land use planning or participatory rangeland management (PRM) have been successfully piloted across several East African countries (Waweru et al. 2021). In West, Central and East Africa where transhumance is common, seasonal variations drive transhumant migrations over vast distances between wet and dry zones, providing pastoralists with access to stock feed, and farmers with improved soil fertility via manure, leading to co-benefits and efficient land use. According to Wane et al. (2023) climate change has become a direct and aggravating factor of other shocks (i.e. animal health, markets, conflicts) that result in considerable quantitative, qualitative and economic losses. Development bodies such as IGAD play a key role in building an understanding of the role of pastoralism in managing landscapes and livelihoods and engaging communities and government to agree on movement between countries, on cross border animal health, mapping of transhumance routes, and early warning systems for drought and extreme weather events. Additionally, linking the design, management and restoration of rangelands to the issues of climate risk management, mitigation and carbon sequestration, may be a way to drive much needed innovation in these long-neglected systems.

Tactical approaches for building resilient livelihood systems

Adopting a flexible risk management strategy informed by multiple information sources to make decisions allows a pastoralist, livestock keeper or farmer to develop tactical management approaches. Such strategies may include pre-season planning guided by seasonal climate forecasts, a set of criteria or 'triggers' for sowing, variety selection, livestock life cycle planning, and a range of in-season responses to the prevailing weather, market signals or other factors. Recent advances in climate science have led to significant improvements in the predictability of climate and weather at scales that are useful in planning and managing agricultural systems. These predictions, when linked to systems information and scenario analyses through simulation models, provide an opportunity to critically evaluate and identify alternative soil, crop and management options that minimize risk and improve productivity and profitability. While pilot studies have established the usefulness of climate information for decision-making, operational delivery 'at scale' of actionable information products requires context-specific granularity, timeliness, formatting and feedback loops for continuous learning (Ramaraj et al. 2023).

While agropastoral systems remain important in the developing world and potentially support more equitable, resilient, and sustainable agriculture than other food systems, climate risk has remained a major disincentive to sustainable intensification. Exacerbating the challenge has been the expansion of cereal farming, especially maize, into the semi-arid regions, leading to a risky food security situation (Tesfaye et al. 2015). Further, the role and potential productive capacity of livestock in agropastoral systems are generally undervalued compared with the farmers' desire for the grain staples. At the farm level, area planned deployment of annual crops (cereals and legumes) within rotations and planning arrangements (e.g. intercropping) must consider temporal (historical and forecasted climate) and spatial (soil fertility, soil moisture conditions) to allow more optimal land use considering risk. The role of dual-purpose germplasm can be made more central for its provision of multiple products options and the end-use decisions that can be made tactically within the season. In crop-based systems, a decision support tool called 'iSAT', which built on earlier work in commercial cropping systems in Australia (see Hochman et al. 2009), defines a process to create context specific climate informed agro-advisories for use in tactical agronomic decisions making at the farm level. In these examples, models have been used in a participatory mode to develop scenarios that farmers face in their day-to-day management and are linked to ICT methods of deployment through a range of public and private dissemination efforts.

For livestock keepers in pastoral or mixed crop-livestock systems, advisory services are much less developed than those developed for agronomic decision making and rarely linked to climate drivers. This represents a significant area for research, by considering the life cycle of fodder or animal components linked to climate information to develop actionable management strategies similar to the agronomic examples of iSAT. For example, the timing of reproduction, management of the herd, timing of marketing or stock movements, prediction of rangeland feed resources could all be linked to climate information. In transhumance systems, Wane et al. (2020) show that the probability of transhumance increases under rainfall delay, drought or with changes in cattle prices. In such systems, livestock itineraries involve detailed planning, adjusting for water conditions and fodder constraints and may be influenced by information coming from a range of sources, for example a multi-stakeholder platform or community of practice (COP). Houessionon et al. (2023) documented a COP in Senegal that made use of decision support tools, market price forecast tools, indigenous and expert knowledge of its members to reach >78,000 herders using various communication channels (e.g. interactive voice response IVR, rural radio). The need for bundled socio-technical innovation bundles comprising of risk financing mechanisms and other services (e.g. inputs, climate information services) is increasingly important for building resilience in the pastoral areas. Research is needed to understand the socially differentiated preferences of pastoralists for such bundled innovations and evaluate their effectiveness ex-ante and ex-post.

Conclusions

The pastoral and agropastoral systems in Africa remain central to the livelihoods and farming systems of millions, but are often highly vulnerable to extreme weather events and affected by land degradation, contested government policies and conflicts. Developing solutions must be considered through a climate lens, with farming system or landscape design co-developed considering future climates. Participatory processes embedded in community dialogue and consultation ultimately supported by government policy, bylaws or customary processes, have been shown to be scalable and sustainable. To maintain livelihoods and food security, farmers and livestock keepers must consider climate risk in their management decisions, especially through the use of advisory and extension information that are linked to climate and indigenous knowledge. Enhanced co-operation of the national agriculture research and extension services, the national meteorological agencies, farmer facing organisations and private sector players (e.g. agri-tech), are needed to develop the digital public infrastructure that support the creation and dissemination of innovations.

Key words: *Mucuna pruriens*, drought, supplementary feed, home-mixed rations.

Abstract

The International Livestock Research Institute is promoting cultivation and processing of *Mucuna pruriens* as a climate-smart fodder which can produce cost-effective feed supplements for livestock on communal rangelands in semi-arid Zimbabwe, to de-risk and improve sustainability of livestock production during droughts. Commercial supplements are generally expensive and not readily accessible to agro-pastoralists. Home-mixed Mucuna-based supplements can be nutrient-dense and effective. In a seven-week on-farm trial, Mucuna hay (MH) reduced weight loss in mature Matebele goats, though its effectiveness was inferior to Bambara nut hay and dried groundnut haulms ($P<0.05$). Goats averaging 28.2kg body weight (BW) and grazing solely on rangeland lost -66g head^{-1} day^{-1}, while those fed 1:2 MH: maize stover (MS), 1:2 Bambara nut hay: MS and 1:2 groundnut haulm: MS at 1% body weight during evenings only achieved -5g, 54g and 63g head^{-1} day^{-1} average daily weight gain (ADWG), respectively at the peak of 2022 dry season. This showed that farmers can maintain goats on MH. East Africa-type does (±25kg BW) supplemented with 45g head^{-1} day^{-1} of coarsely ground Mucuna pods (shell + kennel) at night-time during the 2021 dry season gained even more (150-270g head^{-1} day^{-1}), proving that pods are a richer supplement. Efforts were made to combine Mucuna with other local nutrient-dense feeds and forages to diversify the range of supplementary feeds and so improve accessibility. On-farm demonstrations conducted over a six-week period in 2022 showed that home-mixed rations (21.9 and 21.4% CP) of (i) *Mucuna* grain (MG) + *Lablab purpureus* hay (LpH) and (ii) MG + LpH + *Sorghum vulgare* grain fed to Matebele goats at 1% of body weight increased ADWG to 50g and 70g head^{-1} day^{-1}, respectively. These results led ILRI and national partners to officially register three marketable supplements for goats and sheep in April 2024.

Introduction

Maize-mixed farming occupies 32 million hectares (or 19%) of the total cultivated land in East and Southern Africa (ESA) region (Garrity et al. 2012). Maize is a staple crop in ESA and an important source of livelihood. Farmers usually add diversity to maize through cultivation of grain legumes to reduce the risk of total agricultural failure in the event of droughts and other calamities (Sumberg 1998). Legumes normally sown in rotation or through intercropping with maize were listed by Garrity et al. (2012). Grain and residues from these legumes and from tropical forage legumes can be incorporated in supplementary diets of large and small ruminants. Home-mixed supplements containing non-conventional legumes are cost-effective compared to commercial supplements which are formulated using oil-seed cake (Chakoma *et al*. 2016). Feeding non-conventional supplements to livestock grazing communal rangelands can increase productivity and farmers income.

The International Livestock Research Institute (ILRI) is conducting various studies to mitigate drought and de-risk maize-mixed farming systems in ESA. Several on-farm experiments conducted in Zimbabwe during the past two decades demonstrated that it is possible to sustainably integrate livestock production with maize-groundnut and other maize-legume rotations (Chakoma et al. 2016; Gwiriri et al. 2016). In the Ukama Ustawi (U2) and the EU-Funded LIPS-Zim Projects ILRI is promoting ley farming using two climate-smart forage legumes (*Mucuna pruriens* and *Lablab purpureus*) to diversify and sustainably intensify traditional cropping patterns towards livestock production (Matebesi 2024; Siyamachira 2022). As ESA is predicted to be a climate hotspot (Lugoi *et al*. 2023) there is need to promote resilient climate-smart farming practices, which include goat rearing.

The objective of this paper is to show how farmers practising integrated crop-livestock farming can formulate home-mixed feeds to de-risk and sustainably improve goat production on Savanah rangelands.

2. Materials and Methods

2.1 Study sites

Three participatory on-farm experiments were conducted in villages of Buhera (Ward 15) and Beitbridge (Ward 11) districts during the 2021 dry season and Gwanda district (Ward 24), during the 2022 dry season. All districts are in the semi-arid regions (agro-ecological IV and V) where the dry season normally extends from May-November. At all sites host farmer selection was based on (1) willingness (2) availability of goats for the experiments and (3) availability of planted fodders.

2.2 Dietary treatments

In *Experiment 1 (Beitbridge, Fula ward)* 20 Matebele goats at one homestead were randomly assigned to four treatments diets namely, (T_1) rangeland grazing only (i.e. farmer practice); T_2 comprised of velvet bean hay and maize stover (1:2 ratio); T_3 groundnut haulms and maize stover (1:2 ratio); T_4 Bambaranut (Vigna subterranea (L.) Verdc) haulms and maize stover (1:2 ratio). Five goats were assigned to each treatment. All goats grazed Acacia thornveld during daytime. During the evening, those on supplementary feeding were separated, individually penned and fed different supplementary feeds at the rate of 1% body weight. Water was provided *ad-libitum*. The experiment ran for 49 days from October to November 2021.

In *Experiment 2 (Buhera - Mutunha Vidco)* 30 East Africa-type goats from two villages (15 from each village) were assigned to three supplementary diets namely, (Ti) rangeland grazing only, (T_2) 75 grams of crushed velvet pods (unshelled); (T_3) 280g of a velvet bean-based ration. Five goats from each village were assigned to each treatment. Feeding management was the same as in *Experiment 1*. The experiment ran for 42 days from September to October 2021.

In *Experiment 3 (Gwanda, Ward 24*) 15 Matebele goats were used in the trial. Five goats were allocated to each treatment. Goats across all treatments grazed Acacia thornveld during daytime. Supplementary feed was only provided to goats in Treatment 2 and 3 at the rate of 1% of BW, during the evening. Composition of feed supplements for Treatments 2 and 3 is shown in Table 1.

Table 1: Composition of treatment diets for the goat feeding experiment conducted in Gwanda during the 2022 dry season.

Diet ingredient	Proportion (%) in diet on DM basis	
	Diet 2	Diet 3
Lablab purpureus hay	25.80	25.80
Mucunapruriens grain	58.70	48.30
Molasses	12.10	12.10
Sorghum grain (crushed)	0	10.30
Monocalcium phosphate	0.61	0.65
Limestone flour	1.31	1.36
Coarse salt	1.08	1.05
Ammonium Chloride	0.22	0.22
Vitamin-Mineral Premix	0.21	0.21

Feeding management was the same as in *Experiment 1*. The experiment ran for 41 days from October to November 2022.

2.3 Preparation of experimental animals

All experiments were set out to determine voluntary feed intake (VFI) and live weight changes of goats fed different diets. Goats with average live weights of 26 kg - 32 kg were used in *Experiment 1 and 3* and average ± 25 kg in *Experiment 2*. Experimental animals were vaccinated for Pulpy Kidney (PK), dipped and dewormed (i.e for ecto and endo parasites) prior to trials. Goats were ear-tagged for identification and initial weights were recorded. Fourteen days were permitted for feed induction in all experiments. Animals were weighed once a week. The amount of feed supplied to the goats was adjusted weekly on the basis of their body weight changes. Animal husbandry practices were similar across all treatment groups.

2.5. Laboratory analyses.

Samples of all supplementary feeds were ground through a 1mm screen and dry matter (DM) was determined by oven drying at 70^0C for 48 hrs. Crude protein was determined following the standard Kjeldhal method (AOAC, 1991), ether extract was determined using the Soxhlet apparatus while neutral detergent fibre (NDF) and acid detergent fibre (ADF) were assessed using the methods proposed by Van Soest et al. (1991).

2.6. Statistical design and analysis

In Experiment 1 and 3 dietary treatments were tested using a randomized complete block design (RCBD) with initial weights and sex used as blocking factors. Statistical analyses were conducted using the General Statistical Package software (Genstat 14th Edition, 2017). Data were tested for normality using the Shapiro-Wilk. Daily weight gain and VFI were analysed following a General linear model procedure (GLM). Data were fitted to test the effect of feeding regimes on daily weight gain and feed intake. Differences of means were tested using Least Significant Difference (LSD) *post hoc* test at 5 % level of significance.

In Experiment 2 a RCBD was used to test three dietary treatments with age and breed as blocking factors. Collected data was tested for normality using the Kolmogorov-Smirnov test in SPSS software. PROC GLM procedure of SAS was used to analyse treatments effects on dependent variables.

3. Results

3.1 Experiment 1

Daily liveweight gains were significantly ($P<0.05$) higher in goats fed supplements containing Bambara nut haulms (BNH) and groundnut haulms (GNH) compared to Mucuna hay (MH), even though MH had relatively higher crude protein (CP) content (Table 2). There were no significant differences on NDF content. Heaviest losses (-66g head^{-1} day^{-1}) were observed in unsupplemented goats while MH caused lower weight losses (-5g head^{-1} day^{-1}).

3.2 Experiment 2

There were no significant differences ($P<0.05$) between does on supplements derived from unshelled Mucuna pods (UMP) and the Mucuna-based supplement (MBS). These East Africa-type does gained live weight at 42.9 and 28.6 g $^{-1}$ day^{-1}, respectively during the dry season, whereas those on rangeland grazing only lost weight at -95.2 g $^{-1}$ day^{-1} ($P<0.05$).

3.3 Experiment 3

Efforts were made to incorporate local nutrient-dense feeds and forages to diversify the range ingredients and so improve accessibility (Table 1). Results showed that home-mixed rations (21.9 and 21.4% CP) of (i) *Mucuna* grain (MG) + *Lablab purpureus* hay (LpH) and (ii) MG + LpH + *Sorghum vulgare* increased ADWG to 50g and 70g head^{-1} day^{-1}, respectively in Matebele goats (Fig. 1).

4 Discussion

Traditional dry season goat management practices in Buhera, Beitbridge and Gwanda consist largely of semi-extensive rangeland grazing during the day and overnight penning with limited supplementation. Results from all experiments show that rangeland grazing alone is not sufficient to meet nutritional needs of all classes of goats and may culminate in poverty deaths. This resonates with Charambira *et al*. (2021) who indicated that smallholder farmers ought to adopt practices such as forage conservation, utilization of crop residue and use of cultivated fodder crops.

Supplementary feeds based on MG and GNH or BNH could be a powerful alternative to conventional feeds, judging from the higher levels of live weight gains (54.5 – 71g^{-1} day^{-1}) recorded in Experiments 1 and 3. This collaborates findings by Chakoma *et al*. (2016) and Gwiriri *et al*. (2016) who recommended the same for beef and dairy cattle, respectively. These results led ILRI and national partners to officially register three marketable supplements for goats and sheep in April 2024 under the Ukama Ustawi Project.

Experiment 3 findings suggest that increasing energy to legume-only supplements improves gut fermentation, evidenced by an increase in liveweight gains from 40 g^{-1}day^{-1} on T_2 to 69 g^{-1}day^{-1} on T_3, turning them into effective supplements for maintenance or grower rations. Farmers could feed up to 1.5% of body weight before goats start suffering from antinutritional or depressants factors.

Performance variations in Experiments 1 and 3 are attributable to breed factor (Matebele vs East Africa type) and nature of biomes. Rate of weight loss in unsupplemented goats from Buhera seemed to be higher (-95.2 $g^{-1}day^{-1}$) compared to Gwanda (66.4 $g^{-1}day^{-1}$), during October and November. The nutritive quality of rangelands deteriorates more in sour veld of Buhera compared to the sweet veld of Beitbridge. Therefore, it is more imperative for Buhera farmers to provide supplementary feeding to goats. It would also be even more beneficial is the feeding starts in July or August, especially for young goats.

Fig 1: Average daily weight gain Gwanda district

5 Conclusion

It is not sufficient for ESA farmers to rely on communal rangeland grazing only for subsistence or commercial goat production. These farmers can improve their livelihoods and incomes through goat farming by diversifying and de-risking maize-mixed farming systems through incorporation of *M. pruriens* and *L. purpureus* leys to supply grain and hay, respectively which will be mixed with residues of common grain legumes to improve quality and cost-effectiveness of dry season feeds. Adoption of this technology will be easier when farmers can access appropriate machinery to process the ingredients.

Table 2: Performance of goats fed different types of forage-based supplements and nutritional composition of the formulated supplements.

Climate-smart legume-grass system can reduce greenhouse gas emissions and net SOC

Arshad, A[1]; Hou, F[2]

[1,2] State-Key Laboratory Herbage Improvement and Grassland Agroecosystem, Key Laboratory of Grassland Livestock Industry Innovation, Ministry of Agriculture and Rural Affairs, Engineering Research Center of Grassland Industry, Ministry of Education, College of Pastoral Agriculture Science and Technology, Lanzhou University, Lanzhou 730020, China.

Keywords: Soil organic carbon; legume-native grasses; global warming; soil restoration; climate adaptation

Abstract: Improving forage productivity with lower greenhouse gas (GHG) emissions from limited grassland has been a hotspot of interest in global agricultural production. In this study, we analysed the effects of native grass species (*Artemisia capillaris* L.; *Lespedeza daurica* L. & *Stipa bungeana* L.), with legumes (alfalfa; M-vetch & Pea-shrub), and native grasses+legumes mistures (*artemisia capillaris* + alfalfa; *Lespedeza daurica* + pea shrub; and M-vetch + *Stipa bungeana*) overseeded mixtures were tested to quantify on GHG emissions, net soil organic carbon potential (Net SOC). Fodder forage yield-based greenhouse gas intensity (GHGI), soil chemical properties and forage quality and productivity in Typical Steppe grassland in Gansu province of China during the cropping season on 2023 and 2024. The research results demonstrated that high seeded intensity alfalfa + native grass significantly improved forage production. The maximum total dry matter yield (DMY) during 2023 and 2024 was attained from legumes+native grass at optimum seeding (9,317 and 10,461 kg ha^{-1}), and legumes mixtures vs native grass mixtures (8,513 and 9,892 kg ha^{-1}) at higher seeding rates. The yearly collective GHG emissions from legume + native grass mixtures were lower than alfalfa sole-culture. Alfalfa with native grass mixtures significantly reduced greenhouse gas intensity (GHGI) compared with the native grasses and sole alfalfa planting system. Moreover, experiment outcomes showed that native grass, alfalfa and alfalfa- native grass mixtures differentially affected on chemical properties of soil. Lower soil pH and C/N ratio were documented in higher planting density of alfalfa when grown under sole system, whereas legumes and native grasses mixtures significantly (17%) increased soil organic carbon (SOC) and soil total nitrogen (STN) contents up to 11.2% respectively. Notably, alfalfa maximum planting density with native grasses combinations are essential for improving fodder/forage quality, productivity by mitigating the GHG emissions from the highly-productive agroecosystems. In conclusion, the Legumes+Native grass mixture enhanced Net-SOC and GHGI in Typical Steppe grassland systems, whereas restoring soil nitrogen and ecosystem functioning with high quality forage yield. These climate-smart agricultural practices could contribute to the development of sustainable grassland production in China under extreme weather conditions by investing minimum input resources.

1. Introduction: The Chinese grasslands ecosystem is greatly affected by climate change and human activity via land use and cover change, direct grazing, mowing, infrastructure and recent development. Grasslands of China are vast (approximately 400 Mha), and some 90% are overgrazed and considered degraded, although only 10%

have become so badly degraded and decertified (Kemp, 2019). One of the key challenges is degradation of grasslands in China as about 40% of all agricultural and natural land is occupied by rangelands (Ge et al., 2022; Chang et al., 2024). These grasslands have gone through severe degradation over time under extensive anthropological disturbance and drastic climate change (Arshad et al., 2020; Zhang et al., 2022). Among the complex causes of grassland degradation, overgrazing is considered a major driver (Maestre et al., 2022) leads to poor soil fertility. The growing demand on ruminant-sourced food gives pressure on the natural ecosystems, including the Typical Steppe agroecosystem in Gansu province. Moreover, degradation of rangelands proceeds at a rate of 2 Mha yr^{-1} which is equivalent to an annual loss of 1.5% of the grassland biome area in China. In China, nearly 61% of grasslands suffer from degradation due to intensive grazing (Hou et al., 2021). Degraded grasslands not only fail to provide subsistence for the local people (Zhao et al., 2017; Bardgett et al., 2021), but also fail to mitigate climate change, negative impact on greenhouse gas emissions (GHG) and C-stocks (Wang et al., 2016; Deng and Shangguan, 2021).

Grasslands are among the most important terrestrial carbon pools in China, storing approximately 3.06 Pg of vegetation carbon and 41.03 Pg of soil carbon (Ni 2002). Degradation intensity significantly affects below-ground C and N cycling in grasslands system. Heavy grazing decreases soil C and N pool sizes which critically important ecological and economic values while from various degrees of biodiversity degradation in China (Hou et al., 2021), and left with zero seed bank and facing feed shortage, soil erosion in coming future. Previous studies indicate that pre-season climatic elements such as temperature, precipitation, sunshine and thermal conditions play a dominant role in influencing the phenological period (Gastaldi et al., 2020). For example, increasing precipitation can extend the growing season in Canadian and Ethiopian grasslands, and precipitation in the previous autumn and winter have led to an earlier vegetation SOC in the Tibetan Plateau (Workie and Debella, 2018). Grasslands are sensitive to climate change, and the carbon sequestration ability is closely related to water availability. Increasing temperature followed by prolong-droughts is impacting on different growth stages, thereby reducing the fertility input from grasses to soil (Derner et al. 2006; Zuo et al. 2018). Multiple studies worldwide reported the optimization of seeding rates with changing environmental condition is essential (Li-li et al. 2019; Workie and Debella, 2018) to recover the grasslands productivity, nutritional values of herbage in parallel richness of soil fertility. There is dire need to test combination climate-smart grassland management practices such as high planting density of perennial native grasslands and multiple legumes species. Introduction to conservative agroecosystem including year-around soil mulching followed by no-tillage to reduced emission. Our research aims those changes in land-use management might positively impact on yield and agroecosystem. The key scientific problems to be solved under long-term field experiment: a) How does the area-specific planting density of legume grasses vs native grasses to impact forage productivity, quality and SOC? b) Also quantify the response of grasslands under native + legumes system to current climate variations and ecosystem services? c) Best climate-smart grasslands practices adaptive to the local environmental conditions to promote forage productivity by canceling greenhouse gases emissions?

2.Methods

2.1. Study site: The research area is located in the Huanxian county and typical steppe grassland/agricultural trial station in Gansu province, China (37.12°N, 106.84°E, 1700 m a.s.l), which is the largest inter and intra-annual precipitation variability in the world (Huang et al., 2022). The mean annual temperature is 7.8 °C and the mean annual precipitation is 289.8 mm, occurring mainly (>70%) from April to September (the growing season). The typical soil type is classified as loessal soils with sand texture.

2.2. Experimental design: The field experiment will be carried out in a typical steppe (slope≈5°) with combination of multis-legume species composition and soil conditions under the randomized complete block design (RCBD) followed by No-tillage (mentioned in schematic I & II). The project interventions will be carried out in Huanxian Grassland areas of Gansu Province by integration of three legume grasses Alfalfa (*Medicago sativa* L.); Milkvetch (*Astragalus laxmannii* L.); Pea-shrub (*Caragana korshinskii* L.) of optimum, high, very high seeding rates (15, 20 & 25 kg ha-1); followed by zero-tillage.

2.3. Compute soil organic carbon (SOC): Methods include Walkley and Black and Photometric methods, while dry combustion includes ignition tests (SoilOptix®). Walkley and Black Method relies on the oxidation of potassium dichromate ($K_2Cr_2O_7$) that is acid catalyzed as shown in Fig. 1. The heat from the dilution raises the temperature to induce substantial oxidation of carbon-to-carbon dioxide. A modified Walkey and Black Method called Meibus uses the same procedure but includes sulphuric acid with $K_2Cr_2O_7$ (Usman, et al., 2022). Also applied the IPCC Tier > 1 methodology assumes that the SOC in a specific situation is given by:

SOC = SOCREF * FLU * FMG * FI

where SOCREF is the SOC under native vegetation (assumed to be native grass species), and FLU, FMG and FI are factors dependent on land use by legume crops species, management practices and inputs material.

Figure 1. A graphic representation of the different SOC stock baselines and the associated changes that were sampled and measured under the legumes + native grass species seeding proportion% (optimum>high) production systems.

3. Results & discussions

3.1. Agrometeorology and SOC at a landscape scale: Pastures are particularly important to the global carbon cycle because of their size and relatively high SOC reserves as compared to equivalent croplands in temperate climates. Large portions of the world's grasslands are under intense environmental pressure as a result of deterioration caused by overgrazing, which could affect SOC stocks. At the landscape scale, however, changes in SOC stocks are caused by complicated interactions between various variables, including climate, land management, and inherent soil biophysical characteristics, such as soil texture and/or chemical qualities. The connection between precipitation (mm) and soil organic carbon (g C m^{-2}) at a landscape measurement level. Thus, to quantify management effects on SOC stocks from 2001 to 2022 we compared the effects of abiotic site conditions, long-term plot experiments showed that areas with higher annual rainfall (>300 mm) exhibited greater SOC levels compared to regions with lower precipitation levels (<250 mm). Moreover, at a landscape scale, SOC content was positively correlated (>22.5%) with the amount and distribution of rainfall (> 300mm). Areas experiencing more consistent and higher rainfall showed higher SOC concentrations above 2214 g C m^{-2}) in the topsoil layers from 20-30cm soil pool. Long-term data analysis discovered a significant positive connection among yearly rainfall changeability (250-300mm) and SOC accumulation (~17.3-21.5%) mentioned in table 1, demonstrating the role of rainfall patterns in shaping SOC dynamics over time.

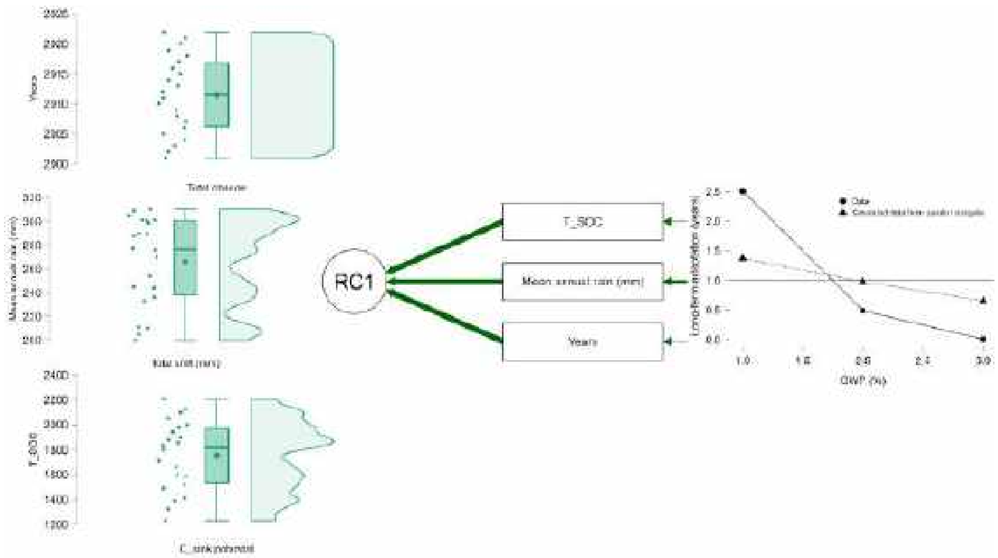

Figure 2. Yearly contribution mechanism determination on the bases of observed field data (RC1) total SOC, rainfall and mean annual shift (mm) at typical steppe, Gansu province of China.

3.2. Legumes vs. native grass species in typical steppe:

When legumes grass species grown with native grasses at optimum seeding (O.S) and high seeding (H.S) rates plots found to significantly ($P < 0.05$) reduced ST (soil temperature) by 3.72% and 5.71%, soil pH by 1.37% and 2.18%, and C:NC/N ratio by 10.03% and 11.18% shown in Fig. 2. Equally, improved SM (soil moisture) content (%) by 2.81% and 3.61%, SOC (soil organic carbon) up-to 2.96% and 3.56%, and soil total nitrogen (STN) by 12.58% and 17.37%, linked to native grass and legumes species sole-cultures in 2024, respectively. Furthermore, winter-cuttings increased soil temperature (2.24% and 2.38%) and CO_2 in Fig. 3, while decreased soil moisture (1.18% and 1.47%) compared to spring-cuttings. Additionally, the initial results indicated that legumes overseed (O.S) with native grasses significantly ($P < 0.05$) increased the forage yield by 51.48% and 39.65%, crude protein (CP) content by 19.86% and 24.13%, ash content by 12.45% and 26.89%, and relative feed values (RFV) by 4.78% and 7.13%.

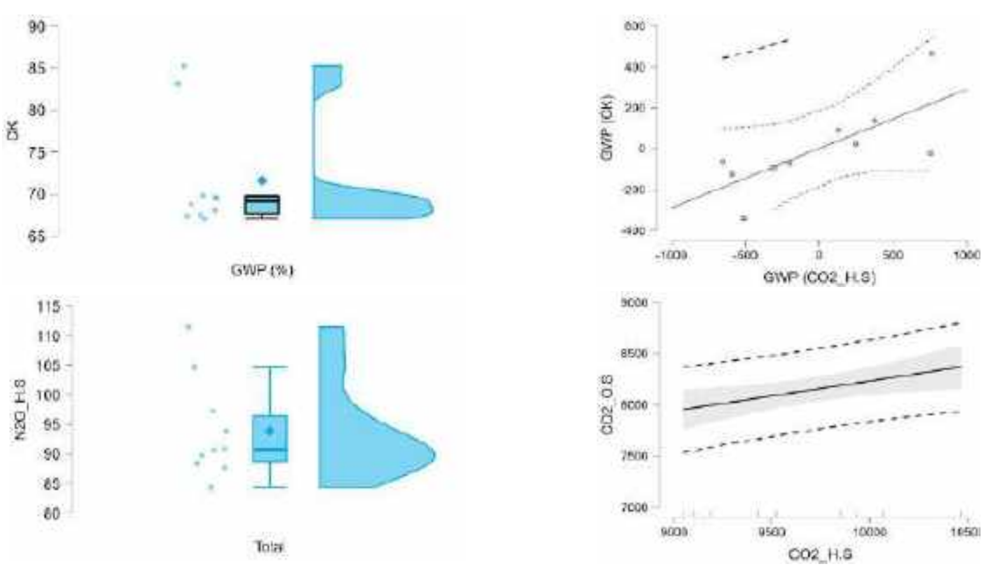

Figure. 3. Accumulated contribution of legume + native grass species production for quality and yield to GHG global warming potential of typical stepper of Gansu province in China.

Cultivating forage crops is crucial to improve feed quality, production, and grazing is an important utilisation method to improve SOC. Improving soil organic carbon (SOC) content and reducing carbon dioxide (CO_2) emission through planting legumes species at different planting proportions with existing native grass species. Soil is the major carbon pool of grassland ecology and stores 26–36% of the carbon in the terrestrial ecosystem (Zhang et al. 2018; Pourshirazi et al. 2022).

4. Conclusion

The increase of storage or SOC sequestration of content is significant to improve crop productivity and soil fertility as well. Conceivable trends in soil organic carbon (SOC) stocks in agroecosystem sequestration scenarios and subsequent implementation of soil carbon sequestration trials. (i) Soil organic carbon (SOC) shares are assumed to be in steady pool/conversion with zero-change in changing climate scenario, (ii) SOC stocks are projected to increase even without C-sequestration measures in the warming potential-as-usual scenario, (iii) Stocks of SOC are expected to decline in the SOC despite the implementation of C-sequestration actions, and (iv) SOC stocks are expected to decline if no C-sequestration measures are implemented under legumes planting proportions.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Business planning for drought preparedness and resilience in the variable climate of Northern Australia

Baker, KM.[1]

[1]Department of Primary Industries, Queensland. Mareeba, Queensland, Australia

Key words: drought; livestock resilience; climate variability

ABSTRACT:
Northern Australia typically experiences an annual wet season (November to April) and dry season (May to October). However, it is common for wet seasons to fail, or be reduced, and dry periods to extend into drought. To survive the highly variable conditions that are predicted to increase with climate change, northern cattle producers are encouraged to implement management strategies for drought preparedness and resilience. Due to extensive land areas and high costs, most properties have limited fencing and water infrastructure which constrains best practice grazing land management.

The GrazingFutures Livestock Business Resilience project (GFLBR) is designed to enable a collaboration of livestock extension agencies to support Queensland cattle producers to analyse their business through the development of Farm Business Resilience Plans. Through the project, producers are supported to develop goals for their business and develop a plan to achieve these goals. Key business risks and challenges are also identified and strategies for risk reduction incorporated into the plan. A developed business plan also enables producers to apply for Queensland Government drought preparedness grants and low interest loans for improving capital infrastructure on their properties.

Kevin and Shelly Taylor on Ooralat Station, near Mt Surprise, Queensland, provide an outstanding case study of the benefits of using drought preparedness grants for improving capital infrastructure. The Taylor's used the grants to fence 11 additional paddocks and improve water distribution. This work increased their ability to rest pastures over the wet season and thereby improve pasture composition and land condition. More water points for livestock have improved pasture utilisation across paddocks and property carrying capacity from 800 to 1,200 breeders. Irrigating pasture for hay production in one of the paddocks, has facilitated feed storage for managing future droughts.

The GrazingFutures Livestock Business Resilience project enables northern beef producers to be better prepared for climate variability, improve productivity and profitability, and landscape resilience.

Introduction
The highly variable climate of Northern Australia is difficult for northern cattle producers to manage, especially with the increasing variability predicted with climate change (CSIRO, 2024). This region typically experiences a

wet season from November to April and a dry season from May to October. Producers rely on a successful wet season for forage production and feed supply over the dry season, however it is common for wet seasons to fail, or be reduced, and dry periods to extend into drought.

Northern beef producers face a variety of challenges in maintaining a successful business. Properties are typically large, family run enterprises and adoption of best management practice is often limited due to the resistance of the older generation to change. It is very difficult to maintain a reliable workforce in these regional areas, resulting in managers that are time poor and incapable of further extending themselves for educational activities such as workshops.

The rising cost of production across agriculture has minimised profit margins and is forcing producers to become more efficient across their business (Rolfe et al., 2016). Despite this, many producers are resistant to adopting known best management practices to improve their grazing and herd efficiency, such as wet season spelling, matching stocking rate to carrying capacity, feeding phosphorous in deficient country, culling unproductive animals, pregnancy testing and keeping records.

Droughts are a common part of managing an agricultural enterprise in Australia. Governments have historically approached drought support for producers in a reactive manner, such as through providing freight subsidies for drought feeding or restocking, as has occurred previously in Queensland. It has been suggested that in-drought freight subsidies legitimise overstocking practices and limit potential beneficial practice change (McCartney, 2017). Reactive approaches are seen as less effective at minimising the impacts of drought and have led to a policy change by governments towards incentivising proactive climate risk management. The GrazingFutures Livestock Business Resilience project was created to enable producers to become better prepared for, and resilient to, drought through developing a business plan to guide implementation of drought management strategies.

Methods

GrazingFutures began in 2015 in western Queensland to 'increase and better align inter-agency extension support through the grazing land management (GLM), animal production and people–business pillars of the livestock operation. The four objectives of GrazingFutures include: (1) *partnering* (government and non-government); (2) *staff training*; (3) *service delivery to* graziers; and (4) assembling project and industry *legacy* (*information*) *products* (Fig. 1) (Rolfe et al., 2021b)'.

Figure 1. The GrazingFutures operating environment, project cycle and objectives. (Rolfe et al., 2021b)

The initial success of the project led to progression to the GrazingFutures Livestock Business Resilience project (GFLBR) which expanded to include the entire state and increased the number of delivery partners. It was developed to enable a collaboration of livestock extension agencies to support Queensland extensive livestock producers to analyse their whole of business through the completion of a Farm Business Resilience Plan. The extension providers include the Queensland Department of Primary Industries, Natural Resource Management groups, Rural Financial Counselling Services and various private consultants (Rolfe et al., 2021a). GFLBR is jointly funded by the Australian Government's Future Drought Fund and the Queensland Government's Drought and Climate Adaptation Program.

Producers undertake a self-assessment checklist Through the planning process that clearly identifies priority areas of focus enabling the development of goals and actions in relation to production, people and family, business, natural resources and climate (Queensland Government, 2022). These goals are developed to consider risk across these four areas and outline actions to build drought preparedness and business resilience. In addition, a Farm Business Resilience Plan (or equivalent farm business plan) also enables producers to apply for Queensland Government funded drought preparedness grant and concessional loans for improving capital infrastructure on their properties (QRIDA, 2024). Common activities are paddock subdivision, water infrastructure installation, dam construction, bore drilling, irrigation equipment and fodder storage sheds (QRIDA, 2024). Once the application to the Queensland Rural and Industry Development Authority (QRIDA) has been approved, applicants have 6 months in which to complete the project outlined in their business plan.

GFLBR also provides extension services to fast-track practice improvements through using a range of methodologies including educational workshops, industry forums, neighbour days, newsletters, case studies, property demonstrations, eExtension and one-on-one support. It also includes the capacity building of staff and producers through training, and the creation of legacy documents (Rolfe et al., 2021). GFLBR funds also contribute to Advancing Beef Leaders (ABL) a capacity building program that develops producer and community leaders to enact change in the industry (Rolfe et al., 2021). In addition to this, staff funded through GFLBR provide support during disaster response situations, such as flooding and fires.

Results

The GFLBR program has enabled many producers to implement planned strategies for drought preparedness and resilience. Ooralat Station, owned by Kevin and Shelly Taylor near Mt Surprise, Queensland, provides an outstanding case study of the transformational change benefits of using drought preparedness grants for improving capital infrastructure (Pickering & Buchanan, 2024).

When the Taylors purchased Ooralat in 2017 there were only four paddocks, one set of cattle handling yards and limited watering points across the 14,500-hectare property. When Ooralat was drought-declared shortly after purchase in 2018 the Taylors found themselves underprepared and set about implementing several drought preparedness strategies. With the support of a Rural Financial Counsellor these strategies were formalised in a Farm Business Resilience Plan, enabling them to apply for a drought preparedness grant (Pickering & Buchanan 2024).

The first action was to subdivide paddocks and increase water infrastructure for improved pasture utilisation and carrying capacity. Ooralat was further fenced into nine breeding paddocks, one bull paddock, three holding paddocks, two weaner paddocks and a few horse paddocks. Water troughs were installed in all paddocks across the property. Another two sets of yards were also built to reduce the stress from walking stock long distances during mustering. In conjunction with best practice management strategies, such as matching stocking rate to carrying capacity and appropriate supplementation programs, the Taylors were able to improve their pasture utilisation and increase their carrying capacity from 800 to 1,200 breeding cows (Pickering & Buchanan, 2024).

The second action was to build a dam and install irrigation infrastructure for hay production, to reduce the cost of drought feeding. A 32 ha hay paddock was developed with irrigation for half of the paddock and dryland for the remaining half. This has enabled the Taylors to have low-cost and weed free hay for dry times, as well as allowing the flexibility to retain stock and sell at an optimum market price (Pickering & Buchanan, 2024).

In conjunction with good grazing land management (GLM) and breeder management, implementing the drought preparedness strategies outlined in their Farm Business Resilience Plan have improved weaning rates from 50% to 80%. This is significantly higher than the average weaning rate of 56% for the region (Rolfe et al, (2016) Weed infestations have also been reduced and the proportion of the property with greater than '70% ground cover' has increased from 32% to 89% in 7 years (Pickering & Buchanan, 2024).

The most recent progress report for the program stated 8,433 producers have participated in GFLBR activities since project commencement in 2021 (Smith & Long, 2024). This is more than double the project target of 4,000. Further success has been achieved in providing individual support services to 3,075 producers which is also double the 1,500-project target (Smith & Long, 2024). A producer survey record 63% of grazing businesses rating GFLBR activities they engaged in at 7 or more out of 10 for enabling them to be more prepared for drought; of these producers surveyed, 79% made at least one business change from being involved in the program (GR Consulting, 2024).

Discussion

The goal of GFLBR is to enable a collaboration of livestock extension agencies to support extensive livestock producers to adopt management strategies that will increase their drought preparedness and resilience, including tailored support to develop holistic farm business plans. The move to increasing privatisation of extension in the 1990s has unsuccessful and reduced the available extension resources for beef producers. (Rolfe et al., 2021a; Bommel et al., 2023). The collaborative industry partnerships developed through this project have now enhanced capabilities across the region to facilitate practice change (Rolfe et al., 2021a). This has been shown through the doubling of extension services in western Queensland from 2015 to 2021 and an estimated gross benefit of $28M from a $6M investment (Rolfe et al., 2021a). Therefore, through its collaborative partnerships the GFLBR model has been effective in improving capacity for facilitating change towards drought preparedness and resilience across Queensland.

GFLBR utilises a holistic 'whole of business' approach that enables producers to identify their specific needs and tailor their actions to these needs. To achieve practice change, support needs to be individually tailored and take a whole of business approach incorporating production, land management, financial and personal dynamics (Larard, 2022; Broad 2016).

Despite success, having the capacity and strategies for effectively facilitating the adoption of best management practice continues to be a challenge across grazing industry extension professionals. Due to the regional locations and time constraints of most producers in the north, workshops are often cancelled or not well attended in northern Queensland. While the program has improved this, staff capacity limits the ability to provide one-to-one follow-up. Specialised and individually-focused support from extension staff located regionally and integrated into the community is deemed most effective in achieving practice change (McCartney, 2017). An increase in extension services and other independent service providers was seen as an opportunity for improving drought management in Queensland grazing enterprises. Producers interviewed for the report noted that, although there was plenty of training and information available there is a shortage of extension staff available to provide this individually-focused supported (McCartney, 2017). Staff need to understand the complex nature of the family livestock business they are working with, and success within the program is typically seen where support staff are familiar with the intricacies of these business (Rolfe et al., 2021b). Therefore, although GFLBR has improved the capacity of extension services since 2015 there is still an opportunity to extend the capabilities of these services through increased staff and capacity building in the regional areas.

Producers typically only engage in the business planning process because it is required to apply for a drought preparedness grant. Nevertheless, producers generally find completing the business plan useful in other ways, such as beginning the conversation about succession, and identifying areas for improvement they hadn't considered. Producers who did not apply for a drought preparedness grant still rated themselves an 8 out of 10 for being better prepared for drought following a business planning workshop (GR Consulting 2024). Nevertheless, it is a genuine concern that if the funding for the drought preparedness grant ceases it will become more difficult for extension staff to engage producers on business planning, potentially limiting improvements in drought preparedness and resilience across the industry. The project needs to improve uptake of the planning by creating an attractive value proposition so that people want to do the planning to improve their business, not just to receive the grant.

Currently the drought preparedness grant can only be used for new permanent capital infrastructure, however there is the opportunity for further management strategies to be incentivised to support greater drought preparedness and resilience (QRIDA, 2024). GR Consulting's (2024) report recommended including strong elements of grazing land management (GLM) practices that improve land condition due to these practices being necessary to build pastures resilient to drought. There has consistently been a low level of GLM changes reported across annual producer surveys from the past 6 years (GR Consulting, 2024). If GLM practices such as wet season spelling, establishing improved pastures and improving land condition were incentivised, a significant change to the drought preparedness capabilities and profitability of these businesses could be made. This incentive also has the potential to be used in conjunction with government policy to improve land condition.

The GFLBR project has vastly enhanced the capabilities of extension staff to facilitate drought preparedness and resilience across Queensland. There is an opportunity for further capacity building through investment in greater numbers of staff that are based in, and integrated into, the regional communities that beef producers are a part of. Continued funding for drought preparedness grants and concessional loans from the Queensland Rural and Industry Development Authority (QRIDA) would support ongoing engagement of producers in the program, noting other motivations for participation could be promoted. There is also an opportunity to expand these incentives to include grazing land management practices for further development towards a drought prepared and resilient Queensland.

Acknowledgements
The author thanks Niilo Gobius, Dave Smith, Geoffrey Bahnisch and Brigid Nelson from the Queensland's Department of Primary industries for their contributions. The participation and generous agreement by Kevin and Shelly Taylor to be a case study is acknowledged with gratitude. GFLBR is jointly funded by the Australian Government's Future Drought Fund and the Queensland Government's Drought and Climate Adaptation Program.

Abstract

In January 2017 the Karoo entered a 58-month drought that destroyed 30% of livestock in the region. Grazing declined by 40-60%, but recovered within two years after the rains returned. Feeding costs ate into profits and real net farm income tracked SPI-12 closely on the way down. While grazing capacity recovered, livestock numbers have not, and financial data must still be collected before financial recovery can be assessed. The government provided adequate drought relief but too little technical support, and limited data collection undermines our ability to evaluate and improve adaptation going forward.

Introduction

Wool provided the foundation for commercial agriculture in the Cape Colony in the 19th century. The Colony's 12 million sheep of 1904 doubled to 25.6 million by 1935, where it remained until 1965 (Department of Agricultural Economics and Marketing 1962; Republic of South Africa Department of Statistics 1964/65). Much of this was in the Karoo, the arid hinterland to Cape Town. After 1965 official sources show the Cape Province[9] losing sheep at a rate of 2.83% per annum (pa) due to drought and other factors (Statistics South Africa 2002, 2017).

The Karoo is an open landscape loosely bounded by the 400 mm isohyet and is spread across the Northern, Eastern and Western Cape Provinces. The winter-rainfall Succulent Karoo transitions into a summer-rainfall Nama Karoo biome (Mucina and Rutherford 2006). The matrix of dwarf shrubs is interspersed with mesembs in the former and grasses in the latter. Despite two centuries of commercial exploitation, farmland supports as much mammal diversity as protected areas (Drouilly et al. 2019). Freehold is the dominant tenure system. Fencing began in the 19th century and paddocks are still being improved. Modern animal husbandry sits along transhumance enabled by proximity to the rainfall divide, although selective purchases by lifestyle investors is disruptive (Reed and Kleynhans 2009) and damaging to the vegetation (Milton et al. 2023).

---

[9] The Cape Colony, Natal and the Boer Republics unified in 1910. The Cape became a province in the Republic of South Africa after 1961 and divided into three provinces in (Northern, Western and Eastern Cape) in 1998. The switch from singular to plural in the text below is therefore deliberate.

It is difficult to determine the contribution of climate to developments in this rapidly changing landscape (Kiem and Austin 2013). This study brings together weather data, data from ongoing vegetation monitoring and one community's farm management data to assess the extent and impact of the 2017 drought.

Methods

A standard precipitation index (SPI-12) measures the severity and duration of the drought. It was fitted to a rainfall series that dates to 1927. Droughts are defined as beginning with SPI-12 < -0.5 and ending with SPI-12 > 0 for a sustained period. Vegetation monitoring commenced in 2017. Line point surveys are conducted at 500 points taken along a 900 m transect running from watering points towards paddock boundaries to capture local grazing gradients. The precise transect is resurveyed every three years and grazing capacity is calculated from a species list according to the method described in du Toit (1998).

The Karoo Management Panel (2012 – 2021) represents a convenience sample of 86 family farms (Conradie et al. 2019). It covers 420 000 ha. This study limits analysis to units whose wool and mutton income exceeds 67% of gross farm income. The observations were partitioned into baseline (control) and drought (treatment) groups whose means were compared using t-tests. There were n = 249 farm-years in the control group and n = 337 farm-years in the treatment group. Five variables were analysed including farm and flock size, stocking density, real feed cost and net farm income. Stocking density is measured in large stock units (LSU) per hectare, with an LSU defined in terms of the energy requirement of a growing ox. Meissner et al. (1983) tabulated LSU coefficients for a range of livestock types from which standard stocking units can be compiled to feed into stocking density calculations. Feed cost and farm income is expressed in ZAR (USD = ZAR 14.50 in December 2020) with a CPI deflator converting nominal to real values. Net farm income was computed in the usual way; gross income minus enterprise-specific costs gives gross margin and net farm income is obtained by subtracting overheads such as labour and machinery cost from total gross margin. Revenues include livestock, crops, farm-based tourism and light manufacturing but ignores salaries and investments. Land is owned and rented, with quality unadjusted.

Results

SPI-12 identifies January 2017 as the beginning of the drought which lasted until October 2021. The index averaged at -1.46 ± 0.67, hovering around -2 from July 2019 to February 2021. The lowest value of -2.56 was recorded 42 months into the drought. Table 1 relates grazing capacity to rainfall and temperature. Long-term grazing capacity equals the legal limit (RSA 2018), while observations for 2018-20 coincide with the drought and the period 2021-23 reflects the degree of recovery. At baseline, site A was 12% below its long-term average capacity with the other sites 22% above capacity. The drought destroyed 30% of measured capacity at sites C and D and twice as much at sites A and B. During the driest periods (2015-2020) all four sites also experienced the most extreme warm days that intensify the impact of the drought. Twenty-four months after the rains returned, grazing capacity was back at 98% of its long-term level at site A and more than 10% above at the other sites. Crown cover, the most important contributor to grazing capacity, improved more quickly than species richness (Table 1).

Table 1: Rainfall, temperature, grazing capacity, species richness, and % perennial crown cover at four Karoo sites before during and after the drought.

	Period	Site A	Site B	Site C	Site D
Rainfall	Long-term	120	230	230	270
mm per annum	2015 – 2017	84	224	248	284
	2018 – 2020	47	198	229	229
	2021 – 2023	148	343	360	299
Temperature	Long-term	149	77	126	87
Days >30℃	2015 – 2017	151	86	134	91
	2018 – 2020	160	86	132	109
	2021 – 2023	145	69	110	96
Grazing capacity	Long-term	42	28	24	22
ha/LSU	2015 – 2017	47	23	18	17
	2018 – 2020	101	69	34	31
	2021 – 2023	43	25	25	18
Species richness	2015 – 2017	13	24	20	26
(perennial plants)	2018 – 2020	10	15	14	19
	2021 – 2023	15	22	13	21
% crown cover	2015 – 2017	15.4	36.8	59.2	70.6
(perennial plants)	2018 – 2020	9.0	17.4	92.6	81.6
	2021 – 2023	19.8	43.6	89.8	70.4

The 2017 drought is one of four major events recorded in the Karoo since 1927 (Table 2). The first drought lasted for most of the 1940s at a low intensity. It reduced Karoo flocks by 14%. Drought relief, if any, was not recorded in the sources we had. The second drought was shorter but more intense. The Cape Province entered it with 21.3 million sheep in April 1968 and lost 3.8 million sheep over the following 35 months. The government spent the current equivalent of ZAR1.7 billion on feed subsidies and railway transport rebates to mitigate its effects, approximately 40% of the value of the national wool crop in 1970. The third major drought occurred in the early 1990s. Conditions deteriorated quickly from February 1991, with the lowest index value reached five months later (SPI-12 = -2.36). The Cape Provinces entered this drought with a third fewer sheep than it had at the beginning of the previous drought but lost the same percentage as in the 1960s. The Cape Provinces entered the 2017 drought with 6.6 million sheep. There is no official record of how many survived, but the Karoo Management Panel can provide anecdotal evidence of how one community was affected by the drought. This panel dates to 2012, with the most recent wave coinciding with the end of the drought. At baseline (2012 – 2016) farms typically ran flocks of 1200 stock sheep on 10 000 ha, stocking at 11% above the legal limit. As rental contracts were abandoned farm size decreased by 12.8% during the drought (t-stat = 2.118). Flocks shrank by 30% (t-stat = 3.761) and consequently stocking density fell to 79.5% of the legal limit (t-stat = 8.526). Feed cost increased threefold, from ZAR430/LSU to ZAR1198/LSU (t-stat = -6.106), rendering many profitable farms unviable. Net farm income dropped from ZAR30/ha to ZAR-1.11/ha (t-stat = 5.457).

Table 2: Four historical Karoo droughts

Period	Drought index SPI-12	Cape Provinces' sheep numbers in each drought Beginning	End	Drought relief ZAR million (2020)
Aug 1940 – Oct 1949	-0.55 ± 0.82	24	20.6	
Apr 1968 – Jan 1971	-1.37 ± 1.12	21.3	17.5	1703
Feb 1991 – Apr 1995	-0.47 ± 0.79	13.8	11.9	1677
Jan 2017 – Oct 2021	-1.46 ± 0.64	6.6		521

In Figure 1 the available farm income data overlay the SPI-12 index for the period 2010 to the present. Single variable analysis of variance indicates year-on-year differences in profitability (F = 4.59) with Bonferroni correlations confirming a structural break in 2017, which supports the SPI-12 data. The break in feed cost is in 2018 while stocking densities were adjusted in 2016 in anticipation of the drought. We are still awaiting the data with which to analyse possible financial recovery.

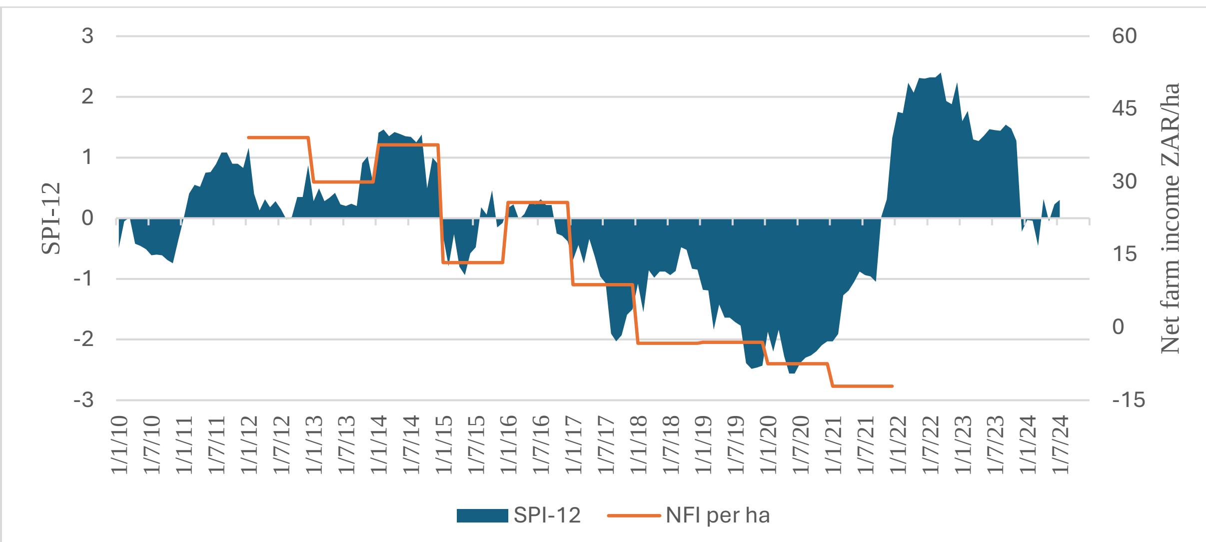

Fig. 1: Correspondence of SPI-12 drought index with net farm income (NFI) per hectare from survey data.

Discussion

The recovery of grazing capacity after the 2017 drought reported in Table 1 is different from how most rangeland ecologists see the effects of drought in the Karoo. In the Succulent Karoo mortality rates varied by species from 9-82% after the 2017 drought (Milton et al. 2023). Expected recovery is predicated on a "recruitment event", i.e. sustained rainfall over several months for shrub seedlings to become established. Excluding all herbivores would be ideal at this time (Milton and Wiegand 2001), but for game farmers it is technically infeasible and for sheep farmers it is unwise to give up the benefits of years of genetic selection even if other investment opportunities existed. Experience suggests that conditions for recruitment were poor at the end of the 1990s drought, which might explain the sharp decline in flock size since, although this is still an open question. Continuous grazing decreases palatability and, in a drought, lowers the perennial fraction of the vegetation (Milton et al. 2024; Wiegand

and Milton 1996). With more short-lived species in the mix, the rangeland becomes less productive and less resilient (Milton et al. 2023).

The 2017 drought was long and intense. It hit an industry that had become a shadow of its former self. The losses suffered remain uncertain as there has not been a census since 2017. Disaster relief decreased drastically in absolute terms, returning to a rate of support provided during the 1960s drought. This has implications for the number of livelihoods the Karoo can support. As the number of livelihoods decline, farm size must rise (Asghari et al. 2021). There are already farms of >20 000 ha spread over several cadastres, units that are rapidly becoming too expensive and time-consuming to operate. Moreover, drought relief was actively biased against large operators (Conradie 2019) which hindered the adaptation needed to bring management systems in line with the expected ecological changes.

Conclusion

The priors for this study were that the 2017 drought was the worst on record, that it permanently damaged the rangeland and that farmers were severely compromised by a lack of drought relief. The analysis showed that 2017 was just one of several serious droughts, that the rangeland recovered quickly and that farmers received the same level of support as before. But we do not know what contributed to the collapse of the industry before 1990, if changes in the weather accelerated the collapse since, or how farmers are faring now. We cannot act on the sound advice to prepare for the next drought now because we missed the opportunity to collect the data for a proper postmortem of the 2017 event. While South Africa's climate change adaptation efforts could benefit from technical assistance to our institutions, we remain the most technically proficient in the region. Colleagues in Namibia, Botswana, Zambia, and Zimbabwe likely face similar technical challenges as we do and almost certainly must contend with more serious funding problems than us. However, funds without proper implementation will achieve little.

Spatial distribution, habitat use, and conservation implications of Himalayan brown bears in Deosai National Park, Pakistan

Deacon, F[1]; Daffue, W[2]

[1]Department of Animal Science, Faculty of Natural and Agricultural Sciences, University of the Free State, Bloemfontein, 9301, South Africa;[2] Kroonstad Animal Hospital, Kroonstad, 9499, South Africa

Key Words: Extreme climate, anthropogenic challenges, extinction, movement patterns, grazing pressure

Introduction

The Himalayan brown bear (*Ursus arctos isabellinus*) is a critically endangered species, with its primary habitat in the Deosai National Park of Pakistan as their last stronghold for survival. This high-altitude plateau, situated between 4,000 and 6,000 meters above sea level, is crucial for the persistence of the species. The park lies within the Himalayan, Karakoram, and Hindu Kush ranges, bordering Afghanistan, China, and India, where political and environmental challenges complicate conservation efforts. The harsh conditions in Deosai, such as extreme cold temperatures reaching -20°C, thick snow and reduced oxygen levels (30% less than sea level), make it a challenging environment for both the bears and the researchers observing them. GPS collaring is an effective method to track these bears' movements and provide valuable data on their behavior and habitat use. The grazing impact and pressure is predominantly from livestock that should not be there. This study aims to understand the movement patterns of the Himalayan brown bear in the face of mounting threats, including habitat degradation, climate change, and human-wildlife conflict.

Methods

Study Area

Deosai National Park, located at the heart of the Deosai Plateau, is the last stronghold of the Himalayan brown bear. The park spans over 3,000 square kilometres (Chaudhary et al. 2019). The habitat is rich with key species such as the Machor (*Capra falconeri*), Himalayan ibex (*Capra ibex*), snow leopard (*Panthera uncia*), and Tibetan wolf (*Canis lupus chanco*). Rangers and veterinarians face considerable challenges due to the terrain, altitude, and climate.

Darting and Collar Fitting

The process of darting (theoretically using a Pneudart dartgun with a 3cc dart, loaded with Fentanyl (10-20 µg/kg) and Medetomidine, aiming for the shoulder for immobilization) involves immobilizing the bear using a tranquilizer dart fired from a distance (no more than 30m) to minimize human-wildlife conflict risks. The tranquilizer is specifically tailored to the bear's body size and weight. Once the bear is sedated, a Africa-Wildlife Tracking device and GPS collar is fitted around the neck, ensuring that it does not interfere with the bear's movements. The collar is designed to remain on the bear throughout the study period, transmitting location data whenever the animal moves and varies between 10min intervals or usually set at 1 hour intervals (Bauer et al. 2020).

Data Collection

Location data was obtained using GPS collars, and additional environmental data such as altitude, aspect, and slope were derived from Sentinel 2 imagery and Shuttle Radar Topography Mission (SRTM) data. These data were used to calculate NDVI (Normalized Difference Vegetation Index) and NDMI (Normalized Difference Moisture Index), both of which provide insights into vegetation density and moisture content, respectively.

Results

Spatial Distribution of Collared Bears

The map in Figure 1 presents the spatial distribution of collared bears in Deosai National Park, with the locations of Bears 7400 and 7401 (male and young male) indicated in the field. The distribution of these bears is shown in relation to various grazing pressure zones: high pressure (red), medium pressure (yellow), and low pressure (green).

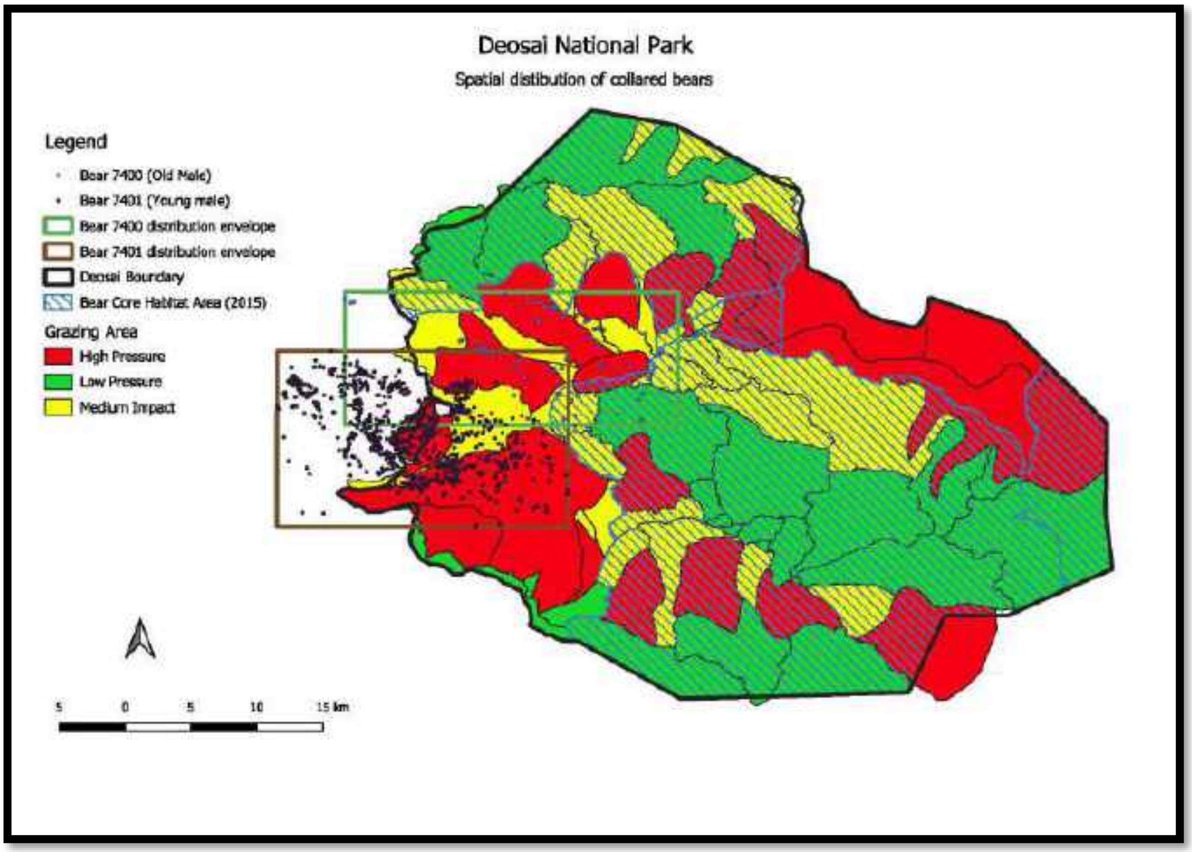

Fig 1 Illustration of the spatial distribution of the collared bears in Deosai National Park

- Bear 7400 (Old Male): The older male bear's distribution envelope overlaps significantly with areas of low to medium grazing pressure. This suggests a preference for less disturbed areas with abundant vegetation and fewer human-induced threats.
- Bear 7401 (Young Male): The young male bear also favours areas with low grazing pressure but appears to have a broader range, possibly indicative of its exploratory behaviour as it establishes its own home range.

This map also highlights the Bear Core Habitat Area and shows that the bears' preferred locations are predominantly within this core area, which is critical for their survival.

Correlation between NDVI and NDMI
Preliminary analysis of NDVI and NDMI values from Sentinel 2 data revealed a strong positive correlation, indicating that areas with higher vegetation density also exhibited higher moisture content. This correlation is critical in understanding the bears' habitat preferences for forage and shelter.

Impact of Environmental Factors
Aspect was found to have a significant effect on both NDVI and NDMI, with north-facing slopes showing greater vegetation and moisture content. However, temperature was not found to be significantly sensitive to aspect, suggesting that other factors such as solar exposure and wind play a role in vegetation growth. No significant correlation was found between altitude and temperature, further suggesting that climate factors are less influential in the selection of habitat.

Discussion
The results indicate that Himalayan brown bears use specific areas within Deosai National Park based on vegetation density and moisture levels, both of which are influenced by the park's aspect. These findings are consistent with studies on other bear species, such as the Grizzly bear (*Ursus arctos horribilis*) in North America, where aspect also influences habitat selection (Miller et al. 2017). The fact that temperature did not significantly affect vegetation or bear movements may suggest that, in Deosai, other environmental variables such as altitude, vegetation, and moisture are more important factors in the bears' habitat use. This is crucial for management, as it highlights the need to protect the most critical vegetation-rich areas, regardless of temperature fluctuations.

Additionally, with the help of the GPS location data, it was surprising to find that the bears do not descend to lower altitudes during hibernation, as was previously expected. Instead, they remain on the plateau, utilizing marmot burrows for shelter under deep snow (confirmed by the park manager and ranger team on site), which could have implications for their survival in the face of warming temperatures and loss of snow cover (Johnson et al. 2016). The results also highlight significant correlations between the Normalized Difference Vegetation Index (NDVI) and Normalized Difference Moisture Index (NDMI), both of which are indicators of vegetation health and moisture content. Our data shows a strong correlation between these indices, particularly in areas with high vegetation coverage, where the bears tend to spend the majority of their time. This suggests that vegetation health is a primary factor influencing bear movement patterns, as also observed in studies on other bear species (Sawyer et al., 2017; Derocher et al., 2018). Moreover, aspect—the direction of slope—was found to influence both NDVI and NDMI, with north-facing slopes showing higher vegetation productivity compared to south-facing slopes. This is likely due to differences in sunlight exposure, which affects the growing conditions for vegetation. Interestingly, temperature showed little sensitivity to aspect, with minimal differences in temperature across the landscape, but the overall temperature range was not a strong determinant of bear movement. It is apparent that both bears tend to utilize areas with relatively low grazing pressure, which is likely indicative of their preference for undisturbed habitats where vegetation can thrive.

Other important findings include Aspect vs. Altitude: A significant correlation was observed, with altitude generally increasing in areas with a particular aspect (i.e., north-facing slopes at higher altitudes). Aspect vs. Slope: No significant correlation was found, suggesting that slope direction did not greatly impact the bears' movements or habitat selection. Temperature and Vegetation Indices (NDVI/NDMI): No significant correlation was found between temperature and the vegetation indices, indicating that the bears do not rely on temperature fluctuations to dictate their habitat use.

The presence of collared bears in areas of low grazing pressure indicates that these zones provide a more favourable environment for the bears, with better access to vegetation and fewer disturbances from livestock. In contrast, high pressure grazing zones are typically avoided, as these areas likely suffer from overgrazing and a reduction in natural vegetation, leading to lower food availability for the bears. Understanding these distribution patterns is critical for management efforts, as it can guide the identification of areas that need to be protected or restored to support the bears' long-term survival.

Additionally, the Bear Core Habitat Area in the map is a zone that should be prioritized for conservation, as it provides the most consistent resources for the bears, and further encroachment or disturbances in this area should be minimized.

Conclusions & Implications

The use of GPS collars to track the Himalayan brown bear provides critical insights into their spatial ecology. These collars have revealed new information about their habitat preferences, hibernation behavior, and the challenges they face due to habitat degradation and human activity. The data supports the need for improved conservation strategies that include better management of high-pressure grazing areas and protection of the bears' core habitat on the plateau. The new understanding of the bears' hibernation patterns, staying on the plateau and utilizing marmot burrows, challenges previous assumptions about their seasonal behavior and suggests a more adaptable strategy for winter survival. This information will guide future management decisions, ensuring that both the bears and their habitat are adequately protected. As the species is critically endangered, continued monitoring through GPS collaring will be essential for understanding their movements, estimating population densities, and making informed management decisions to ensure their survival.

Implementing social-ecological resilience principles in the Australian government's future drought fund program: opportunities, challenges and lessons learned

El Hassan, M

Department of Agriculture, Fisheries and Forestry, Future Drought Fund, Agriculture House, 70 Northbourne Avenue Canberra ACT 2601

Key words: Future Drought Fund; Social-Ecological Systems; Resilience; Transformation

Abstract

Climate change impacts are increasing, leading to more frequent, longer and more severe droughts and other climatic events. The complexity of these issues requires proportional systems-based adaptation and transformation approaches to build resilience and achieve sustainability. The Australian and State and Territories governments commit to sustainability, adaptation and resilience to a changing climate in the National Statement on Climate Change and Agriculture. These commitments are reflected in multiple governmental initiatives and programs, one of which is the Department of Agriculture, Fisheries and Forestry's Future Drought Fund (FDF). The FDF offers a unique pathway to achieving sustainability through building drought and climate resilience, founded on robust scientific principles of social-ecological resilience. The FDF supports farmers and communities to learn about, be prepared for, and have the capacity and options to respond to drought and other climatic shocks, including through transformational change. The FDF programs fund projects, including in the rangelands, to achieve its objectives. This paper discusses how the FDF implements resilience principles and fosters collaboration and collective adaptive learning and action to achieve shared resilience and sustainability outcomes. Progress to date is presented and links to case studies of successful and impactful FDF-funded projects are provided. Lessons learned, opportunities and challenges facing FDF highlight the important role it can play in supporting resilient social-ecological systems in Australia.

Introduction

Drought is a recurring feature of Australia (DAFF 2024). Climate change is increasing the frequency, duration and severity of inter-connected climatic events, including drought (DAFF 2024; ABARES 2022; DAFF 2025b). The complexity of this issue requires proportional systems-based adaptation and transformation approaches to build resilience and achieve sustainability (IPCC 2023). The Australian and States and Territories governments commit to sustainability, adaptation and resilience to a changing climate in the National Statement on Climate Change and Agriculture (DAFF 2023a). It has several initiatives that aim to address sustainability and resilience to climate change, including the Climate Smart Sustainable Agriculture Package, National Soil Action Plan, Carbon Farming Outreach Program and the

Future Drought Fund (FDF) (DAFF 2025b). The FDF is aimed at achieving public good through building resilience to drought and broader climate impacts (DAFF 2025a). This work is uniquely underpinned by the systems-based social-ecological resilience theory (Folke 2016). Since its inception, the FDF has progressively improved the implementation of this theory, including through communicating and engaging with its stakeholders and supporting projects on the ground.

This paper provides an overview of the FDF and explores how it implements resilience principles. Quotes and examples from program guidelines and other key FDF documents are provided, as well as links to successful case studies. Lessons learned, opportunities and challenges are briefly discussed.

The Future Drought Fund: an overview

The FDF is a $5 billion initiative that was set up in 2019 under the *FDF Act 2019* (DAFF 2025a). $100 million is available each year to fund programs aimed at supporting farmers and regional communities to build social, economic and environmental resilience, through learning about, being prepared for, and having the capacity and options to respond to drought and other climatic shocks (DAFF 2025b). The FDF constitutes a unique and distinct pathway to sustainability, through a focus on building whole-of-system resilience to achieve sustainability. This approach includes innovative and, where needed, transformative management of natural capital that underpins landscape function and ecosystem goods and services, agricultural businesses and agriculture-dependent communities. Delivery of FDF programs is governed by 4-yearly Drought Resilience Funding Plans (FP) that set FDF objectives and aims (DAFF 2025a). Under the new 2024-28 FP and supporting Investment Strategy (IS) 10 programs will be delivered over the next 8 years. In addition, funding will be available for monitoring, evaluation and learning (MEL) activities and knowledge sharing, to share and facilitate learning from FDF outcomes (DAFF 2025b).

Social-Ecological resilience theory: FDF as an implementation pathway

Social-ecological resilience theory defines resilience as "*the capacity of a system to absorb disturbance and reorganise so as to retain essentially the same function, structure and feedbacks";* in other words, *"the ability to cope with shocks and keep functioning in much the same kind of way*" (Walker and Salt 2012) – where a system is *"an interconnected set of elements that are coherently organized in a way that achieves something*" (Meadows 2008), and social-ecological system (SES) as a linked system of humans and nature (Folke 2016). The FDF adapted this definition in its FP by stating that "*a key aspect of drought resilience is the ability to adapt, reorganise or transform in response to changing temperature, increasing variability, and scarcity or changed seasonality of rainfall, for improved economic, environmental and social resilience*" (DAFF 2025a,b), and looking at landscapes as complex and adaptive SES and farmers and regional communities are actors in, or part of these systems (DAFF 2025b). The FDF supports both adaptation and transformation, taking into account the adaptability and transformability of a system as defined by Walker and Salt (2012).

The FDF enables building specified resilience of landscapes, farmers and communities to drought, focussing on activities that help ensuring that SES avoid crossing critical social, economic or ecological thresholds into undesirable regimes, sometimes irreversibly (Walker and Salt 2012) – which makes these SES untenable: "*Increased adoption of whole-of-system thinking approaches to manage landscapes, including knowledge of and capacity to define and act on critical tipping points or thresholds, and contributing to connectivity across broad landscapes"* (Resilient Landscapes Program). In addition, FDF programs promote and support building general resilience to drought and broader climate impacts (DAFF 2025b), including the principles of complex adaptive systems thinking, safe-fail experimentation, broad participation, diversification, networks and connectedness, and adaptive learning (Carpenter et al. 2012; Biggs et al. 2015). Examples are provided below.

As outlined in the FP and IS, the FDF has 3 inter-connected strategic objectives of building social, economic and environmental resilience to drought, an approach that recognises the complexity of SES and maximises the impact of FDF investments (DAFF 2025b): *"In line with whole-of-system thinking, feedbacks and interactions between components of complex systems (in this case the land, people, industry, governance and so on.) lead to non-linear changes that are not necessarily the sum of the characteristics or dynamics of components, or any pair of interactions between these components. The whole system is therefore often more than the sum of its parts* (Drought Resilience Soils and Landscapes Program).

The FDF supports safe-fail experimentation with, and adoption of all forms of change, i.e. incremental, adaptive, transitional and, especially, transformational when the system becomes untenable (DAFF 2025b): "*The program allows for 'safe-fails', which will help participants learn from the experience, and assist primary producers and rural communities to adopt innovative, diverse, adaptive and/or transformative approaches to build drought resilience in agricultural landscapes"* (NRM Drought Resilience). The FDF also promotes diversification: *Increased diversification in land use and management, so that multiple options and pathways are available to farmers to prepare, respond, and recover from drought* (Resilient Landscapes Program).

The FDF values networks and connectedness, and the diversity they bring. It collaborates and partners with diverse stakeholders to design and deliver programs. It seeks opportunities to enact community-led, co-design, and / or end-user approaches, in collaboration with existing community networks, Indigenous organisations and communities, natural resource management organisations, businesses, industry and farmer groups (DAFF 2025b). Our delivery partners are similarly encouraged to form and maintain networks: "*Networks are established or strengthened between stakeholders who partner and share responsibility for managing natural resources (including public and private land managers), which improves connectedness and diversity of approaches across the landscape*" (NRM Drought Resilience Program). One program – Networks to Build Drought Resilience – is dedicated to that (DAFF 2025a). We support consortia of partners to deliver projects under other programs: *"[the program] fosters collaboration, in the form of consortia of partners and stakeholders collectively working on shared issues and outcomes to improve integration, coordination, communication, planning and implementation of drought resilience activities, and avoid unnecessary duplication"* (Resilient Landscapes Program). This approach enables learning as a tool to build resilience: *Collective adaptive learning and capacity building through stronger collaborative networks between farmers and other land managers, including First Nations land managers, in support of increased adoption of drought resilient practices, technologies or approaches* (Resilient Landscapes Program). To further support learning, successful case studies continue to be built and published (DAFF 2023a).

Opportunities and Challenges

Since its inception, the FDF has been communicating with its stakeholders and delivery partners how it's aiming to support building resilience and the principles and theories underpinning its work. This includes

FP and IS, program guidelines, meetings and workshops, and general communication material. The FDF stresses that resilience is about embracing change, particularly transformational where needed, and that to be resilient does not mean 'not to change' (Walker and Salt 2012). This engagement has been an iterative process. We realised the need to sensibly and progressively utilize and promote the adoption of technical concepts, as our experience and that of our delivery partners matured. As programs were rolled over the last 5 years, the FDF re-focussed its messages.

One of the unique aspects of FDF is its proactive support for transformation, especially through safe-fail experimentation. Transformability of a system is underpinned by 3 determinants: preparedness to change, capacity to change and options for change (Walker and Salt 2012). The FDF supports all three, by helping in changing paradigms towards accepting the need for transformation where needed, and providing funding for experimentation with transformative practices and approaches that go beyond current best practice. One of the most important lessons we learned is that change, especially transformative, takes time, hence the new suite of longer and larger programs (DAFF 2025b).

As mentioned above, the FDF recognises and focusses on fostering networking and collective adaptive learning and action to achieve shared resilience and sustainability outcomes (DAFF 2025b). In addition to the approaches mentioned above, and as part of its new suite of programs, the FDF provides funding for a strong MEL strategy. Having a robust MEL system enables both learning and sharing knowledge. Evaluation of earlier FDF program, currently underway, will help us determine and share how and to what extent FDF is succeeding and contributing to the broader resilience and sustainability ecosystem. We also created a MEL Community of Practice (COP) where our staff, stakeholders and external experts exchange ideas and share insights and lessons learned. We equally participate in other government COPs and working groups, and have an ongoing collaborative engagement with industry and research. All this work allows FDF to contribute to breaking silos.

The FDF recognizes that dealing with complex systems is itself a complex task. Behaviors, beliefs, world views, values and knowledge that influence actions and attitudes of people need to be taken into account to build trust and openness and achieve change (Dyball and Newell 2015). Policies that do that probably work best, and this has been our experience. Giving our delivery partners ownership of program design and outcomes is proving to be empowering and motivating. This is helping FDF to facilitate changing behaviors and promoting adoption of resilience practices, approaches and systems at scale. Delivery of various programs by consortia of partners further enables that, by aiming to collectively achieve change beyond projects' life and scope (DAFF 2025a).

Conclusion

There is a current momentum to build resilience to drought and broader climate risks. FDF is a key player in that, given the nature of its activities, robust theoretical foundations, and the perpetuity of its funding. Implementing its various approaches puts the FDF in a unique position to contribute to policy, on one hand, and academic deliberations of social-ecological resilience theory on the other. The more the FDF evolves and learns, the better it will get at that. This is a remarkable opportunity that needs to be leveraged and supported, and it is. FDF is effectively an enabler of systemic and transformational change, through continued experimentation, learning and sharing knowledge with its networks of stakeholders and partners. As Walker (2020) states, transformational change "*is and will always be an ongoing process of exploring, learning and keeping options open*".

Heritage beef cattle genetics: A climate adaptation tool in desert rangelands

Estell, R[1]; Spiegal, S[1]; Cibils, A[2]; Nyamuryekung'e, S[3]; McIntosh, M[4]; Duni, D[5]; Torell, G[6]; Rodriguez Almeida, F[7]; Blanco, L[8]; Herrera Conegliano, A[8]; Armstrong, E[9]; Utsumi, S[6]; Bestelmeyer, B[1]

Key words: Criollo**;** ranching; cow-calf; resilience

Abstract

Climate trends are exacerbating the challenges associated with raising beef cattle in desert rangelands. In the North American Southwest, where longer heat spells and extended drought periods are becoming more common, increasing levels of costly external inputs are required to wean a crop of marketable calves every year. A group of scientists at the United States Department of Agriculture Agricultural Research Service Jornada Experimental Range provided leadership for an international team of researchers who examined the feasibility of using heritage Criollo cattle as a climate adaptation tool in desert ranching systems. Criollo cattle exhibit phenotypes thought to be largely shaped by natural selection which is known to favor rusticity traits at the expense of rapid growth rates and offspring weight. Over the past 20 years, the team studied grazing behavior, animal production (including meat quality and yield), and the economics of raising Criollo cattle. A recent special issue of Journal of Arid Environments titled '*Heritage cattle genetics as a potential climate adaptation strategy for producers in arid regions*' compiled 12 articles that report results from this large research effort. Fifteen years of research results largely confirmed anecdotal accounts regarding the desirable grazing traits present in Criollo cattle. Our data strongly suggest that Criollo heritage genetics could be an important adaptation tool for desert cow-calf systems. Raising Criollo cattle could be a means of strengthening the economic sustainability of desert beef cattle ranching systems

Introduction

Ensuring food and nutrition security in a hotter world with more frequent extreme weather events will require developing resilient crop and livestock genetics (Mbow et al. 2019). Modern high-producing crops and livestock have been selected for enhanced production in high-input systems. Over the past six decades, per capita food production worldwide increased 30% subsidized by a 100% and 800% increase in irrigation water and nitrogen fertilizer use, respectively (Mbow et al. 2019). The long-term sustainability of such approaches to agriculture and food production are increasingly uncertain.

Frequently overlooked indigenous and heritage crops and livestock possess remarkable drought and heat tolerance traits shaped by centuries of close-to-natural selection (Mbow et al. 2019). The value of natural vs. artificial selection was perhaps most eloquently articulated by Charles Darwin (1872) over a century ago. In 'The Origin of Species by Means of Natural Selection', Darwin frequently drew parallels between natural and human-driven selection of organisms (wild vs. domestic). He argued that 'Man selects only for his own good: Nature only for that of the being which she tends' (p.65). This powerful idea, which Darwin would likely word somewhat differently today, captures the essence of differences in climate adaptation potential of commercial vs. heritage crop varieties and livestock breeds. There is growing consensus nowadays about the urgent need to recuperate indigenous and heritage genetic material and assess its potential to contribute to climate adaptation and mitigation of global agricultural systems (IPCC 2019).

In this context, an international team of researchers in North and South America came together to summarize research findings from 15 years of studies comparing aspects of rangeland cow-calf systems that raise commercial (British) vs. heritage (Criollo) cattle. Criollo, also referred to as Creole cattle, are a heritage type of livestock brought to the Americas by conquistadors more than five centuries ago (Anderson et al. 2015; Armstrong et al. 2022). Spanish, Portuguese, and African breeds provided the genetic basis for these cattle that spread rapidly throughout the Americas. By the end of the 19th Century, commercial breeds had mostly displaced Criollos to marginal regions unsuitable for specialized beef and dairy newcomers (Armstrong et al. 2022). Anecdotal accounts of ranchers from South to North America who raise these cattle consistently point to their ability to thrive under harsh conditions. The objective of this paper is to summarize research published recently in a special issue of Journal of Arid Environments that focused on the use of heritage cattle genetics as a potential climate adaptation strategy for producers in arid regions (https://www.sciencedirect.com/special-issue/103WLV70KVZ). Much of this research was both motivated by and co-produced with ranchers seeking novel climate adaptation solutions.

Methods Overview

Foraging patterns and thermotolerance of Criollo vs. British beef cows

Grazing behavior results summarized here are from studies ranging from one to three years in duration conducted between 2005 and 2021 at sites in the Chihuahuan Desert, New Mexico, USA (Nyamuryekung'e et al. 2022; Roacho Estrada et al. 2023), Colorado Plateau, Utah, USA (Duni et al. 2023), California Chaparral, California, USA (Duni et al. 2023), Sierra Madre Foothills, Chihuahua, Mexico (Roacho Estrada, et al. 2023) and Arid Chaco, La Rioja, Argentina (Herrera Conegliano et al. 2022). Mean annual precipitation at research sites ranged from 600 mm at the California site to 207 mm in Utah.

Raramuri Criollo was the heritage breed used at the four North American sites, and Argentine Criollo was used at the South American site. Phenotypic characteristics, origin, and ancestry of each of these biotypes are discussed in detail by Armstrong et al. (2022). Commercial beef breeds included Black Angus (California, Chihuahua, and La Rioja), Red Angus (Utah), Hereford (Chihuahua) and Black Angus x Hereford crossbred cattle (Chihuahua and New Mexico). At each site cattle grazed undisturbed in extensive rangeland pastures.

In all cases, study protocols were approved by the corresponding Animal Care and Use Committees. Raramuri Criollo cows used at the North American sites were on average 179 kg lighter than their commercial breed counterparts (388 vs. 564 kg for R. Criollo vs. beef breeds), whereas Argentine Criollo cows weighed roughly the same as their Angus counterparts (400 vs. 420 kg, for A. Criollo vs. beef breed). Five to eleven cows of each breed were fitted with GPS collars at each site. GPS data were used to calculate movement, activity, habitat use, and social cohesion metrics.

One of the Chihuahuan Desert studies included fecal sample collection for diet analysis (Estell et al. 2022). DNA metabarcoding was used to determine the proportion of plant species in fecal samples collected from 10 cows of each breed during the growing and dormant seasons for three consecutive years. DNA metabarcoding with chloroplast gene trnL primers were used. Plant taxa were identified using the global and locally developed reference libraries (Estell et al. 2022).

Body temperatures were measured in another of the Chihuahuan Desert studies using temperature loggers affixed to a blank CIDR (Controlled Internal Drug Release device) devoid of hormones inserted intravaginally and set to record body temperature at 10 min intervals (Nyamuyekung'e et al. 2022). Temperature loggers were deployed on 6 to 11 cows fitted with GPS collars with temperature sensors in summer and winter during two consecutive years. Logger data were compared with GPS collar and weather station temperature sensor readings. Soil surface temperature was mapped via a 30 x 30 m pixel raster file derived from the thermal infrared band 10 of the Landsat 8 satellite.

Economics of raising Criollo vs. British cattle in the Chihuahuan Desert

The profitability of raising Criollo cattle in an alternative production system (grass finishing) in the Chihuahuan Desert was investigated by producing enterprise budgets for a herd of Raramuri Criollo cattle at the USDA ARS Jornada Experimental Range (Chihuahuan Desert Research site; Torell et al. 2023). Costs, returns, and beef production rates and practices for the typical commercial breed ranch (4662 ha; 150 Animal Unit Year) were defined from published budgets and summary statistics. Property and livestock taxes were defined using mill rates ($1 in taxes per $1,000 in taxable value) for Southwest New Mexico counties. Revenues for the herd were calculated based on expected sale weight and price for the year 2013, considering steers and heifers sold and retained, as well as cull animals (Torell et al. 2023).

Results

Foraging patterns and thermotolerance

Across all sites and seasons, compared to commercial cows, Criollo cattle traveled on average 2 additional km each day, explored twice the area (206 vs 110 ha/day for Criollo and British cows, respectively), grazed about the same amount of time (~ 9 h/day), and showed more dispersed foraging tactics by traveling greater distances and covering larger areas for every hour they spent grazing (see data summary in Cibils et al. 2023). Breed differences were typically greatest in the dormant season. Criollo cattle showed significantly greater ability than British breeds to make seasonal (dormant vs. growing) and annual (dry vs. wet) adjustments in foraging behavior (Cibils et al. 2023). Criollo and Criollo crossbred steers finished on grass in the Chihuahuan Desert showed grazing patterns similar to those of Criollo cows (McIntosh et al. 2021).

At the Chihuahuan Desert site, Criollo cows showed less herd cohesion, spent less time in each landscape pixel and revisited previously grazed sites less often (Nyamuryekung'e et al. 2022 and Spiegal et al. 2019) than their British counterparts. Criollo cows also spent less time grazing patches dominated by black grama (*Bouteloua eriopoda*), a palatable Chihuahuan Desert grass of high conservation value, and tended to include less of this species in their diets compared to commercial beef cows (Nyamuryekung'e et al. 2022, Estell et al. 2022). Criollo cattle diets tended to include more mesquite (*Prosopis glandulosa*) and Yucca (*Yucca spp.*) than diets of their British peers. At the Utah and California sites, Criollo cattle were more likely to forage in shrub dominated areas and tended to spend less time in sensitive riparian lowlands (Duni et al., 2023) compared to their Red and Black Angus counterparts.

Criollo cattle were better able to cope with Chihuahuan Desert summer heat relative to British cows; they exhibited lower body temperature and higher collar temperature (ambient heat in the proximity of the animal) during the hottest hours of the day. Breed differences in activity (Criollo > British) were greatest during the hottest hours of the early afternoon (Nyamuryekung'e et al. 2021).

Economics

Criollo cattle in the Chihuahuan Desert had lower operating and overhead costs when compared to British beef cattle. This reduction in costs allowed the Criollo cattle operation modeled in this study to have greater net returns to land and risk when compared to a typical desert beef cattle operation. Importantly, grass-finished Criollo steers in the Chihuahuan Desert exhibited excellent meat quality parameters (McIntosh et al. 2021), a finding that is consistent with earlier South American research (Anderson et al. 2015; Armstrong et al. 2022).

Discussion and conclusions

Fifteen years of research results largely confirmed anecdotal accounts regarding the desirable grazing traits present in Criollo cattle. These characteristics, which are thought to favor overall animal fitness, likely evolved through centuries of close-to-natural selection. Our data strongly suggest that Criollo heritage genetics could be an important climate adaptation tool for desert cow-calf systems. Raising Criollo cattle could be a means of strengthening the economic sustainability of desert beef cattle ranching systems. Research addressing the environmental, economic, and social sustainability (including tradeoffs) of raising heritage beef in desert ranching systems is currently underway (Spiegal et al. 2023).

Balancing challenges and benefits: climate change impacts and microclimatic regulation by *Macrochloa tenacissima* in north African arid steppe

Krichen, K; Chaieb, M

Laboratory of Biodiversity and Ecosystems in Arid Environments (LEBIOMAT), University of Sfax, Faculty of Sciences, Sfax 3000; Tunisia

Key words: *Macrochloa tenacissima*; Temperature; Precipitation; Moisture; Bare soil; climate change.

Abstract

Macrochloa tenacissima steppes in Tunisia are facing significant challenges due to the effects of climate change, which exacerbate the problem of desertification. *Macrochloa tenacissima* L. play a critical role in regulating microclimatic conditions and it is considered as a nurse species. An urgent need for sustainable land management and conservation strategies of *M. tenacissima* to mitigate the adverse effects of climate change and desertification on arid steppes. This study examines both the impacts of climate change on these steppes and the beneficial effects of *M. tenacissima* tussocks on microclimate regulation. Historical trends and future climate projections in Tunisia were studied in relation with the distribution of *M. tenacissima* steppes. Furthermore, microclimatic stations with temperature and moisture sensors were used to explore microclimate conditions under tussocks and in bare soil. Our findings reveal that rising temperatures and altered precipitation patterns are reducing the extent of *M. tenacissima* habitats, affecting biodiversity and ecosystem services. Concurrently, *M. tenacissima* tussocks create microhabitats with lower soil temperatures and higher moisture levels, enhancing water infiltration and reducing evaporation rates. These microclimatic modifications are essential for maintaining soil health and supporting biodiversity. This dual role underscores the importance of *M. tenacissima* in both mitigating adverse climate impacts and promoting ecosystem resilience. Effective conservation and sustainable management practices are essential to leverage these benefits, ensuring the stability and productivity of Tunisia's arid landscapes in the face of ongoing climate change.

Introduction

Climate change is a major issue impacting species distribution across ecosystems, community dynamics, and ecosystem functioning (Weiskopf et al. 2020). Endemic species are the most susceptible to climate change, which are plants that only exist in restricted distribution regions with distinct ecological characteristics (Refaat et al. 2024). Variations in temperature and precipitation patterns cause spatial and temporal species distribution change, often leading to biodiversity loss and alteration of ecological interactions. Changes are most evident in arid and semi-arid areas, such the steppes of *Macrochloa tenacissima*. In these ecosystems, microclimatic conditions, temperature and humidity variations, play a crucial role in species' responses to climatic changes (Tan et al. 2023). Macro- and micro-climate heterogeneity exposes populations to mosaics of resource availability, varying abiotic conditions, and influencing biotic interactions (Denney et al. 2020). Tussocks *M. tenacissima*, a dominant perennial grass in Mediterranean steppes, exemplify such microhabitats. Acting as nurse plants, these tussocks modify the surrounding microenvironment by reducing soil erosion, enhancing soil fertility, and regulating temperature and humidity (Navarro et al. 2008). These facilitative interactions are essential for seedling establishment, community stability, and ecosystem resilience. Understanding the interplay between climate change, and microclimatic conditions is crucial for predicting species distribution patterns and managing fragile ecosystems like *M. tenacissima* steppes. This study explores the critical role of microclimatic conditions and the current and future species distribution patterns in responses to climate change in arid and semi-arid ecosystems in order to establish a rescue program for *Macrochloa tenacissima* to ensure its survival and to maintain the health of arid ecosystems.

Methods

Study Area and Microclimatic Data Collection

The study was conducted in Tunisia, covering its diverse climatic and ecological zones. Microclimatic conditions were monitored over one year using sensors installed at a height of 2 m above ground to measure air temperature (°C) and humidity (%), and at soil level to record soil temperature (°C) and soil moisture (%) in bare soil and under tussocks in Kasserine region. Measurements were recorded at hourly intervals. Occurrence data for the target species (*Macrochloa tenacissima*) were obtained from field surveys. These data were used to model habitat suitability under current and future climatic conditions.

Environmental Variables

Climatic variables for the current period were sourced from WorldClim at a spatial resolution of 30 arc-seconds (~1 km^2) representing the historical climate data (1970-2000). Future projections were based on the HadGEM3 climate model for the SSP5-8.5 scenario, representing the years 2081-2100. Five bioclimatic variables (e.g., maximum, mean, and minimum annual temperature and mean annual precipitation) were selected based on ecological relevance. Elevation data were included to test topographic influences.

Habitat Suitability Modeling

MaxEnt (Maximum Entropy Modeling) was used to predict habitat suitability under both current and future conditions. The model was trained using occurrence data and current environmental layers. Predicted suitability maps were generated for both scenarios and classified into binary maps using a threshold value of 0.5, representing areas of suitable habitat. The total area of suitable habitat was calculated by summing the pixels with values exceeding the threshold and converting this to square kilometers.

Statistical Analysis

Different statistical analyses, models and Maps of current and future suitability were analysed and fitted using R software. A post hoc Tukey test at $p < 0.05$ determined differences among microclimatic conditions.

Results

Microclimatic conditions

The soil temperature and humidity under *M. tenacissima* tussocks were lower than bare soil (Fig. 1). Air and bare soil temperature almost displayed the same value. The temperature under tussocks is 1.61°C lower compared to bare soil. The mean air temperature was 25.4°C. The soil moisture showed a better response under tussocks, with a mean humidity difference of 2.26%. The mean air humidity was 52.7°C. The mean soil humidity is 10% lower than air humidity.

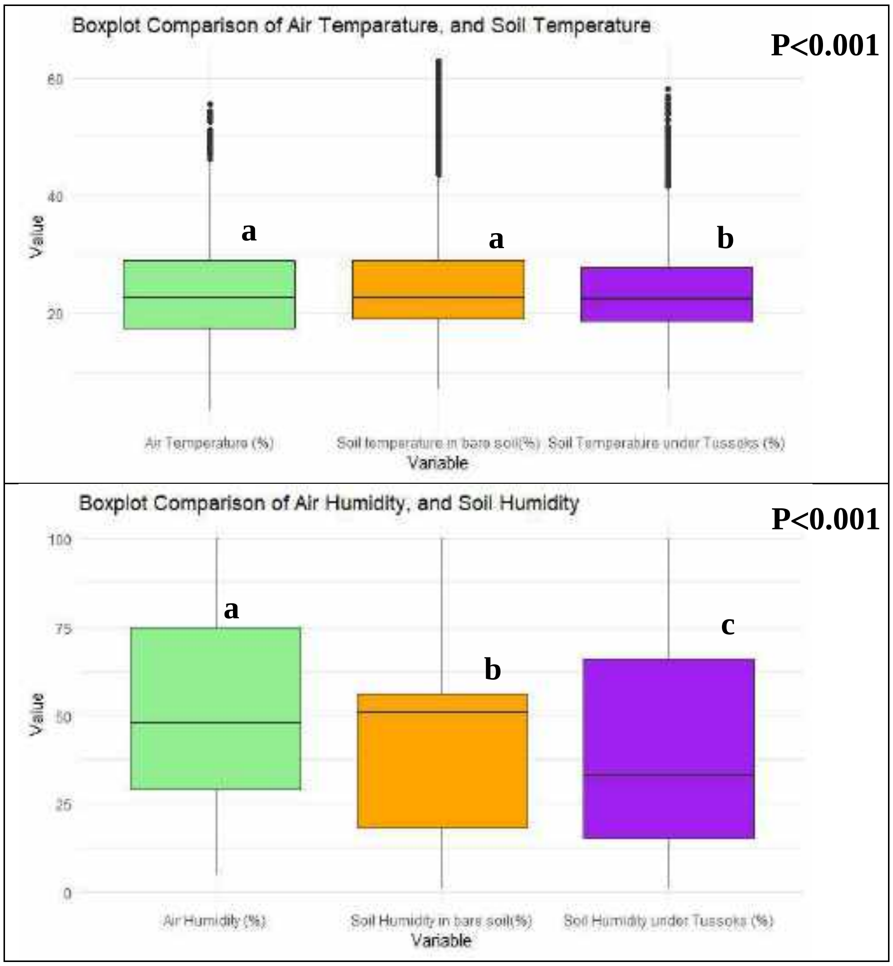

Fig.1. Boxplot comparison of air and soil temperatures and humidity under tussocks and bare soil.

Species distribution model

The binary maps indicate a clear reduction in suitable areas under future climate conditions of *Macrochloa tenacissima*, particularly in Kasserine region (Fig. 2.). The total suitable area decreases from 6735 km² to 4290 km², resulting in a net loss of -2445 km². Some areas, like Matmata mountain (Gabes) show new suitability under future conditions, but these gains do not offset the losses.

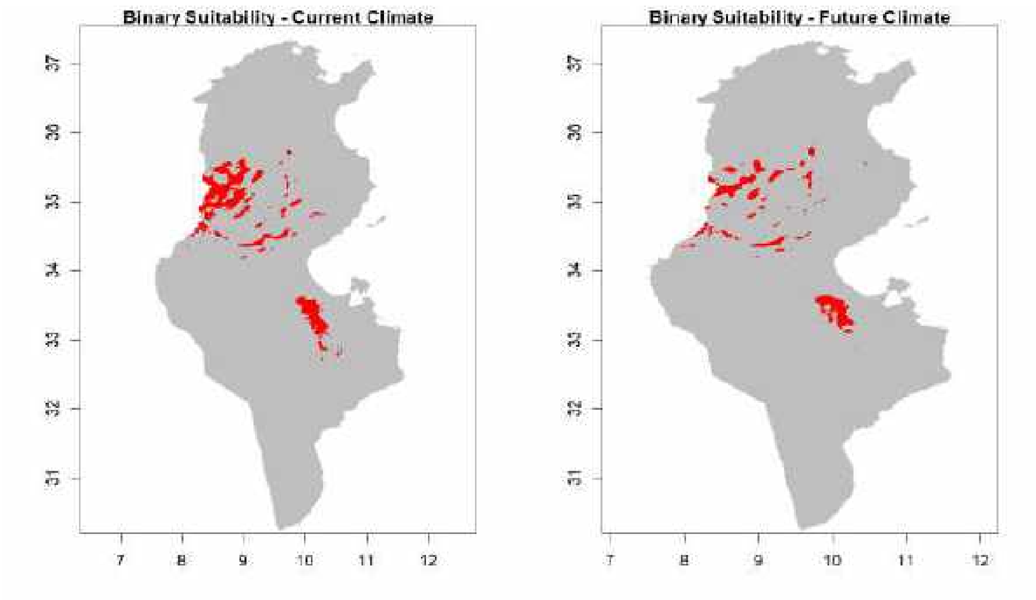

Fig. 2. Binary Suitability Maps for Current and Future Climate at 0.5 thresholds, with suitable region shown in red and non-suitable region in white.

Discussion [Conclusions/Implications]

The nurse and microclimate enhancer effects of *Macrochloa tenacissima* have been documented in several scientific studies (Navarro et al. 2008; Saiz and Alados 2011). Our study gives a precise projection by providing microclimatic conditions in each minute under the tussocks and in bare soil associated with atmospheric temperature and humidity. The presence of *M. tenacissima* moderates' temperatures and retains moisture, leading to better micro-environment conditions compared to bare soil. The Shade soil reduces direct solar radiation, preventing soil evaporation quickly which helps to retain moisture and regulate temperature fluctuations (Navarro et al. 2008). Under *M. tenacissima* tussock the temperature is decreased by about 2°C and the humidity is enhanced by 2%. The amelioration of arid microclimatic conditions facilitates co-occurring conditions for other species (Saiz and Alados 2011). The soil temperature under the tussocks is generally lower than that of bare soil, especially during the hottest parts of the day. Navarro et al. (2008) found higher K+, organic carbon, carbon:nitrogen ratio, and available water content inside and below the tussocks. In *M. tenacissima* steppe, under harsh climatic conditions, adaptation of co-occurring species results in facilitation by the amelioration of arid microclimatic conditions (Navarro et al. 2008; Saiz and Alados 2011).

The analysis of the species distribution model proved that *M. tenacissima* steppe occurred in Kasserine region and Matmata Gabes. It is generally related to the Tunisian Dorsal mountains chain, Matmata Mountains and steppes ecosystems characteristic of central Tunisia. The results showed that climate changes will significantly affect *M. tenacissima* suitability. According to the Maxent model maps, the suitable area will differ between current and future, the current distribution will decrease considerably. Ben Mariem and Chaieb (2017) found the same tendency of the decline of *M. tenacissima*. However, these authors found that *M. tenacissima* current cover (2000) was about *19304* Km^2 which could be very high in relation to the field observation. In this regards, Le Houérou (1995) estimates the *M. tenacissima* steppes cover to 32,000 km^2 in the western Mediterranean Basin. This finding confirms our estimation and reflects the significant habitat loss that *M. tenacissima* has experienced in Tunisia over recent decades due to climate change, land degradation, and changes in land use (e.g., overgrazing, agricultural expansion, and urbanization).

In conclusion, *Macrochloa tenacissima* is an important species to combat desertification, especially in arid areas. It plays a protective role by creating a microclimate that favors the growth of other plants and participates in the ecosystems' functioning. Since the species' suitable habitat is expected to decline in the future, there is a pressing need for a conservation program for *M. tenacissima*. Conservation in such areas is important to protect this species and the associated ecosystem services.

‘Place-based’ planning and governance for drought resilience - Southern Queensland, Australia.

Lyons, Ben[1]; Mellor, R[2]; Drysdale, A[2].

[1] Institute for Resilient Regions -UNISQ, *Ben.Lyons@unisq.edu.au*; [2] Institute for Resilient Regions -UNISQ ; [2] Institute for Resilient Regions -UNISQ

Key words: drought; resilience; preparedness; planning

Abstract
The Australian Government launched the Future Drought Fund (FDF) in 2019 with an initial investment of $3.9 billion and $100 million per annum for program costs (Australian Government, 2024). Under the FDF’s core Regional Drought Resilience Planning (RDRP) program, regional communities across Australia have been supported to develop RDRPs including initiatives to build drought resilience through: better planning and preparedness; more effective responses during drought; and actions to build future resilience. In southern Queensland, the program has been jointly funded by the Australian Government and the Queensland Government, and delivered by UniSQ’s Institute for Resilient Regions (IRR) using their participatory planning model that was:

- 'Placed-Based' - involving three levels of government, NGOs, civil society, business sector and individuals.
- 'Holistic' - addressing impacts and proposing actions for: people & communities; regional economy; landscape & natural environment; and infrastructure & built environment.
- 'Co-Designed' - both the process and outputs have been created with local stakeholders.
- 'Locally-Voiced': the RDRPs capture the vital stories and knowledge of people in the region as well as data, science and advice from outside ‘experts’.

This paper describes the key learnings from IRR’s development of RDRPs in southern Queensland. It outlines: the model; the challenges encountered; and the solutions generated to meet these challenges. Lessons from this work should inform future drought resilience initiatives and governance arrangements.

Introduction
The Australian Government launched the Future Drought Fund (FDF) in 2019 with the aim to “…boost drought and climate resilience” by helping: “…farmers and producers to plan, access climate tools, and share resilient farming practices” and “…communities to plan, and fosters rural and regional leaders and networks” (Australian Government, 2024). The core RDRP program aims to move the management of drought from being reactive to proactive. The Institute for Resilient Regions at University of Southern Queensland (IRR) is a consortium member of the Regional Economies Centre of Excellence (RECoE) and is responsible for the design of the state-wide

RDRP program and the delivery across southern Queensland. Thus far, IRR has completed 5 Regional Drought Plans in southern Queensland that include practical and achievable actions to build drought resilience.

Methods

The Queensland Government replicated the regional boundaries of the Regional Resilience Strategies (QRA, 2020) for the RDRP program – 14 regions across the state. Whilst guided by broad instructions from government, IRR developed a co-design model (Mellor, 2022) that actualised the government goals of 'locally-owned, locally-led and co-designed'. The model (see Figure 1.) was highly participatory and included key elements of 'Collective Impact' (e.g. Kania and Kramer, 2011), 'Ethno-Narrative' research (Mellor, 2009) and 'Deliberative Decision-making' (e.g. Fishkin, 2009). Work with regional stakeholders was undertaken by multi-skilled and multi-disciplinary teams and the reiterative co-design process took between 12-18 months per region.

IRR chose to organise the examination of drought under four 'themes' (see Figure 2.): People, Culture & Community; Economy; Landscape & Natural Environment, Infrastructure & Built Environment. After testing with focus groups, a modified versions of Crossman's D-RAMP model (2018) was used to develop actions to: Plan/Prepare for Drought; Respond to Drought; and Build Resilience to Future Droughts (see figure 3.)

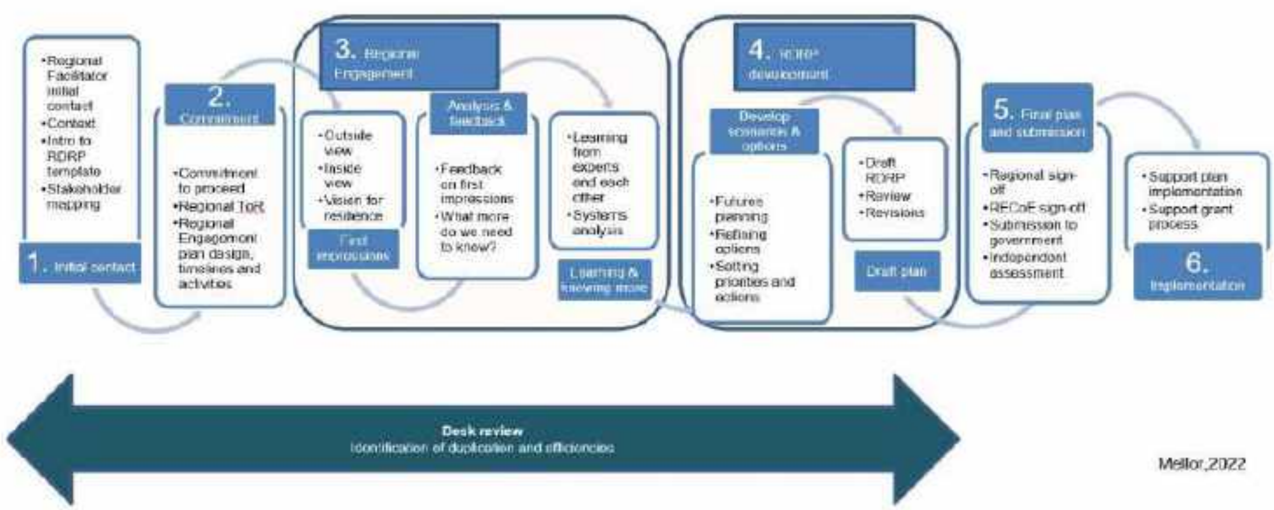

Fig. 1. IRR's participatory and deliberative model of engagement

Fig. 2. Queensland RDRP elements of drought resilience. Source: IRR

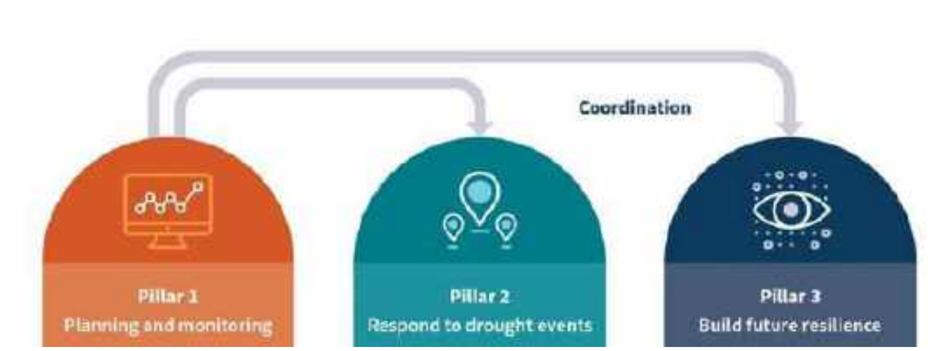

Figure 3. Modified D-RAMP Model. (Adapted from Crossman,2018)

Results

There are currently five completed Regional Drought Resilience Plans (RDRPs) for southern Queensland – some awaiting Ministerial approval. The RDRPs are documented 'Plans of Action' and are intended for use by the regions themselves as well as by government decision-makers and potential funders/investors. Our research and involvement in the RDRP project thus far has revealed a number of critical lessons, outlined below.

Drought Resilience Planning is more than just the Plan... it's the Process.

The process of engagement and co-design is a critical factor that: identifies community champions; brings together key stakeholders; provides 'backbone' support; and helps people in regions develop practical actions that meet their priorities. It involves important aspects of 'ethno-narrative' work as people are encouraged to tell stories of drought from their own perspectives and in their own words. They are also supported to explore possible scenarios and 'story-build' their agreed actions for future drought resilience. It requires a reiterative and deliberative process.

Hence, it takes time, it takes patience, and adequate scheduling must allow people 'pauses' and breaks to reflect, consider and learn more in order to make informed decisions.

Every region has its own unique 'Drought Personality' …so drought resilience planning has to be 'place-based'.

This work has revealed that the typography, impacts, and narratives of drought vary significantly from region to region. Climates, topography, hydrology, history as well as the past and present human interactions with the land, combine to create very different 'stories' of drought in different places. Drought amplifies existing place-based issues related to: community health and wellbeing; agricultural and business practices; remoteness; access and infrastructure; competitive (dis)advantage and the capacity of local communities to adapt and innovate. This complexity makes each region unique and requires a place-based approach to drought planning and governance. As noted by one participant, this requires "…*viewing the world from inside out*".

Place-based approaches require multi-disciplinary perspectives and multi-skilled teams.

Drought is not just about water, rainfall or climate. It is not just about the natural environment or human practices on that land. Drought is most beneficially viewed, concurrently, from multiple perspectives – we summarised them into four themes and that model proved practical and appropriate for working with regional stakeholders. This requires that the planning approach draws on a wide range of skills and perspectives. This can often be a challenge for government agencies that are typically organised around a single perspective or function.

Utilising many kinds of knowledge and information to make informed decisions.

Critical to our success has been a commitment to using (and respecting) many sources of knowledge to inform the process and assist communities to make better decisions. We have brought data, science, 'innovations' and so-called 'outside knowledge' into the regions we work with, but also valued the tremendous wealth of 'local knowledge'. Local knowledge has often been 'historical', 'traditional' or 'cultural', and in some cases we have been granted access to knowledge from traditional owners or First Nations people. It is critical to often 'triangulate' pieces of knowledge – in some cases they confirm the local stories, and in others they challenge historical tropes or offer new insights or possibilities. The challenge for scientists, academics, and 'experts' is to be able to communicate or 'package' their knowledge in such a way that it can be a valuable asset to a wide range of people and contribute to better local outcomes.

'Resilience' is hard to define…but that doesn't matter

The World Bank defined resilience as: "…the ability to anticipate, absorb, accommodate or recover from the effects of a hazardous event in a timely and efficient manner" (World Bank, 2019). However, in practice, resilience is much harder to define. For some (government agencies in particular) this is problematic and there are continued efforts from some quarters to define resilience 'more clearly or 'more precisely'. Our approach has been to embrace the lack of precise definition and use the question "What does resilience mean to you?" as a prompt to open valuable local conversations. Those conversations developed into collective, regional understandings of what resilience has meant in the past and what it could mean in the future. That understanding can then lead to developing and deciding on appropriate priorities and actions.

Conclusions

IRR's work on the Regional Drought Resilience Plans has provided not only important outcomes – the RDRPs themselves are now reliable and valued regional assets for future investment in, or decisions about, drought preparedness and resilience – but also highlighted some critical issues that should be considered in future programs related to building resilience to drought and climate variability. The work has also helped shape ideas about the governance processes and structures needed to effectively manage drought in the future.

Key words: Legume; persistence; *Arachis*; *Desmanthus*

Abstract

Over the decades, hundreds of pasture evaluation trial sites have been established across northern Australia with the aim of discovering plant accessions suitably adapted to particular climatic and edaphic conditions. The majority of such sites now lie abandoned, despite the fact that they represent a valuable repository of potentially useful genotypes, that have often been thoroughly tested by droughts, floods, fire, grazing and insect attack.

One such site was a legume evaluation trial established in 1992, at what is now the College of Public Health, Medical and Veterinary Sciences at James Cook University in Townsville. The objective of the trial was to evaluate the agronomic and morphological characteristics of 13 tropical pasture legumes sown on a low fertility, mildly acidic (pH 6.5), coastal duplex soil, with an AAR of 1,143 mm. The trial included a range of accessions from the genera *Arachis, Centrosema, Desmanthus, Glycine, Neonotonia, Macroptilium and Stylosanthes*. Following establishment, the site was abandoned after one season and has since endured heavy crash-grazing by sheep, earthworks disturbance, regular slashing, continuous macropod grazing pressure, and has been exposed to periods of significant drought over the last 32 years.

This paper summarises the results of the most recent survey of the site. Of the 13 genotypes originally planted, a number of resilient legumes continue to survive including *Arachis paraguanensis* (CPI 91419), *Desmanthus leptophyllus* (CPI 38351) *Stylosanthes hamata* cv. Verano and *Stylosanthes scabra* cv. Seca. These are persisting within a mixed sward dominated by *Chaemacrista rotundifolia*, *Bothriochloa pertusa,* and *Desmodium triflorum.* Additionally, *Centrosema brasilianum* (CPI 55698), and to a lesser degree *Macroptilium martii* (CPI 55782) were observed growing on a stream embankment, approximately 10 m from the site.

These surviving plants represent a potentially valuable collection of robust and persistent legumes, not only for northern Australia but similar climates across Africa, Asia and central and south America.

Introduction

Across northern Australia various institutions such as CSIRO, governmental agriculture departments, universities and seed companies have over the decades sown hundreds of pasture trials, consisting of multiple species and accessions with the aim of identifying new pasture plants that are well-adapted to particular edaphoclimatic conditions. Such trials are very often located on private properties and only receive operational funding for relatively short periods of time (2-4 years), before being discontinued and abandoned. The value of such sites however, is very often not exhausted at the conclusion of the associated experimental period as in many cases, many of the planted accessions possess traits for hard-seededness, permitting them to persist for decades.

As a result, such sites represent a valuable repository of potentially useful genotypes, that have often been thoroughly tested by droughts, floods, fire, grazing and insect attack. Such plants are potentially valuable not only for northern Australia but similar climates across Africa, Asia and Central and South America.

In 1992, one such legume evaluation trial was sown at the James Cook University Veterinary Science Precinct with the aim of evaluating the agronomic and morphological characteristics of thirteen tropical pasture legume accessions from the genera *Arachis, Centrosema, Desmanthus, Glycine, Neonotonia, Macroptilium and Stylosanthes* (Ossiya 1993). In 2024, a follow-up plant survey of the site was undertaken in order to identify persisting accessions. The results of this survey are summarised.

Methods

In 1992, a legume evaluation trial was sown at the James Cook University Veterinary Science Precinct (19_{0} 19’S 146_{0} 45’E) with the aim of evaluating the agronomic and morphological characteristics of the following 13 tropical pasture legume accessions:

- *Arachis paraguanensis* (CPI 91 4197)
- *Arachis paraguanensis* (CPI 1780) (formerly *Arachis erectoides* (CQ1780))
- *Arachis triseminalis* (CPI 91423) (formerly *Arachis pusilla* (CPI 91423))
- *Centrosema brasilianum* (CPI 55698)
- *Centrosema pascuorum* (CPI 55697)
- *Desmanthus leptophyllus* (CPI 38351)
- *Desmanthus virgatus* (CPI 79653)
- *Glycine latifolia* (CQ 3368)
- *Macroprilium martii* (CPI 55782)
- *Macroptilium bracteatum* (CPI 55770)
- *Neonotonia wightii* cv. Cooper
- *Stylosanthes hamata* cv. Verano
- *Stylosanthes scabra* cv. Seca

A factorial completely randomised block design was applied and included three blocks with three plots nested within each block. Within each block, the nested plots were assigned one of three superphosphate treatment rates (0, 125 or 250 kg/ha). The plot dimensions were 9.95 m x 2 m, thus providing a buffer spacing of 0.75 m between rows. The spacing between plots within each block was 0.5 m and 1 m between blocks.

The site is characteristic of a coastal, seasonally dry tropic environment and the soil is described by Murtha (1982) as a soil with a light grey-brown sandy loam A1 overlying a highly bleached sandy loam A2 horizon which changes abruptly to a mottled brownish grey and yellow brown heavy clay B horizon. The pH of both the A and B horizons is mildly acidic (pH 6.5). Following establishment, the site was abandoned after one season and has since endured heavy crash-grazing by sheep, earthworks disturbance, regular slashing, continuous macropod grazing pressure, and has been exposed to periods of significant drought over the last 32 years. The site has also endured significant climate variability since its establishment, including periods of significant drought.

In 2024, an approximate boundary of the old trial was demarcated using old photographs and satellite imagery for reference. Mowing was suspended for a period of three months from mid-January to permit sufficient regrowth for species identification, as well as an opportunity for surviving plants to flower and set seed. Following the spelling period, the entire site (200 m^2) was surveyed using a 1 m^2 quadrat. The top three dominant species (by visually estimated biomass) were recorded by two operators working in tandem for each quadrat. Individual plant counts were also performed for all occurrences of originally sown accessions present, with the exception of *S. hamata* and *scabra*, as these are naturalised and abundant within the local district. All sundry species present were also recorded.

Results

Of the 13 accessions originally sown, four were recorded persisting at the site 32 years after establishment including *A. paraguanensis*, *D. leptophyllus, S. hamata* and *S. scabra*.

A total of 80 *A. paraguanensis* plants were recorded across the site, equating to a plant density of 0.4 plants/m^2. Two *D. leptophyllus* plants were recorded, giving a density of 0.01 plants/m^2. As noted, *S. hamata* and *scabra* plants were not individually recorded.

Dominance rankings of all species are presented in Table 1. The most prevalent species was *C. rotundifolia*, which dominated 60% of quadrats followed *B. pertusa*, which dominated in 30% of quadrats. Both species ranked within the top three for dominance in 90% of quadrats. Other prevalent species recorded were *Sida rombifolia* and *Richardia brasiliensis*. Of the originally sown legumes, *S. hamata* ranked within the top three for dominance in 26% of quadrats, while *A. paraguanensis* and *D. leptophyllus* only ranked for dominance in three and one quadrat respectively. No visible effect of the phosphorus treatments was observed.

Table 4: Species dominance rankings recorded at the site from a total of 200 quadrats.

Species	*Number of times spp. recorded 1st dominant within a quadrat.*	*Number of times spp. recorded 2nd dominant within a quadrat.*	*Number of times spp. recorded 3rd dominant within a quadrat.*	*Weighted dominance score**
Chamaecrista rotundifolia	154	64	23	613
Bothriochloa pertusa	81	129	29	530
Sida rombifolia	15	15	20	95
Richardia brasiliensis	7	20	31	92
***Stylosanthes hamata* cv. Verano**	0	11	59	81
Eragrostis spp.	3	4	10	27
Alternanthera ficoidea	1	6	6	21
Corchorus olitorius	2	2	8	18
Alysicarpus vaginalis	1	3	5	14
Desmodium triflora	0	3	8	14
Ziziphus mauritiana	1	0	5	8
Desmodium scorpiurus	0	1	2	4
***Arachis paraguanensis* (CPI 91419)**	0	0	3	3
Desmanthus leptophyllus	0	1	0	2
***Stylosanthes scabra* cv. Seca**	0	0	2	2
Asteraceae spp.	0	1	0	2

Mimosa pudica	0	0	2	2
Ocimum americanum	0	0	1	1

* Species dominance records applied to weighting multipliers of 3, 2 and 1 for 1st, 2nd and 3rd dominance rankings respectively and summed.

Discussion

The most recent survey of the site indicates that of the 13 accessions originally sown, four were recorded persisting at the site 32 years after establishment including *A. paraguanensis*, *D. leptophyllus, S. hamata* and *S. scabra*. This represents a further decline in species representation since the previous survey of the site conducted in 2017, in which Gardiner et al. (2017) additionally recorded *C. brasilianum* in abundance and to a lesser extent *M. martii*. *A. triseminalis, C. pascuorum, D. virgatus, G. latifolia, M. bracteatum and N. wightii* were not recorded in either the present study or the 2017 survey and thus appear to have failed the test of time under the combination of edaphoclimatic factors and prevailing patterns of disturbance particular to the site. *S. hamata* and *S. scabra* are naturalised in the local area and are known to be well adapted to the region.

While a total of 80 *A. paraguanensis* plants were recorded, equating to an average plant density of 0.4 plants/m^2, it should be noted that these plants were not distributed uniformly across the site and tended to cluster in association with subterranean seeding from parent plants. These plants were also observed to be low yielding in comparison to *C. rotundifolia* and *S. hamata* and *scabra,* however it should be noted that analyses of other forage peanut accessions withing the *Arachis* genus have recorded nutritional values equivalent to Lucerne (Lascano 1994). Within the context of the seasonally dry tropics, any additional protein source within grass dominated pastures is potentially advantageous to livestock production. It is also interesting to note that while *A. triseminalis* has not persisted at this site, it continues to survive in harsher, lower rainfall inland sites such as Hillgrove Station, north of Charters Towers and at Redlands Station, west of Balfes Creek (Gardiner and Swan 2008, Gardiner, pers. comment).

D. leptophyllus has continued to persist at the site, despite not being as well adapted to the soil texture or the heavy grazing and mowing pressures characteristic of the site when compared to species such as *C. rotundifolia* and *S hamata* and *scabra*. It is likely that its persistence is due to the existence of an accumulated seed bank with a high degree of hard-seededness.

The environmental and stressors exerted upon the site over the years are reflected in the dominant species recorded (Table 1). These represent species that adapted to the seasonally dry environment, infertile soils and the continual pressure imposed by macropod grazing and mowing.

The original phosphorus treatment plots were not visibly discernible, however they may be influencing survival and plant dominance rankings, as phosphorus is known to be both critical for legume growth and persistence.

Of note is the observation that a number of the originally sown accessions were found persisting in an adjacent streamline at the time of the survey, including *C. brasilianum*, *A. paraguanensis* and to a lesser degree *M. martii,* and *D. leptophyllus*. *A. paraguanensis* has also been observed growing well and spreading steadily at another local alluvial site, having spread approximately 1m from the original planted row over the course of four years.

The value of such abandoned sites cannot not be overstated as they represent potentially valuable repositories of accessions that have been thoroughly tested by droughts, floods, fire, grazing and insect attack. These robust and persistent pasture legumes are of potential utility not only for northern Australia but similar climates across Africa, Asia and central and south America. Indeed, the value of such sites has been underscored in recent years by the development of several new commercial lines of *Desmanthus* and *Stylosanthes* that were originally observed to be thriving at abandoned historical trial sites spread across Queensland, some planted over forty years ago (Gardiner 2016, Gardiner and Swan 2008, Peck et al. 2021). It is recommended that research organisations continue to invest in identifying persistent accessions at discontinued experimental sites as they may hold considerable value for grazing industries in the future.

Ephemerals to the rescue! Or not?

Saayman, N[1]; Kirkman, K[2]; Swart, R[3]; Rheeder, CG[4]

[1] Western Cape Department of Agriculture, Elsenburg, South Africa, nelmarie.saayman@westerncape.gov.za; [2] University of KwaZulu-Natal, Pietermaritzburg, South Africa; [3] Western Cape Department of Agriculture, Worcester, South Africa; [4] Western Cape Department of Agriculture, Lambert's Bay, South Africa

Key words: seasonal grazing; arid; plant cover; rainfall

Abstract

The vegetation along the west coast of South Africa is known for the floral displays by ephemerals during good winter rain seasons. Previous studies found that livestock will preferentially consume ephemerals over perennials when available and concluded that the presence of ephemerals allows for perennial forage plants to rest and set seed, regardless of grazing taking place during the growing season. Do these conclusions stand up to scrutiny?

A seasonal grazing trial in which paddocks were grazed for three monthly periods, was conducted at the Nortier Research Farm on the west coast of South Africa from September 1989 – September 1995. In this region, rainfall occurs primarily in the winter months of May through to August. The percentage canopy cover of the perennial plant species and ephemerals were determined every year at the start, June, and end, September, of the winter-grazing season.

Autumn rain determined the percentage cover of ephemeral plants by June. When both autumn and winter were dry, both ephemeral and perennial plant cover decreased during the winter grazing season. In wet winters, when ephemerals are in abundance, the perennial plant cover increased toward the end of the grazing season.

When ephemerals were abundant in winter, it allowed for perennial plants to regrow despite grazing. Farmers should take autumn rainfall into account in their fodder flow planning for the coming winter months. Dry autumn months resulted in fewer ephemerals being present, which resulted in livestock utilizing a greater amount of the perennial plants. As a result, they received minimal rest during winter and should receive rest from grazing during spring.

Introduction

The vegetation along the west coast region of South Africa is known for its floral displays by ephemerals during good winter rainy seasons (Van Rooyen et al. 1991). Ephemerals are herbaceous plants which are available for livestock grazing for only a few months during the wet season (Samuels et al. 2016). Livestock will preferentially consume ephemerals, which usually have a high nutritional value, over perennials when available. It is assumed that the presence of ephemerals, and their appeal to livestock, allows for perennial forage plants to rest and set seed while ephemerals are abundant during the wet season (Samuels et al. 2016). However, it has not been tested whether ephemerals in abundance contributed to an improved canopy cover of perennial plants at the end of the grazing season.

The vegetation of the west coast region of South Africa is divided into two biomes, namely the Succulent Karoo to the north and Fynbos to the south (Mucina and Rutherford 2006). This arid region has a mediterranean climate with cool wet winters and hot dry summers and is recognized as a biodiversity hotspot (Mittermeier et al. 2011). The primary land use of the region is livestock grazing. Sustainable utilisation with livestock is thus very important to ensure the conservation of this highly biodiverse area.

The objective of this study was to 1) determine the effect of rainfall on the percentage cover of ephemerals and 2) determine if ephemerals in abundance have a positive impact on the canopy cover of perennial plant species grazed during the wet season.

Methods

The trial was conducted at the Nortier Research Farm on the west coast of South Africa in the Fynbos biome. The site has a mean annual rainfall of 200 mm, receiving 64% from May–August based on rainfall data recorded daily at the research farm. Nortier is situated in the West Strandveld bioregion, on undulating dune fields that supports tall dense shrubland, with dominant perennial plant species including *Ehrharta calycina*, *Eriocephalus racemosus, Roepera morgsana, Salvia lanceolata, Tetragonia fruticosa,* and *Willdenowia incurvata*, and ephemerals, mainly forbs, include *Oncosiphon suffructicosum, Senecio arenarius, Wahlenbergia annularis* and *Zaluzianskya affinis* (Mucina and Rutherford 2006).

A seasonal grazing trial ran from September 1989 – September 1995. Treatments included four grazing seasons (Spring, Summer, Autumn, Winter) and three stocking rates (Low, Moderate, High). Each paddock was grazed for three months and rested for nine months. There was a total of 12 treatments with two replicates each and in a completely randomised design. As the impact of grazing/browsing on vegetation can be measured by the change in the percentage canopy cover of plants (Du Toit 1998), plant surveys were undertaken using the descending point method (Roux 1963) to determine the percentage canopy cover of the perennial plant species and ephemerals. These surveys were undertaken every year in June at the start of the wet season and in September towards the end of the wet season in each of the paddocks. This coincided with the start and end dates of the winter grazing season.

Data were analysed using Pearson's correlation, ANOVA, Fischer's Least Significant Difference test, and linear regression analysis.

Results

The percentage cover of ephemerals in June is strongly correlated with the previous three months' rainfall (r = 0.850; $p < 0.0001$) regardless of grazing season, but especially with the previous month's rainfall (r = 0.870; $p < 0.0001$) (Table 1). No significant correlations ($p > 0.05$) were found between the cover of ephemerals and the previous three month's rainfall from surveys done in September, December, and March.

Table 1: Pearson's correlation coefficients between percentage canopy cover of ephemerals present in June and the rainfall of the previous month and previous three months at Nortier Research farm. All correlations were highly significant ($p < 0.0001$).

Grazing season	Previous month	Previous three months
Autumn	$r = 0.849$	$r = 0.823$
Spring	$r = 0.899$	$r = 0.881$
Summer	$r = 0.921$	$r = 0.914$
Winter	$r = 0.901$	$r = 0.861$
Overall	$r = 0.870$	$r = 0.850$

A strong positive correlation ($r = 0.731$; $p < 0.0001$) was found between the change in the canopy cover of perennial plants from before, to after the grazing season and the percentage cover of ephemerals before grazing commenced in June in the winter grazed treatment. The better the cover of ephemerals are before grazing the more the cover of the perennial plants will improve during the winter grazing period.

The ANOVA showed significant differences in the changes in canopy cover of ephemerals ($p < 0.0001$; F = 7.168) and perennial plants ($p < 0.0001$; F = 15.725) between the years. When the veld is grazed during the growing season (winter) the ephemerals and perennials decreased significantly when the rainfall was less than 50% of the average in the autumn, such as in 1991, regardless of good winter rain (Fig. 1). There was also a non-significant decrease in cover of both ephemerals and perennials after grazing during the winter of 1992 following autumn rainfall of less than 40% of the average. This small decrease was most probably because of the carry-over effect of the 70% above average rainfall received during the previous winter (Fig. 1). In 1995 when the autumn and winter rain were less than 10% below average, the ephemerals slightly increased during the winter, but it was not enough to supply sufficient fodder for the animals to not utilise the perennial plants that decreased significantly compared to the years when average autumn and winter rainfall were received. The winter rain of 1995 was not sufficient to allow for regrowth of the perennials in the presence of grazing (Fig. 1). When above average autumn and winter rain was received there was an increase in canopy cover of ephemerals and perennials from June to September in the winter grazed treatment (Fig.1). The linear regression analysis however showed an interaction with stocking rate, where canopy cover of perennials ($p < 0.01$) and ephemerals was greater in the low than moderate and high stocking rates, and rainfall for the last three months influenced ephemeral cover ($p < 0.01$) (Data not shown).

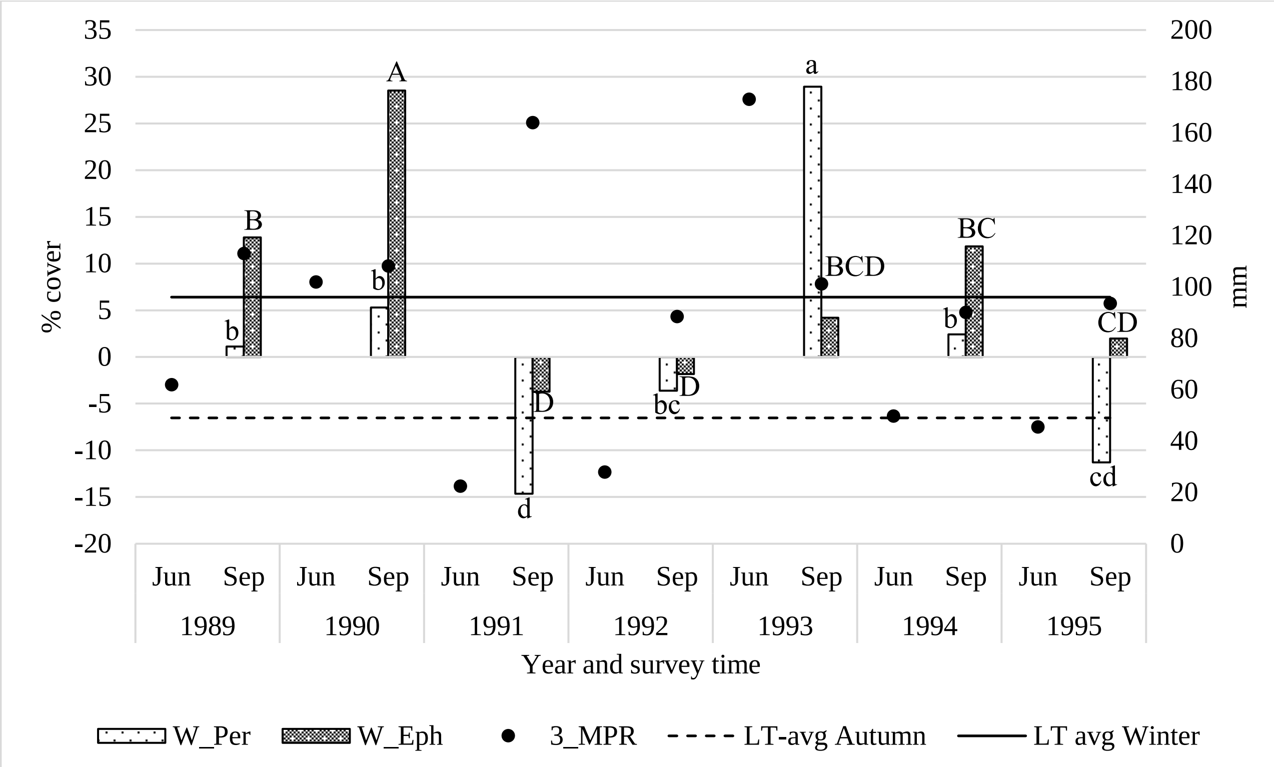

Fig. 1: The change in the percentage cover of the perennial plants and ephemerals, averaged across all stocking rates, during the winter (Jun -Aug) in the winter grazed treatments showing the rainfall (mm) in the three months prior to the surveys (3_MPR). W_Per = Winter-grazed treatment Perennial plants, W_Eph = Winter-grazed treatment Ephemerals; LT-avg Autumn = Long term average rainfall for Mar-May; LT-avg Winter = Long term average rainfall for Jun-Aug (Letters above bars indicate significant differences at the 0.05 level; small letters for perennials; capital letters for ephemerals)

Discussion

Different studies showed that rainfall of the preceding months plays an important role in the presence of ephemerals on the west coast of South Africa and other ecosystems across the world (Van Rooyen et al. 2018). In the transition zone between the Fynbos and Succulent Karoo on the west coast it is no different, as this study found a strong positive correlation between the cover of ephemerals present during June, at the start of the growing season, and the rainfall received during autumn and especially during the month of May. This is further supported by Van Rooyen et al. (1991) who found that ephemeral germination took place during autumn to mid-winter. Saayman et al. (2022) found that the grazing season and stocking rate are the drivers of vegetation change in this vegetation type, but it seems that for ephemerals, rainfall is the main driver of change (Van Rooyen et al. 2018) with only 5% of the change in ephemeral cover that is accounted for by grazing as found in another analysis in this study.

Ephemerals do not provide fodder for a long period of time and has little carry-over forage to the next season (Van Rooyen et al. 2018), but when present are preferred by livestock as a source of fodder over perennial plants (Samuels et al. 2016). This study found that after a dry autumn when the cover of the ephemerals was low at the start of the winter grazing season, little fodder from ephemerals was available and the livestock utilized the perennial plants more than they did during years with abundant ephemerals. In this situation, the cover of both the ephemerals and perennial plants decreased during the winter grazing season, ultimately lowering the cover of the perennial plants by the end of the grazing season (winter). In contrast, in wet years when ephemerals were abundant, the cover of the perennial plants increased by the end of the grazing season, since livestock likely have preferentially grazed ephemerals, allowing perennial plants to grow and increase in cover (Samuels et al. 2016). Applying low stocking rates will also have a positive impact on the growth of perennials during winter grazing.

Conclusions and Implications

Ephemerals make a large contribution towards the fodder supply during winter and spring in the winter rainfall region of South Africa and are largely dependent on the rainfall received during the month of May. This study supports the notion that when ephemerals are present in abundance during the winter grazing period it allows for perennial plants to regrow and set seed.

Farmers should take the autumn rainfall into account in their grazing management planning for the coming winter months. Dry autumn months will result in fewer ephemerals. This implies less forage material from ephemerals and livestock will utilize more of the perennial plants, lowering its cover. Therefore, the plants won't get the anticipated rest during winter and should receive rest from grazing during spring.

Abstract
Climate change is projected to diminish the rainfall and lead to more frequent droughts in the cold arid desert of the west coast of South Africa. Long-term area-wide precipitation trend analysis indicates all-year reductions, but particularly in autumn (March–May), driven by the poleward contraction of mid-latitude storm tracks. The region has historically reliable winter precipitation and generally very dry summers. This study analysed the 60-year rainfall and 56-year ungrazed perennial plant cover recorded at Nortier Research Farm in the West Strandveld bioregion to identify possible climatic shifts, and the relationships between rainfall, Standardized Precipitation Index (SPI) and perennial cover. The hypotheses were that rainfall in a certain period preceding the plant survey is a strong predictor of perennial cover, and that climate change is already driving changes in cover. No significant rainfall trends were found but there was a shift towards wetter summers in the last 30 years. The Standardised Precipitation Index (SPI) indicated moderately to extremely dry years in 1966–1973. Apart from 1978 and 2017, no other drought periods (SPI $\leq$ -1.0) were identified. Around eight years were moderately to very wet (SPI $\geq$ 1.0) and occurred randomly. The study found a strong positive correlation (r^2 = 0.524) between the rainfall of the previous 18 months and the perennial plant cover, supporting the hypothesis that preceding rainfall is a strong predictor of perennial cover. However, no discernible changes driven by climate change were found. Rangeland managers should take the rainfall of the previous 18 months into consideration when making grazing decisions. Weather monitoring is continuing to track possible long-term climate changes. This research contributes to understanding the impact of climate change on arid regions.

Introduction
Perennial vegetation forms the basis of terrestrial ecosystems and rainfall is a key driver of vegetation dynamics. In semi-arid regions, plant cover is sensitive to rainfall variability, seasonality and cyclic droughts (Munson et al. 2016). Projected more frequent and extended droughts and rising temperatures under climate change will reduce water availability and negatively impact the vegetation.

The semi-arid southern west coast of South Africa has a Mediterranean-type climate with very dry summers and reliable winter rainfall, receiving less than 250 mm of rain per annum (Mucina and Rutherford 2006). The region is renowned for the high species diversity and endemicity of the Fynbos and Succulent Karoo biomes. A moderate and stable climatic history is key to this diversity, and the vegetation could be highly vulnerable to climate change

(Midgley and Thuiller 2007). Grazing of more palatable species and rainfall variability combine to determine plant cover in semi-arid south-western South Africa (Saayman et al. 2022). While research has focused on leaf- and stem-succulent shrubs and rare species, little information is available on total perennial cover in relation to short- and long-term rainfall dynamics, especially when livestock are excluded over a long period.

In this region, climate change will likely reduce rainfall, and droughts will become more frequent and intense. Some sub-regions may experience much stronger rainfall reductions than others due to different climatic drivers (Wolski et al. 2020). The long-term (1900–2020) area-wide precipitation trend analysis (Jack et al. 2022) shows a significant reduction in autumn (March–May) rainfall, associated with the poleward contraction of the rain-bearing mid-latitude cyclones and the dynamics of the Southern Annular Mode (Wolski et al. 2020).

This study focused on a coastal area that is historically cool and semi-arid with winter rainfall but is projected to shift in future towards hot and arid. Changes in perennial plant cover are expected to be driven by both short- and long-term rainfall dynamics. The hypotheses for this study spanning 57 years (ungrazed vegetation) were that rainfall in a certain period preceding the plant survey is a strong predictor of perennial cover, and that climate change is already driving changes in cover.

Methods

The study was conducted on the Nortier Research Farm near Lambert's Bay (-32.03524; 18.33274) on the west coast of South Africa. It is situated in the West Strandveld bioregion, a transitional zone between the Fynbos and Succulent Karoo biomes (Mucina and Rutherford 2006) and receives on average 205 mm rain per annum. Fifty eight percent of the rain falls during the winter months of June to August with only 8% falling during the summer months.

Daily rainfall data were collected on the farm since 1964. Livestock grazing was excluded from one of the paddocks, the Reserve, from 1965. Forty-six plant surveys, measuring plant cover and species composition, were done from 1967 until 2023. For the plant surveys the descending-point method (Roux 1963) consisting of 1000 points on a fixed line was used, recording canopy-spread cover of all the plants encountered at each point.

Using the data for 1964–2023, the Standardised Precipitation Index (SPI) was calculated to assess the degree of meteorological drought (National Drought Mitigation Center 2018). The monthly rainfall and ungrazed perennial plant cover data for 1967–2023 were analysed using Principal Component Analysis (PCA), Ward's Clustering and ANOVA to determine significant differences between clusters. Linear regressions were performed to determine if rainfall can predict perennial plant cover. All data was analysed using XLSTAT (Addinsoft 2023).

Results

The SPI shows moderate to extreme dry years (SPI < -1) from 1966 to 1973. Thereafter, there were no more periods of drought, except in 1978 and 2017. In the 60-year period, there were eight years that were moderately to extremely wet (SPI > 1), but these occurred randomly (Fig. 1).

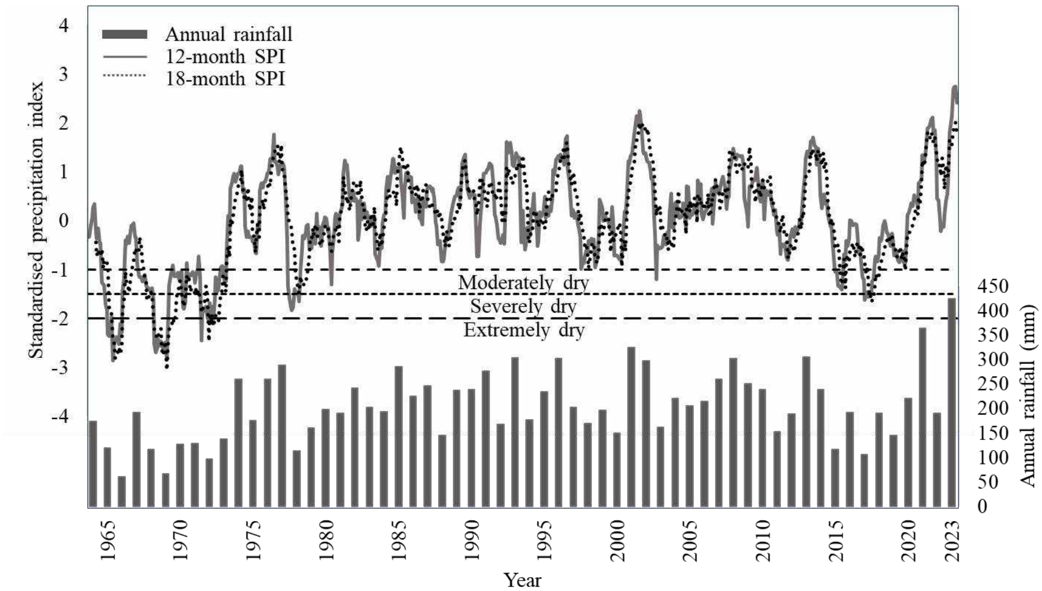

Fig. 1 Annual rainfall at Nortier Research Farm in 1964-2023 (bars) and expressed as Standardised Precipitation Index (SPI) for 12-month and 18-month periods, highlighting periods of increasing dryness.

To determine if there were any trends in the rainfall over time, further analysis using Principal Component Analysis (PCA), was done. Ward's clustering grouped the rainfall into five clusters, namely, driest years (all seasons), drier summers than usual, drier winters than usual, wetter summers than usual, and wetter winters than usual. From the PCA and Ward's clustering there were no definite trends, except for a shift towards wetter summers in the last 30 years (Fig. 2). The year 2023 was an outlier with a wetter summer than normal, and the wettest winter on record.

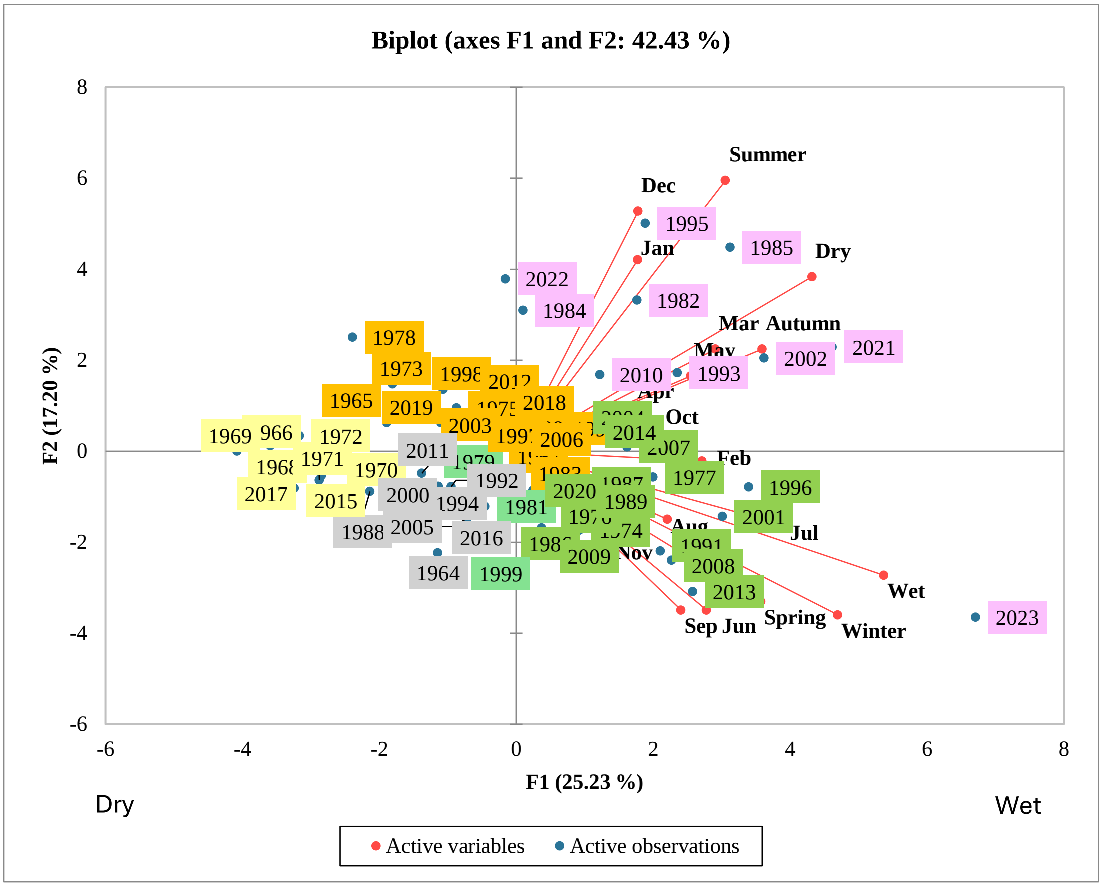

Fig. 2 Principal Component Analysis (PCA) of rainfall data from 1964–2023 at Nortier Research Farm. Ward's clustering is indicated with different colours (green = wetter winters; pink = wetter summers; grey = drier winters; orange = drier summers; yellow = driest years overall).

The study found a relatively strong positive correlation ($r^2 = 0.524$) between the rainfall of the previous 18 months and the perennial plant cover. A highly significant linear regression model ($p < 0.0001$) using the previous 18 months rainfall (18moPr) was developed to predict the perennial vegetation (Perennial = 27.613+0.178*18moPr). All the recorded plant cover values fell within the 95% confidence limits of the predicted plant cover.

Discussion

In a previous study of the succulent karoo (Hoffman et al. 2009), SPI analysis also identified drought periods in the 1960s–1970s and no significant trends in mean annual rainfall for 1900–2000. Despite the severely dry year of 2017 and an extended dry period in 2015–2019 at Nortier, the mean annual rainfall during the last 30 years (1994–2023) was higher (+37.2 mm) than in the first 30 years (1964–1993). Wolski et al. (2020) analysed the 2015–2017 rainfall anomalies across the southern winter rainfall region in the context of the 1900–2017 data set. Spatially and seasonally different rainfall trends in the short- and long-term are influenced by different climate drivers. The sub-region around Nortier commonly showed a wetting trend in 1981–2014, and the Nortier station itself experienced a weaker drought in subsequent years.

Our findings of summer wetting at Nortier align with previous studies (Wolski et al. 2020; Jack et al. 2022). This trend is likely associated with local, non-hemispheric process drivers such as cut-off lows, ridging highs, and convective summer rainfall. A possible increase in the latter may be associated with the increased convective available potential energy (CAPE) and regional synoptic changes brought about by climate change. Advective moisture-bearing coastal fog associated with the cold Benguela current is prevalent in summer, but analyses of trends and future projections of fog are unavailable (Midgley and Thuiller 2007). These drivers require further research.

The relatively strong positive correlation found between rainfall in the preceding 18 months and the perennial plant cover indicated that rainfall is a strong predictor of perennial plant cover in the absence of grazing and that there is a carry-over effect from the rainfall received in the previous seasons (Hoffman et al. 2009). This implied that there will be less cover following dry years and the vegetation will take longer to recover after a drought (Munson et al. 2016). If droughts along the west coast become more frequent it will negatively impact the perennial vegetation and ultimately the fodder availability for herbivores, increase the soil erosion potential and have a negative effect on essential ecosystem services (Munson et al. 2016). Rangeland managers should take the rainfall of the previous 18 months into consideration when making grazing decisions to lower the impact of droughts.

The second hypothesis, that climate change is already observed and driving changes in plant cover, was not supported. The 60-year observed Nortier data set showed no evidence of long-term reductions in annual or seasonal rainfall as projected (Jack et al. 2022). This may, however, change in the future as hemispheric and local climatic drivers respond. Therefore, weather and vegetation monitoring efforts are continuing to track possible long-term climate changes and their impact on the vegetation.

Abstract
Mulga (*Acacia aneura* and related species) is a drought-tolerant tree that dominates large parts of Australia's arid and semi-arid zone. Following a severe drought in 2017-2019, mass mortality was reported across the distribution of mulga. In 2021-2022, there was substantial rainfall in some regions that was expected to stimulate a mulga recruitment pulse. In this study, we quantify mortality and recruitment following these events in two land uses that differ in their grazing pressure. We surveyed inside and outside the Arid Recovery Reserve, Roxby Downs, SA. Inside the conservation reserve, small native mammals are present—bettongs, bandicoots, and bilbies. Outside the reserve, the land is managed for pastoralism, with livestock, native kangaroos, and feral rabbits. During 2023-2024, we surveyed ten 0.5 ha plots in each land use. In each plot, we counted alive and recently dead mulga plants to quantify mortality and mulga seedlings to assess recruitment. We found that adult drought mortality was 1.8 times higher outside the reserve (50%) than inside (28%). Recruitment after the rainfall was insufficient to offset the drought mortality in either land use type. Inside the reserve, plots had 0.01 seedlings per dead adult and outside the reserve, there were no seedlings. Our results reveal high drought-induced mortality in mulga is exacerbated outside reserves, where livestock and feral animals are present. Low subsequent recruitment indicates that these mulga populations may be at risk. It is imperative to predict mulga population trajectories to conserve the vegetation and functioning of Australia's arid and semi-arid ecosystems.

Introduction
Mulga (*Acacia aneura* F. Muell. Ex Benth and nine related species; Miller et al., 2002) are dominant or co-dominant trees throughout much of Australia's large arid and semi-arid zone. Droughts and high temperatures are common in the Australian arid/semi-arid zone. Mulga has several adaptations, such as phyllodes, to cope with these stressful conditions. However, during the 2017-2019 drought, large dieback events in mulga were reported anecdotally across its distribution. During this period, rainfall was approximately half the long-term average (Bureau of Meteorology, 2023a). Additionally, many regions experienced their highest temperatures on record, especially during the dry months. Dieback events in mulga have occurred in the past (Evans, 1903; Godfree et al., 2019). However, with ongoing climate change, hot and dry conditions are predicted to increase in frequency and intensity (Jenkins and Warren, 2015).

Previous research indicates that mulga mortality is a function of rainfall deficit (Fensham et al., 2019) and other factors such as soil depth which determines water availability (Fensham, et al., 2012). Additionally, heavy grazing pressure can intensify mortality rates (Evans, 1903; Godfree et al., 2019) by reducing water availability due to reduced water infiltration and retention capacities (Witt et al., 2011), and by reducing nutrient availability due to lower diversity and cover of soil crusts (Williams et al., 2008). To predict the likely trajectory of mulga populations in the future, it is essential to quantify mortality and its dependence on climate and other factors. Additionally, an important question is whether recruitment will be sufficient to maintain the population despite severe dieback. Previous research suggests recruitment in mulga is particularly contingent on the timing and intensity of rainfall (Preece, 1971a and b) and is also strongly affected by grazing pressure (Hall et al., 1964; Munro et al., 2009). In 2021-2022, following the drought, significant rainfall occurred in some regions: annual rainfall totals in parts of central South Australia were 100-200% higher than the long-term averages (Bureau of Meteorology, 2023b). The rainfall may have stimulated a recruitment pulse.

Here, we quantify the 2017-2019 drought mortality and 2021-2022 rainfall-induced recruitment in mulga to assess if recruitment offsets mortality, under two land use types that differ in their grazing communities. We surveyed plots inside a conservation reserve (Arid Recovery Reserve), which has small native herbivores, and outside the reserve, on pastoral stations, which have livestock, native kangaroos, and feral rabbits. We compare i) drought-induced mortality and ii) recruitment between the two land use types. We hypothesise that mortality rates will be higher in the pastoral regions because mortality increases with grazing pressure, which we assume to be higher where livestock and feral grazers are present. We also hypothesise that seedling recruitment will be higher inside the reserve where livestock and feral grazers are excluded.

Methods

The study was conducted in and around the Arid Recovery Reserve (-30.33943 N,136.89982 E), near Roxby Downs, South Australia (Fig. 1). This fenced conservation reserve (123 km^2) was established in 1997 (Moseby and Read, 2006). In the part of the reserve where we conducted the study, all herbivores were removed in 1998 and native small herbivores were reintroduced over time, including western barred bandicoots, burrowing bettongs, and greater bilbies (Munro et al. 2009). Outside the reserve, on the adjoining pastoral stations, the chief herbivores are cattle, native kangaroos, and feral rabbits. The different grazing communities inside and outside the reserve represent the two land use types in this study. During 2017-2019, hot-dry conditions prevailed in the study area. The long-term average annual rainfall in the area is 182 mm (at Andamooka Station, Bureau of Meteorology 2023c). During the three years of the 2017-2019 drought, the mean annual rainfall was 86 mm, causing a cumulative rainfall deficit of 288 mm over the period. The long-term average daily maximum temperature of the driest quarter (January to March) is 34.8°C. During the drought, the average was 1 – 1.2°C higher, with some days hitting the highest on record at 48.1°C. However, above-average rainfall followed in 2021-2022. In these two years, the average rainfall was 231 mm, ~50 mm more than the average, and the average dry-quarter maximum temperatures dropped to 33.7°C.

In each land use type, we surveyed ten plots. Each plot was a circle of 40 m radius (0.5 ha) centred on an adult mulga tree. In each plot, we counted alive and recently dead adult mulga plants, and seedlings. Plants were classified as '*alive*' if green leaves were present. Plants were classified as '*recently dead'* if green leaves were absent, but fine twigs were present, and bark was intact; indicating that these plants died following the recent drought. Plants ≥2 m in height were classified as adults which have a recruitment potential, as most of these had flowers or pods. Plants ≤0.3 m in height were classified as seedlings and assumed to have recruited following the 2021-2022 rainfall events. We tested the effect of land use type on mortality and recruitment using a generalised linear model (Dobson 1990). For comparing mortality and recruitment percentages, the response variable was the ratio of the counts to the total with binomial family and logit link (i.e., the response variable for mortality was the number of recently dead tree counts divided by the total number of alive and recently dead trees and, total as weights). All analysis was done in R v.4.2.1 (R Core Team, 2022). The study area map was made using QGIS v.3.30.3 (QGIS.org, 2023).

Results

The average adult (alive and recently dead) density of mulga was 78 trees ha^{-1} inside the reserve and 59 trees ha^{-1} outside the reserve. The 2017-2019 drought caused an average mortality of 39% in mulga adults. Plots outside the reserve recorded higher adult mortality (50% outside and 28% inside, $p<0.01$) (Fig. 2). Despite the above-average rainfall in 2021-2022, a recruitment pulse was not observed. Only one plot inside the reserve had any evidence of recruitment, with one seedling present. Outside the reserve, no plots had seedlings. The recruitment did not offset the observed mortality. There was only one seedling for 288 dead adults.

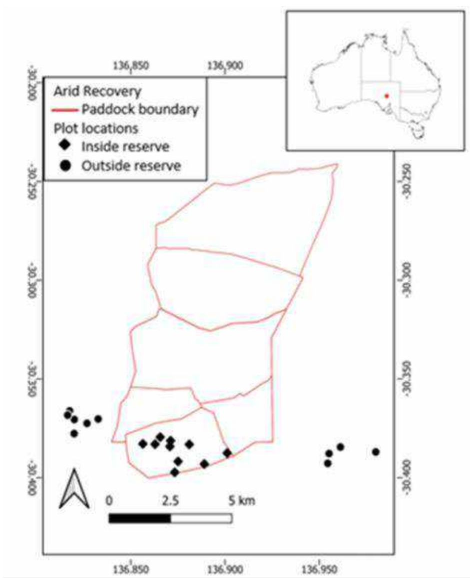

Fig. 1: Plot locations inside and outside the Arid Recovery Reserve. The map inset shows the location of the Arid Recovery Reserve within Australia, in a red star.

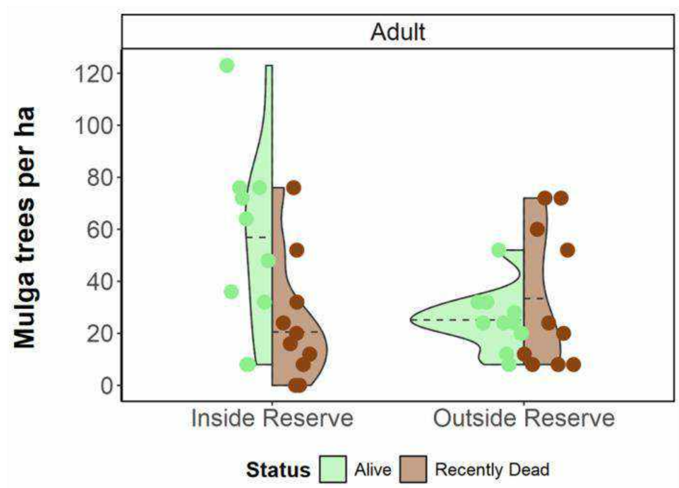

Fig. 2: Number of alive and recently dead mulga adults (≥2 m height) in plots inside and outside the Arid Recovery Reserve. The dashed lines indicate the respective medians.

Discussion

Many regions of Australia received less than half their average rainfall during 2017-2019, along with record-high temperatures. In the study area, this 3-year rainfall deficit and high temperatures caused significant mortality in mulga (39% of all adult plants). Moreover, despite above-average rainfall during 2021-2022, a recruitment pulse has not occurred (only one seedling was observed across all plots). The high mortality and low recruitment indicate that subsequent recruitment was insufficient to offset the occurred drought-induced mortality. The high mortality rate, coupled with poor subsequent recruitment rates, could lead to a local population decline in mulga. Drought-induced population declines are not restricted to our current study area; surveys during 2021 at Uluṟu-Kata Tjuṯa National Park also reported a 42% drought mortality in mulga (Wright et al., 2023). While drought-induced mortality has occurred in the past (Fensham et al., 2019), the lack of recruitment despite the subsequent above-average rainfall highlights the need to assess the population trajectory of mulga under a changing climate.

To understand population trajectories, it is vital to examine the drivers of mortality and recruitment. From our study and others (Fensham et al., 2019; Wright et al., 2023), it is evident that a rainfall deficit of less than half of total rainfall that lasts more than one year causes considerable dieback in mulga. This threshold can vary with soil depth (Fensham, et al., 2012), but this was not tested in this study.

Our study indicates that increased grazing pressure exacerbates drought-induced mortality. We found that the grazed areas outside the reserve had 1.8 times higher mortality than inside, supporting our hypothesis that mortality rates are higher where livestock and feral grazers are present. Anecdotal reports from the 1900s (Evans, 1903 in Fensham et al., 2019; Godfree et al., 2019) indicate high mortality in mulga occurred in overgrazed areas, but few studies have systematically studied the interaction between drought and grazing in determining mortality. Fensham et al., (2012) assessed mulga mortality as a function of a grazing intensity index (distance to watering points) but did not find a consistent relationship between grazing intensity and mortality rates. However, heavy grazing pressure reduces water availability and nutrient availability (Witt et al., 2011; Williams et al., 2008), indicating mechanisms by which grazing could increase drought-induced mortality.

Mulga seedlings were too rare in either land use to draw conclusions on the drivers of recruitment. However, recruitment clearly has not offset the drought-induced mortality.

The preliminary analysis presented here demonstrates an important effect of grazing on drought-induced mortality. Reducing grazing pressure may be important for maintaining mulga populations under future climate conditions. In future work, we will analyse the relationship of recruitment and mortality rates to more detailed drivers, including impacts of different grazer types and other factors such as soil and topography.

Abstract

Soil erosion poses a significant global threat, leading to widespread land degradation and the depletion of nutrient-rich topsoil. Understanding the spatial distribution of soil erosion is crucial for implementing effective management practices and preventing further erosion. This study utilized an analytical tool integrating the Revised Universal Soil Erosion Equation (RUSLE) with geographic information systems (GIS) to estimate water-induced soil erosion across the rangelands and other land use categories in Ethiopia. Rangelands, constituting 68% of Ethiopia's total land area, are essential for the livelihoods of millions of pastoralists and agropastoralists. Input data for the analysis were gathered from multiple sources, including in situ observations and remotely sensed data with various spatial resolutions. The estimated soil erosion rates were validated using previously published data from literature. Our results revealed significant variation in soil erosion, ranging from zero to 250 t ha^{-1} yr^{-1}. The average soil loss across the country was estimated at 13.5 t ha^{-1} yr^{-1}, amounting to an annual soil loss of about 1.5 billion tons, making Ethiopia one of the most severely affected countries by soil erosion worldwide. Disaggregated annual soil erosion estimates indicated that the highest soil loss occurs in rangelands (18 t ha^{-1}), sparsely vegetated (bare land) areas (16 t ha^{-1}), cultivated areas (10 t ha^{-1}), and forest areas (8 t ha^{-1}). These results underscore the urgent need to implement appropriate soil and water conservation practices across rangelands, embracing Sustainable Land Management practices that can significantly reduce soil erosion. Such efforts will support sustainable land resource use and potentially unlock new opportunities for the country.

Introduction

Water-induced soil erosion is a leading cause of land degradation worldwide, resulting in the loss of nutrient-rich topsoil. This process not only diminishes agricultural productivity but also disrupts ecosystems and contributes to reservoir sedimentation (Nathan et al., 2022; Stocking, 2003). Water-induced soil erosion presents significant challenges for sustainable land management and environmental conservation efforts. Although this issue affects regions globally, it is particularly severe in sub-tropical and tropical areas (Lal, 2001). In Africa, the threat of soil erosion poses a substantial risk to food security (Gomiero, 2016; Hossain et al., 2020; Rhodes, 2014). This challenge is further intensified by factors such as climate variability, unsustainable land management practices, and population pressure. Tackling soil erosion requires a comprehensive strategy that includes estimating its current and future spatial distribution, setting priorities, and implementing sustainable land management practices in vulnerable regions. This can be achieved using various models to assess current levels of erosion and forecast future trends.

There are various ways of estimating the spatial distribution of water-induced soil erosion, encompassing both biophysical and empirical statistical models (Borrelli et al., 2021; Golmohammadi et al., 2014; Pal and Chakrabortty, 2019; Wang et al., 2011). These models focus on evaluating the effects of agricultural management practices on several parameters, including plant growth, soil erosion, and surface runoff at various scales and environmental conditions.

Biophysical models require extensive data inputs for accurate parameterization and calibration, such as daily climate and streamflow data, soil properties, and sediment data. This reliance on detailed data can be a limitation in areas with limited data availability. In contrast, empirical models, like the Universal Soil Loss Equation (USLE) and its updated version, the Revised Universal Soil Loss Equation (RUSLE), offer simpler approaches, using fewer input parameters to estimate soil erosion. USLE incorporates core factors influencing soil erosion, such as rainfall intensity, soil type, landscape position, and land use. RUSLE builds on USLE by adding factors that account for erosion control practices and integrates these into computer applications, providing more refined estimates.

RUSLE’s ability to capture the effects of soil and water conservation practices allows it to assess management strategies' effectiveness in reducing soil erosion. The choice between biophysical and empirical models depends on the purpose of the study and data availability: while biophysical models require extensive, high-resolution data, empirical models need fewer inputs and deliver reasonably precise results. Additionally, empirical models like RUSLE are compatible with spatial applications, making them advantageous for mapping soil erosion.

Researchers and land managers use RUSLE to assess and manage soil erosion risks, guide land-use planning, and develop erosion control strategies. The model is particularly valuable in identifying areas vulnerable to soil erosion, understanding the impact of different factors on erosion rates, and evaluating the effectiveness of soil conservation practices. RUSLE has been widely applied in agricultural and environmental research, contributing to sustainable land management practices and erosion prevention strategies.

This specific study concentrates on assessing the spatial distribution of soil erosion in the rangelands and other land use groups of Ethiopia. The objective of this study is, therefore, to integrate RUSLE within GIS and evaluate the spatial distribution of soil erosion across Ethiopia. This study will contribute to the body of knowledge on soil erosion, which has limited comprehensive studies across Ethiopia.

Methods

The spatial distribution of soil erosion across the rangelands and other land use groups of Ethiopia were estimated using the RUSLE method. The methodology involved mapping essential factors such as rainfall intensity, soil texture and organic carbon content, landscape position, land use, and conservation practices, which significantly contribute to soil erosion. Those factors under RUSLE were represented with rainfall erosivity factor (R-factor), soil erodibility factor (K-factor), slope length and slope steepness factor (LS-factor), land cover management factor (C-factor), and conservation practice factor (P-factor). Input data required to estimate RUSLE factors, including annual average rainfall from 2000 to 2020, were collected from ground observation stations and Climate Hazards Group InfraRed Precipitation with Station data (CHIRPS) when there is no or limited gauged rainfall data. Additionally, information on soil texture and organic matter, digital elevation model (DEM), and land use/cover were gathered from diverse global data sources with various spatial resolutions. The diverse factors were mapped, resampled, and overlaid using the ArcGIS platform to compute the spatial distribution of soil erosion. The validation of the estimated soil loss across the three countries was undertaken through a thorough literature review, which involved an examination of existing scientific studies and reports. This process aimed to assess the accuracy and reliability of the soil loss estimates generated using the RUSLE integrated with GIS. Finally, the soil erosion was disaggregated across the different land use groups and reported.

Results

Spatial Distribution of the Soil Erosion Factors

Rainfall erosivity (R-factor) in Ethiopia ranged between 64 and 1,388 MJ mm ha^{-1} hr^{-1} yr^{-1}, averaging 510 MJ mm ha^{-1} hr^{-1} yr^{-1}. The southeastern region exhibits the highest rainfall erosivity, while lowland areas that receive less than 300 mm of annual rainfall experienced the lowest rainfall erosivity. High R-factor values indicate strong rainfall energy, which can lead to significant soil erosion.

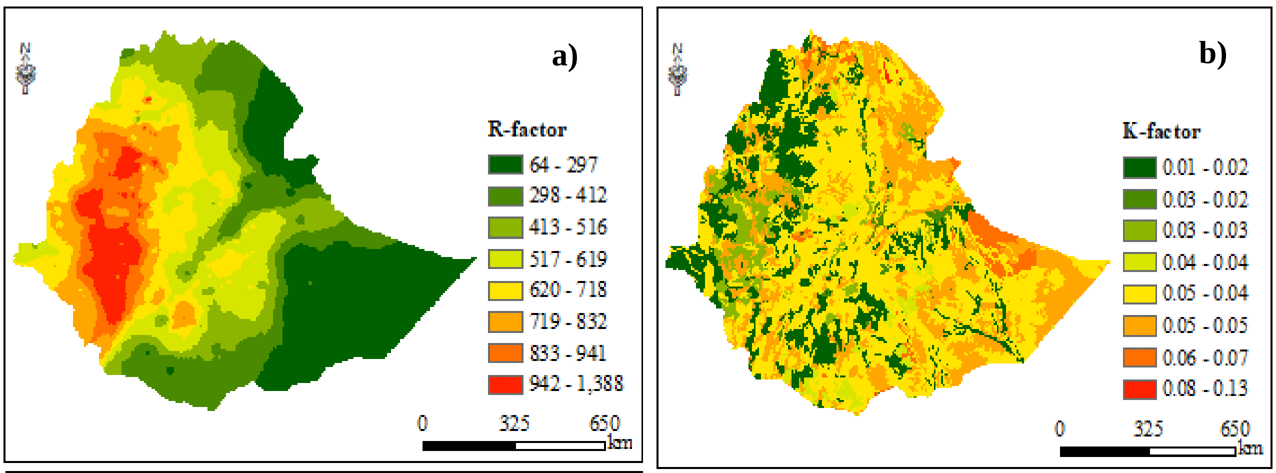

Figure 1. a) Rainfall erosivity (R-factor) [MJ mm ha^{-1} hr^{-1} yr^{-1}] and b) Soil erodibility (K-factor) [t ha hr ha^{-1} MJ^{-1} mm^{-1}] of Ethiopia.

The soil erodibility factor values estimated across Ethiopia ranged from 0.01 to 0.13 t ha hr ha^{-1} MJ^{-1} mm^{-1}, averaging about 0.04. The result of the analysis, in general, indicated that soil textures, including clay, silty clay, and silty clay loam, have lower K-factor values since those soils are resistant to particle detachment. Meanwhile, coarse-textured soils with lower resistance to detachment, such as sand, loamy sand, and sandy loam, were characterized by a higher K-factor value, signifying higher erosion rates.

The slope length and slope steepness factor (LS-factor [unitless]) estimated across Ethiopia exhibited the most significant variability with a coeffect of variation of 606%. The average LS-factor value for Ethiopia was approximately 13.2. The average C-factor for Ethiopia, determined from land use/cover conditions was approximately 0.15. A higher C-factor value signifies a higher potential for soil erosion under the current land cover and management condition. The conservation practice factor (P-factor) value estimated using slope class and land use condition indicated an average value of 0.66 across the country.

RUSLE Estimated Annual Soil Loss.

The estimated annual soil erosion rate in Ethiopia varied from zero to more than 250 t ha^{-1} yr^{-1}, with a coefficient of variation of 380%, showing a significant variation due to the largest range in rainfall, soil, and altitude. The average soil loss across the country was 13.5 t ha^{-1} yr^{-1}, which amounts to an annual soil loss of about 1.5 billion tons, making Ethiopia one of the most severely affected countries by soil erosion worldwide (Tamene and Vlek, 2008; Tsegaye, 2019). Levels of soil erosion estimated across the major land use groups indicated that the highest soil loss is estimated in the rangelands (18 t ha-1), sparsely vegetated (bare land) areas (16 t ha^{-1}), cultivated areas (10 t ha^{-1}) and forest areas (8 t/ha). Soil erosion was classified based on severity classes as indicated in Haregeweyn et al. (2017); the results show that 21% of the country is experiencing "Moderate" to "Excessive" soil erosion risk, of which 4% is "Severe" and 6% is "Excessive". The remaining 79% of the country is experiencing "Low" and "Very Low" erosion risk. The finding of this work is consistent with Tsegaye (2019) and Tamene and Vlek (2008). From among the 72 administrative zones in Ethiopia, the highest soil erosion is estimated in Hadiya (45 t ha^{-1}), Dawuro (38 t ha^{-1}), and Wolayita (27 t ha^{-1}), located in the Southern Nations and Nationalities region, and in Wag Hemira (32 t ha^{-1}) and East Gojam (30 t/ha) in the Amhara region. Soil erosion in Ethiopia is one of the most serious causes of soil degradation, which has been directly linked to a substantial decrease in soil fertility and crop yield (Aleminew and Alemayehu, 2020; Taddese, 2001; Yebo, 2015). This underlines the urgent need for soil conservation measures across the country.

Discussion and Conclusions

This study highlights the urgent soil erosion risks affecting Ethiopia's rangelands, revealing critical insights for sustainable land management in regions essential to the livelihoods of pastoralists and agropastoral communities. The RUSLE-GIS-based analysis illustrates that rangeland, covering the majority of Ethiopia's land, face the highest rates of soil erosion, estimated at 18 t ha^{-1} annually. Given that these areas are vital for livestock and agriculture, the findings underscore a pressing need for targeted soil and water conservation practices in Ethiopia's rangelands to mitigate erosion and its adverse effects on land productivity and environmental health.

High rainfall erosivity and soil erodibility in specific regions further exacerbate the erosion risk, particularly in Hadiya, Dawuro, Wolayita, Wag Hemira, and East Gojam zones, which show some of the highest soil loss rates. This calls for immediate action in these zones through localized erosion control practices, emphasizing sustainable land management practices like reforestation, conservation tillage, and optimized grazing management to protect soil resources.

The study's findings reinforce the need for policy interventions that prioritize soil conservation strategies, particularly in the most vulnerable rangelands. Integrating these practices into Ethiopia's broader environmental policy and development programs could significantly alleviate soil degradation. Further research could refine the model by incorporating additional local data, enabling even more accurate soil erosion mapping and, ultimately, more effective interventions. In conclusion, this study offers a critical foundation for advancing Ethiopia's land conservation efforts, aiming to support sustainable land use while protecting vital rangeland ecosystems.

THEME 6. LIVESTOCK PRODUCTION SYSTEMS IN A WORLD OF CHANGING DRIVERS

Animal productivity

A general faecal nitrogen model for estimating intake in cattle and sheep fed multi-species native forage

Savian, JV[1]; De Barbieri, I[1]; Azevedo, EB[2]; Jaurena, M[1]; Kozloski, GV[2]

Key words: faecal crude protein; grazing; Pampa biome; rangeland; ruminant

Abstract

The Rio de la Plata grassland ecoregion in southern America, which includes Uruguay, south of Brazil and part of Argentina, plays a crucial role in providing feed to livestock in outdoor extensive production systems due to its high plant species richness, chemical composition and annual production. Estimating animal intake in this heterogeneous grassland environment poses a significant challenge. Therefore, our goal was to develop a general linear regression model based on faecal nitrogen excretion (FNe) to estimate organic matter (OM) intake in cattle and sheep fed multi-species native forage using data from different zones of the Rio de la Plata region. We collated data from previous studies conducted based on the same protocol in Brazil and Uruguay, comprising 219 individual observations (72 from cattle and 147 from sheep); 15 data points from sheep in Uruguay remain unpublished. The trials were conducted using metabolism cages and animals were fed fresh or hay native forage. Mixed linear models were developed using R software. The best-fitting model was selected based on the Bayesian information criterion (BIC) and Akaike information criterion (AIC). The predictive accuracy of the fitted OM intake model was evaluated using 5-fold cross-validation. The resulting linear regression model revealed a positive relationship between FNe and OM intake ($p < 0.001$; $R^2 = 0.851$) across the entire dataset [Intake (g OM/kg BW/day) = 3.335 + 106.321 × FNe (g N/kg BW/day)]. The animal species effect was not significant ($p = 0.337$). Pearson correlation between predicted and observed values of the animal forage OM intake model was 0.957, with a root mean square error (RMSE) of 1.598, a mean absolute error (MAE) of 1.241 and a concordance correlation coefficient (CCC) of 0.937. In conclusion, our findings highlight that a general linear regression model, developed using combined data from both cattle and sheep, can be used to precisely estimate OM intake using FNe for animals fed multi-species native forage from the Río de la Plata region.

Introduction

In the Rio de la Plata region of South America, which includes all of Uruguay, the central-eastern part of Argentina, and a portion of southern Brazil (Baeza and Paruelo 2020), most ruminants graze on native grasslands. These grasslands are characterised by highly diverse native vegetation (Andrade et al. 2018), with a rich variety of plant species that create a heterogeneous environment. Therefore, estimating animal forage intake in this grazing environment is challenging. To address this, several studies have focused on developing specific linear regression models using faecal nitrogen excretion (FNe) to estimate organic matter (OM) intake in beef cattle and sheep fed native forage in Brazil (Kozloski et al. 2018; Azevedo et al. 2024) and Uruguay (Tafernaberry et al. 2024). These studies indicated that it is possible to develop accurate models for estimating OM intake in cattle and sheep separately or together for southern Brazil forage based on FNe. Given that faecal nitrogen is a well-established proxy for estimating intake in ruminants (Lancaster 1949; Peripolli et al. 2011), an important question arises: can a single model reliably estimate OM intake for both sheep and cattle fed native forages with similar vegetation across different zones of the Rio de la Plata region? We hypothesize that a general linear regression model can accurately predict OM intake for both species using data from different zones of the Rio de la Plata region. The objective of this study was to develop and validate a general linear regression model using FNe to estimate OM intake in cattle and sheep fed multi-species native forage from the Río de la Plata region.

Methods

This study was conducted using a comprehensive database compiled by researchers from Uruguay and Brazil. The database included data from previous experiments performed between 2014 and 2022 with beef cattle and sheep housed in metabolism cages and fed fresh or hay-preserved multispecies native forages typical of the Rio de la Plata region in South America ($n = 219$). Most of the data in this database ($n = 204$) have been previously published in peer-reviewed scientific articles (Kozloski et al. 2018; Azevedo et al. 2024; Tafernaberry et al. 2024). However, 15 data points from sheep in Uruguay remain unpublished. Of the 219 individual observations, 72 were from steers (Angus and Hereford breeds) and 147 were from male sheep (Corriedale and Texel × Corriedale crosses). The body weight (BW) of the animals was 273 ± 73 kg for steers and 38 ± 9 kg for sheep, respectively.

All experiments adhered to a consistent methodology as described by Rymer (2000). Briefly, in all experiments, all animals had a 5-day acclimatisation period in metabolism cages before starting the 10-day adaptation period to the different amounts of forage offered, followed by a 5-day period for forage and faeces sampling. During the first 5-day acclimatisation period, the same amount of forage (*ad libitum*) was offered to all the animals, while during the following 10-day adaptation period to the treatments and the 5-day sampling, they received different amounts of forage, which corresponded to their treatment. The treatments in each trial differed, but in general, animals were receiving forage in daily amounts ranging between 15 and 25 g of dry matter (DM) per kg BW or *ad libitum*. When forage was offered fresh, every day, the forage required to feed the animals was harvested using a mower and stored overnight in a refrigerator. For the trial in which animals were fed hay, native forage was cut 3 cm above the ground, dried in the field, and stored in a shed for later feeding. Fresh forage or hay was offered twice a day (at 8 and 17 h) to animals individually according to their BW and treatment. Every morning, prior to feeding the animals, forage refusals of each animal from the previous day were removed and weighed. During the 5-day sampling period, samples of offered and refused forage were collected, oven-dried at 55°C, and ground (1 mm) for subsequent analysis of DM and OM; these data were used to determine OM intake. To estimate daily faecal excretion, each animal was equipped with a harness and bag. Dung bags were emptied once daily for sheep and twice daily for cattle before feeding. The total daily fresh faecal excretion of each animal was weighed and homogenized. A sub-sample representing 20% and 10%, for sheep and cattle, respectively, was taken from the total and oven-dried at 55°C for subsequent analysis of DM, OM, and nitrogen.

The analysis, performed in R software, aimed to develop and validate a predictive mode for OM intake using FNe as a predictor in linear mixed-effects models. Five candidate models, each including animal species (sheep and cattle) as a fixed effect and differing in random effects structures, were compared using Akaike information criterion (AIC) and Bayesian information criterion (BIC). The coefficient of determination (R^2) and Pearson correlation (r) were calculated to assess the model's explanatory power, while ANOVA was used to test the significance of fixed effects. The predictive accuracy of the fitted OM intake model was evaluated using 5-fold cross-validation (James et al. 2014), where the dataset was randomly split into 80% training and 20% testing subsets for each fold. Performance metrics included mean absolute error (MAE), root mean squared error (RMSE), concordance correlation coefficient (CCC), and Pearson correlation (r), ensuring a comprehensive evaluation of predictive accuracy.

Results

Figure 1a shows the representation of the best model developed to estimate OM intake in sheep and beef cattle fed native forage. The resulting linear regression model revealed a positive relationship between FNe and OM intake ($p < 0.001$; $R^2 = 0.851$) across the entire dataset [Intake (g OM/kg BW/day) = 3.335 + 106.321 × FNe (g N/kg BW/day)]. The best model was identified as having animal species as a fixed effect and random effects structured as ~1|Trial, and showed the best predictive performance, with the lowest AIC (945.7) and BIC (962.5). The animal species effect was not significant ($p = 0.337$).

The cross-validation using the model developed in this study is shown in Figure 1b. Pearson correlation between predicted and observed values of the animal forage OM intake model was 0.957, with an RMSE of 1.598, an MAE of 1.241 and a CCC of 0.937.

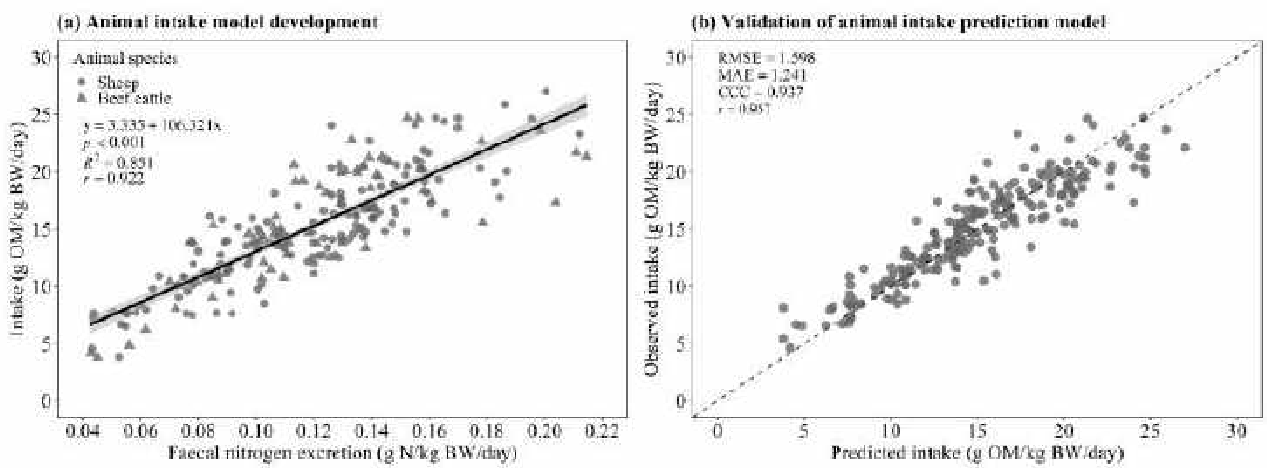

Figure 1. Relationship between faecal nitrogen excretion and organic matter intake in beef cattle and sheep (a) and predicted and observed animal organic matter intake validation using the developed model (b).

Discussion

This is the first study to utilize a database comprising 219 individual observations (72 from cattle and 147 from sheep) from two countries within the Rio de la Plata region to develop a general model for estimating forage intake in both beef cattle and sheep fed native forage, using FNe. The previous studies using sheep and cattle fed native forage in this region proved that the FNe can be precisely used to estimate intake in those animals (Kozloski et al. 2018; Azevedo et al. 2024; Tafernaberry et al. 2024). Nevertheless, the primary goal was to develop a single linear model using combined data from both beef cattle and sheep to estimate their intake. Our hypothesis was that this approach would be feasible. The results confirmed this hypothesis: FNe has a strong relationship with OM intake, regardless of the animal species. This finding demonstrates that a single general model can precisely ($r = 0.922$; Figure 1a) and accurately ($r = 0.957$; Figure 1b) estimate intake in both sheep and cattle consuming this multispecies native forage. Therefore, this represents a significant advancement in pasture and animal science in our region, particularly within the context of heterogeneous environments such as multispecies native grasslands. In conclusion, our findings support the hypothesis that a general linear regression model, developed using combined data from both beef cattle and sheep, can be used to precisely estimate OM intake using FNe for animals fed multi-species native forage from the Río de la Plata region in South America.

Abstract

Metabolisable energy (ME) intake determines productivity in ruminant production systems and estimates of the ME content of feeds underpin nutritional production models and feeding standards across the world. An inaccurate estimation of ME content of a feed means nutritional models and decision support tools are erroneous, resulting in significant variance in expected liveweight gain or carrying capacity of a pasture. Currently in Australia there are a range of equations used to estimate ME of feeds. Utilising appropriate ME equations suitable for Australian forages, in this case, lucerne, is vital for predictive modelling for production and for any required ration or supplement formulation. The current study compared 24 ME equations in lucerne. Lucerne samples were taken at four different vertical strata grown in field trials of plants of different heights to generate samples of differing nutrient quality.

This research demonstrated that different ME estimation equations generate different ME values for the same lucerne sample. This is exemplified with ME values ranging from 10.25 to 16.58 MJ ME/kg DM for a sample in the top strata, and 7.7 to 13.75 MJ ME/kg DM for another sample in the bottom strata. The Minson (1984) equation, ME (MJ/kg DM) = 0.157 DOMD + 0.059 CP – 1.073, appeared the best equation to use for lucerne according to its lowest SD. This was congruent to the ME equation analysis for forage sorghum samples (Lwin et al. 2022).

This study did not determine which equations were biologically correct, however ME equations based on a combined regression using DOMD and CP parameter were most suitable for use in both forage sorghum and lucerne. This work needs to be validated across multiple forages in Australia to develop ME feeding standards for wider and improved applications for the extensive grazing industry.

Introduction

The ME is a nutritive characteristic and cannot be determined using standard analytical techniques. Feed ME values are estimated via regression equations based on chemical composition (Weiss et al. 1992), estimation of digestibility with *in vitro* methods (Minson 1984; Givens et al. 1990) or gas production methods (Menke &

Steingass 1988; Robinson et al. 2004). These regression equations were originally developed on the basis of calorimetry feeding trials and then related to analytical attributes of a dataset of feeds. Over time, many ME equations have been derived independently using different feed datasets. Equations are then applied, often without consideration of the dataset and parameters with which the equation was determined.

There is limited standardisation of ME equations in Australia. Feeds can be analysed by different methods, using different ME equations through domestic laboratory services but also international laboratory services. Feed ME values can also be obtained by nutritional text feeding tables or using online nutritional tables such as feedipedia. The different equations cause a disparity in ME estimations, particularly in tropical forages. Discrepancy between ME equations was established by Robinson et al. (2004). This work compared and evaluated six ME equations to predict ME based on chemical and *in vitro* components, from US (NRC 2001, University of California at Davis (UC Davis)) and UK (Agricultural Development and Advisory Service - ADAS: Morgan 1972) across a range of feeds. They concluded that no procedure they assessed was able to reliably predict the ME values determined *in vivo* for all feeds. Additional to this in Australia, McLennan (2005) found that ME content estimated by the Australian feeding system standards such as SCA (1990) or Nutrient requirements of domesticated ruminants (NRDR) (Freer et al. 2007) and the Cornell net carbohydrate and protein system (CNCPS) (Fox et al. 2004), which is also commonly used in Australia, differed in tropical forages. Furthermore, Lwin et al. (2022) demonstrated in a study comparing 24 ME equations, that vastly different ME values were generated for each of the 120 forage sorghum samples, and that most equations were not comparable, nor did samples rank similarly across ME equations.

There is a lack of agreement on the appropriate ME equation to use across different environments and production systems in Australia. Livestock production models often use different ME equations to derive intake of ME and predict ruminant production (Robinson et al. 2004). Given the variability between ME equations and lack of information on contextual appropriateness of different models, it is not surprising that these models do not often agree with production results observed in the field. This is particularly so in the predictive productive performance of ruminants fed subtropical forages. Overestimation of ME in a feed will be associated with lower in field production values. This is particularly apparent in tropical forages, as the high NDF content (particularly indigestible NDF) also limits feed intake.

This study aims to compare ME equations to predict the ME content of lucerne. The study objectives were (1) to establish if ME values differed for each lucerne sample and, (2) establish the most appropriate ME predictive equations for lucerne (Best Bet). Appropriate ME assessment will improve the accuracy of ration formulation and production modelling, and integration in existing decision support tools will enable producers to make more informed grazing, supplementation and animal management decisions to maximise productivity.

Methods

Lucerne samples

The lucerne variety, Titan seven was grown at Gatton Research Facility (27°32′45″S, 152°19′44″E) during 2018 and 2019. Different heights of lucerne pasture were sampled. At sampling, plants were harvested 5 cm above the ground, plant height measured, then samples were cut into four equal vertical strata (Benvenutti et al. 2016) tagged and placed into labelled sample bags. Samples were dried in an oven at 60ºC and ground through a 2 mm screen (Retsch Mühle rotary grinder, Germany). A total of 96 samples were selected from a large sample set and used for further analysis. These samples were selected to represent a diverse range of nutritional parameters.

Laboratory analysis

Subsamples were sent to the Dairy One Forage testing laboratory (Ithaca, NY, USA) for nutritional analysis according to CNCPS. Samples were analysed to determine crude protein (CP), ethanol-soluble carbohydrates, lignin, crude fat, acid detergent fiber (ADF), amylase, sodium sulfite treated neutral detergent fiber (NDF) and mineral content by using wet-chemistry services (Dairy One 2007). The Dairy One Forage Lab uses a multiple component summative approach, using total digestible nutrients (TDN) for ME prediction employing a CNCPS approach (Eqn 1 in Table 1).

Subsamples were further analysed locally by using an *in vitro* two-stage rumen fluid pepsin procedure (Tilley and Terry 1963) modified for a Daisy ANKOM system. Estimations were made of dry-matter digestibility (DMD), organic matter digestibility (OMD) and digestible organic matter in the DM (DOMD; Holden 1999). Organic matter (OM) was determined by ashing dried samples at 600°C in a muffle furnace (Modutemp, Midvale, WA, Australia) for 3 hours. Ash-free NDF content was determined according to the method of Goering and Van Soest (1970) modified by Mertens (2002), by using the ANKOM system (ANKOM 200 Fiber Analyzer, Macedon, NY, USA). Other required values for equation application were derived from Dairy One laboratory analysis.

Metabolizable energy equations

A total of 24 equations were used to estimate the ME content in lucerne samples (Table 1). These same equations were applied for the Lwin et al. (2022) study and obtained from a range of Australian, UK and USA feeding standards. All ME equations were utilized for forages.

Table 1. Estimation of ME from different equations in analysis of lucerne samples

Equation number	Author	Equation
Equations based on chemical composition		
1	CNCPS (Fox et al. 2004)	DE (MJ/kg DM) = ((TDN%/100) x 4.409) x 4.184
	NRC (2001)	ME (MJ/kg DM) = ((DE (Mcal/kg DM) x 1.01) – 0.45) x 4.184
2	Minson (1984)	a) ME (MJ/kg DM) = 0.260 CP (%) + 4.653
		b) ME (MJ/kg DM) = 21.574 – 0.207 NDF (%)
		c) ME (MJ/kg DM)) = 16.654 – 0.241 ADF (%)
		d) ME (MJ/kg DM) = 13.764 – 0.165 CP (%) – 0.118 NDF (%)
		e) ME (MJ/kg DM) = 10.738 + 0.161 CP (%) – 0.131 ADF (%)
		f) ME (MJ/kg DM) = 7.735 + 0.17 CP (%) – 0.335 lignin (%)
3	Abate and Mayer (1997)	ME (MJ/kg DM) = 8.11 + 0.1341 CP (%) – 0.1065 ash (%)
Equations based on digestibility		
4	ADAS (Morgan 1972)	ME (MJ/kg DM) = 0.84 + 0.14 DOMD (%)

5	Givens et al. (1990)	ME (MJ/kg DM) = 0.37 + 0.0142 DOMD (g/kg DM) + 0.0077 CP (g/kg DM)
6	Minson (1984)	a) ME (MJ/kg DM) = 0.153 DMD (%) – 1.057 b) ME (MJ/kg DM) = 0.15 OMD (%) – 1.126 c) ME (MJ/kg DM) = 0.184 DOMD (%) – 1.827 d) ME (MJ/kg DM) = 0.157 DOMD (g/100g) + 0.059 CP (%) – 1.073
7	AFRC (Alderman and Cottrill 1993)	ME (MJ/kg DM) = 0.0157 DOMD (g/kg DM)
8	NRDR/CSIRO (Freer et al. 2007)	a) ME (MJ/kg DM) = 0.172 DMD (%) – 1.707 b) ME (MJ/kg DM) = 0.169 OMD (%) – 1.986 c) ME (MJ/kg DM) = 0.194 DOMD (%) – 2.577
9	AFIA (2011)	ME (MJ/kg DM) = 0.203 DOMD (%) – 3.001
10	SCA (1990)	a) ME (MJ/kg DM) = 0.18 DOMD (%)– 1.8 b) ME (MJ/kg DM) = 0.16 OMD (%)– 1.8 c) ME (MJ/kg DM) = 0.17 DMD (%) – 2.0
11	Freer et al. (2004)	ME (MJ/kg DM) = 0.172 DMD (%) – 1.71

Where; Dry matter digestibility (DMD) = (feed DM – residual DM)/feed DM

Organic matter digestibility (OMD) = (feed OM – residual OM)/feed OM

Digestible organic matter in DM (DOMD) = (feed OM – residual OM)/feed DM

Statistical analyses

The set of predicted ME values generated by the 24 equations for each of the 96 lucerne samples underwent a series of analyses. Firstly, an ME index was calculated to account for each height stratum within each sample. The ME index was calculated by ranking from lowest to highest, the average ME values for each stratum within each sample across all ME equations. The predictions generated by the different ME equations were then regressed against the ME index by fitting linear mixed effects (LME) models. Model comparisons using Akaike, and Bayesian information criterions indicated that a random slope and intercept structure was optimal. The set of ME equations was narrowed by selecting only those equations whose random slope and intercept fell within the 95% confidence interval of the overall LME fixed effect slope and intercept, i.e., those equations that generated ME predictions closest to the overall mean predictions across all ME equations combined. The 'optimal' ME equation was then identified by selecting the equation from the narrowed subset of equations with the lowest standard deviation of its predictions, i.e., had the lowest variability across the range of ME values tested.

Results

The 24 ME equations had variable ME predictions for each lucerne sample. The full set of 24 ME equations was narrowed to eight preferred equations based on their random slopes and intercepts falling within the 95% confidence interval of the overall fixed effect slope and intercept. These eight equations were all based on digestibility, whether as a sole parameter or digestibility combined with a CP parameter. (equation 6d, 8a, 8b, 8c, 9, 10b, 10c and 11). When SD were taken into account equations: 10b (SCA 1990) was considered Best Bet for the top strata, 6c (Minson 1984) for strata 2, 6b (Minson 1984) for strata 3 and equation 5 (Givens et al. 1990) for the bottom strata. This is not practical to have different equations preferred for the various strata and as such a preferred equation was considered across all strata. These equations that were within the 95% Cl of both fixed effect slope and intercept were then ranked using standard deviations (SD) (Figure 1). The equation with the lowest SD was selected as the Best Bet ME equation for lucerne. The ME equation with the lowest SD was Eqn 6d (ME (MJ/kg DM) = 0.157 DOMD (%) + 0.059 CP (%) – 1.073) (Minson 1984).

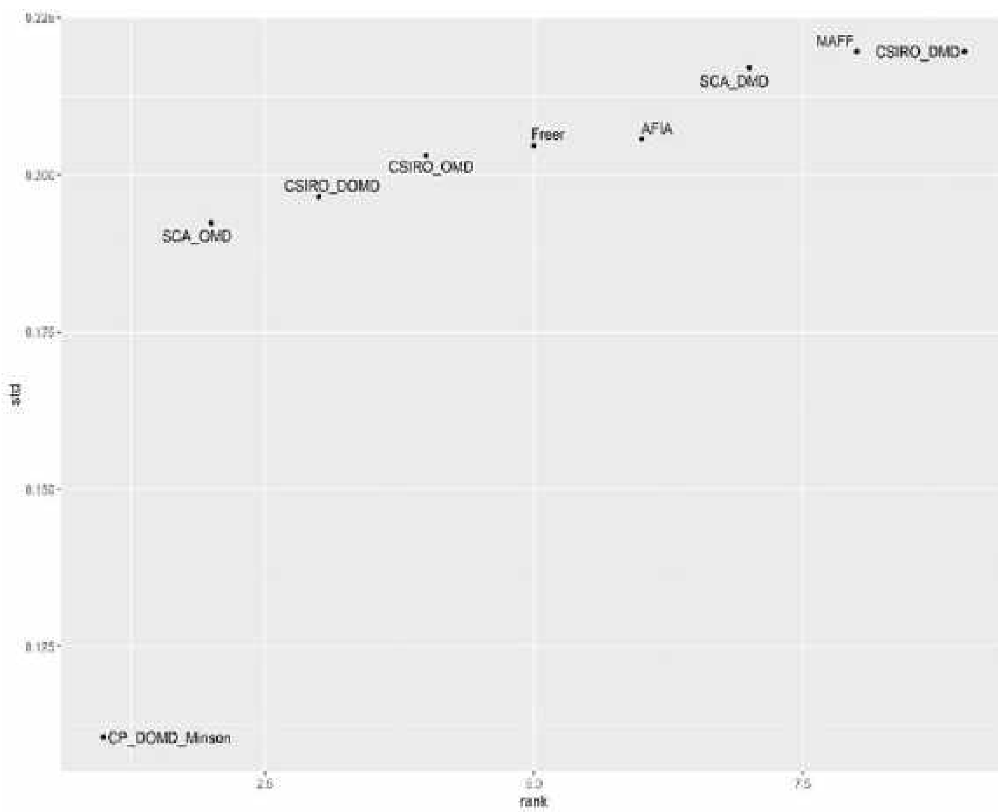

Figure 1. Equations ranked by standard deviations (SD) from lucerne sample dataset. Equations are: CP_DOMD_Minson = Equation 6d, SCA_OMD = Equation 10b, CSIRO_DOMD = Equation 8c, CSIRO_OMD = Equation 8b, Freer = Equation 11, AFIA = Equation 9, SCA_DMD = Equation 10c, MAFF = Equation 9, CSIRO_DMD = Equation 8a. Each equation (Eqn) is defined in Table 1.

Discussion

This research focused on the estimation of ME in lucerne as a model crop for legumes. The ME value is the first limiting nutrient and determines the maximum productivity of the ruminant. The content of ME in feed is most accurately measured via ruminant calorimetry studies (Blaxter & Clapperton 1965) but this is not practical for a feed analysis measurement. As such ME equations have been derived from regression relationships between digestibility or chemical composition with ME values. It is assumed that this relationship varies between feeds and that ME can be predicted satisfactorily by different laboratory methods (Minson 1980). An accurate estimation of ME content is fundamental to accurate prediction of productive performance of ruminants and to better assist producers to make grazing management decisions. The current study compared 24 equations to estimate the ME content in a lucerne dataset of 96 samples. Lucerne samples were taken at four different vertical strata grown in field trials containing plants of different heights. The ME equations were that used by Lwin et al. (2022) and was not an exhaustive list but rather a selection of equations that are utilized in recognized feeding systems. These equations selected were either developed using chemical composition, digestibility data, or a combination of both chemical composition and digestibility data. It was also important to have knowledge regarding the equations associated feed databases such as the number of feeds and type of feeds. Only equations derived from forage databases were utilized.

Our research shows for each individual lucerne sample, different ME estimation equations will give vastly different ME values. Similarly, Lwin et al. (2022), using the same equations for comparison, observed very different ME estimations on individual forage sorghum samples. In many of these samples, ME estimations were not biologically sensible (over 17 MJ/kg DM). This variability in estimations was even greater in higher quality lucerne (top strata 1 and 2) compared to lower quality forage (bottom strata 3 and 4). This variability between ME estimations for the same sample in this research using legumes and also in Lwin et al. (2022) using a topical grass, exemplifies the importance of utilizing appropriate ME equations. Utilising an ME equation that is not suitable for a feed type would likely provide incorrect ME values. It is also imperative to know the derivation of feed ME values (when using feed laboratories or feed table values) when comparing different feeds e.g. for ration formulation, as this research has shown that there will be major inconsistencies when comparing ME values from different equations.

As with the Lwin et al. (2022) equation analysis for forage sorghum, this study with lucerne samples, could not definitively determine which equation was biologically correct, however through a series of statistical approaches, these equations were compared and Best Bet equations were ascertained. For lucerne, ME equations using a digestibility parameter provide acceptable ME estimations compared to those equations based solely on chemical composition. In particular, the equations based on a combined regression using the parameters digestible organic matter in the DOMD and CP were most suitable for use, The predicted ME equation from Minson (1984) based on CP and DOMD is the best equation to use for lucerne according to its lowest SD which is ME (MJ/kg DM) = 0.157 DOMD + 0.059 CP – 1.073. These results are congruent to the ME equation analysis for the forage sorghum study.

Utilizing digestibility as a parameter in an ME estimation equation is biologically appropriate. ME is the energy in the feed remaining after subtracting the energy of the faeces, urine and combustible gases such as methane. There is a biological correlation of ME with digestibility (Alderman and Cottrill 1993; Freer et al. 2007). Minson (1984) further discussed that ME has a high correlation with DMD and OMD with lower error compared to feed ME estimations from chemical composition when working with *Digitaria setivalva*. Similarly, Armstrong (1964) noted less SD of ME estimation from digestibility based values compared to utilizing chemical composition attributes in sixteen grasses.

The inclusion of CP as a parameter is also significant. The calorific value of digestibility of OMD has a significant relationship with CP as higher digestibility occurs with increasing proportion of CP in forages (Terry et al. 1974) attributable to a higher N supply for microbial activity (Satter and Slyter 1974). The protein also when broken down is a further source of energy to the animal that needs to be accounted for. Lwin et al. (2022), in an analysis of 24 ME equations found, using forage sorghum as a sample set, the Best Bet equations were DOMD and CP from Givens et al. (1990) and Minson (1984). As such, based on the current research, ME equations which utilized the parameters of DOMD and CP can be used universally in both tropical grasses and lucerne. Moreover, the Best

Bet equation from CP and DOMD in Minson (1984) can easily be analyzed in the laboratory and also obtained through faecal NIRS estimates from rangeland animals.

Conclusion and implications

There is a need for agreement on the appropriate ME equation to use in various production systems, as this will improve the accuracy of ration formulation, and importantly for grazing management decisions and livestock production modelling.

Assessing risk of plant-associated toxicosis using sentinel farms and historical records

Smith, SR; Lea, K; Romano, M; Gotsick, E

University of Kentucky, Lexington, KY, USA

Key words: tall fescue; fescue toxicosis; ergovaline; ergopeptine alkaloids; species composition; cool-season pasture

Abstract

Assessing toxicity of grassland/rangeland plants and their impact on livestock production and morbidity is an issue around the world. Tall fescue (*Schedonorus arundinaceus* Schreb.) is a naturalized grass species occurring on over 14 million ha in the USA with the majority infected with a fungal endophyte that produces ergopeptine alkaloids (primarily ergovaline). The objective of this paper is to show how an innovative pasture evaluation system at the University of Kentucky has been used to incorporate plant toxicity information and species composition measurements to assess risk to livestock. Over the last 20 years over 500 horse farms have been intensively evaluated to determine total botanical composition and the ergovaline content of tall fescue present in pastures. Using various strategies, these measurements have been used to develop risk categories, which have then been communicated to the farms to enable stocking decisions. This project will establish sentinel farms that will provide additional information on seasonal variability for ergovaline levels and the potential impact on livestock. This assessment strategy can be used to assess risk to livestock in many ecological regions around the world.

Introduction

Traditional methods to alleviate risk of plant-associated poisonings in livestock on rangelands and grasslands have been to monitor species composition and livestock health and then to avoid/reduce exposure or remove toxic plants by mechanical or chemical methods (van Raamsdonk et al. 2015). There are situations where the plants of concern are endemic and/or compromise a major component of a grassland system. For example, the tall fescue cultivar Kentucky 31 (KY-31) was widely planted in the eastern USA after being released in 1943 because of superior persistence, long growing season, and biomass production. It is now considered a naturalized species and occurs on 14 million ha in the USA. In the 1980's, it was discovered that the persistence of KY-31 was primary due to the mutualistic relationship with a fungal endophyte (*Acremonium coenophialum*). Unfortunately, this endophyte produces toxic ergopeptine alkaloids which cause a range of symptoms which vary depending on livestock species. Pregnant broodmares in the last 30-60 days of gestation are most sensitive (Bacon, 1995). Ergovaline and other ergopeptine alkaloids consistently cause decreased or absent colostrum and milk production in late-gestational mares and failure of passive transfer in their foals. Other effects in mares include prolonged pregnancy, dystocia, premature placental separation, and other reproductive abnormalities. Dysmaturity, overmaturity, postmaturity, and septicemia can occur in foals. In cattle, low weight gain, reduced pregnancy rates, decreased milk production, and temperature-dependent effects of vasoconstriction (e.g., heat stress during warm temperatures or sloughing of hooves, ears, and tail switches during extreme cold). Non-toxic endophyte-free and novel endophyte tall fescue cultivars have been developed, but it is not feasible to replace all 14 million ha due to the terrain of many farms, reduced persistence, and the cost of reestablishment. When properly managed, toxigenic tall fescue can be a useful or at least a tolerated species in grasslands.

The effects of toxic tall fescue on pregnant mares can be significant, but risk is difficult to evaluate. While testing for endophyte presence and ergovaline concentration are easily conducted, a true risk assessment must include an estimation of the amount of tall fescue in the diet. Ergovaline concentrations also vary seasonally and based on pasture management. The University of Kentucky (UK) Horse Pasture Evaluation Program combines ergovaline and endophyte testing with species composition data to objectively assess the risk to horses grazing individual pastures, assist farms in “triage” of pastures, and help determine when mitigation and management strategies can be utilized or when complete renovation is recommended. Additionally, several farms have committed to becoming sentinel farms and conduct monthly sampling of pastures to inform the entire livestock industry in the region when ergovaline levels are increasing or decreasing in general.

Methods

To evaluate livestock risk on pastures, “Ergovaline in Total Diet” is calculated using the percentage of tall fescue in the pasture compared to other available forages, and the concentration of ergovaline within tall fescue plants.

Species composition is determined using an occupancy method (Payne et al., 2023; Vogel and Masters, 2001) with 75cm x 75cm wire grids that contain 25 smaller squares, 15cm x 15cm. Each smaller square is evaluated individually for botanical composition and the most dominant species or category is recorded. Species and categories include tall fescue, Kentucky bluegrass (*Poa pratensis* L.), orchardgrass (*Dactylis glomerata* L.), white clover (*Trifolium repens* L.), broadleaf weeds, nimblewill (*Mulenbergia schreberi* J.F Gmel.), warm-season annual grasses, bare soil and “other forages”. Grids are randomly placed at 10 to 20 locations depending on pasture size with a normal range of 0.25 ha to 16 ha. By evaluating all plant species and not just the amount of tall fescue present, the amount of tall fescue in the grazing diet can be calculated, and other management recommendations such as seeding and broadleaf weed control can be tailored to the needs of the pasture.

Grab samples of tall fescue material are also collected from 10-20 locations within the pasture at average grazing height, ranging from 7 to 10 cm from the soil. These samples are submitted to the University of Kentucky Veterinary Diagnostic Laboratory for analysis. Details on sampling, handling during transport and storage and analysis can be found in Lea et al. (2014). The total concentration of ergovaline plus its epimer ergovalinine is reported on a dry matter basis in parts per billion (ppb) within the tall fescue sample.

Previous research suggests that horses graze different forage species in similar proportions to how they are present in the pasture (Morrison et al., 2008). Therefore, the species composition data collected and the ergovaline analysis can be combined to calculate ergovaline in total diet using the formula below:

$$\left(\frac{\%\ \text{TF}}{\%\ \text{TF} + \%\ \text{BG} + \%\ \text{OG} + \%\ \text{WC} + \%\ \text{OF}} \right) \times \begin{array}{c}\text{Ergovaline}\\ \text{(ppb)}\end{array} = \begin{array}{c}\text{Ergovaline in}\\ \text{Total Diet (ppb)}\end{array}$$

Figure 3. Formula for calculating ergovaline in total diet.
(TF=Tall Fescue; BG = Kentucky Bluegrass; OG = Orchardgrass; WC = White Clover; OF = Other Forages

Results

Assessment of Pastures by calculating Ergovaline in Total Diet

Using the calculation of Ergovaline in Total Diet instead of simply ergovaline concentration or tall fescue percentage provides farm managers with additional stratification of pastures when evaluating the farm as a whole. Table 1 contains an example abbreviated datasheet containing several pasture species compositions and ergovaline concentrations.

Table 1. Abbreviated datasheet from a Lexington, KY, USA, area horse farm.

Pasture	Acres	%Tall Fescue	% Desirable Forages	% Undesirable Components	Ergovaline (ppb)	Ergovaline in Total Diet (ppb)
Pasture 6	29.7	7	88	5	309	23
Pasture 7	31.1	68	31	1	119	81
Paddock 3	0.7	67	19	14	384	302
Paddock 10	0.5	17	38	45	564	172
Paddock 12	1.8	63	29	8	741	500

Pasture 7 and paddock 3 and 12 all contained similar percentages of tall fescue (63-68%), however, the ergovaline concentration ranges widely (119 – 741 ppb). Therefore, ergovaline in total diet was quite low in pasture 7, high in paddock 12, and moderate in paddock 3. Pasture 6 and paddock 10 contained less tall fescue and only moderate ergovaline levels, but very different amounts of desirable forages. Pasture 6 contained a high percentage of other desirable forages, therefore ergovaline in total diet was very low (23 ppb). Paddock 10 contained a high percentage of undesirable components, limiting ergovaline dilution in the diet and resulting in a higher ergovaline in total diet (302 ppb).

Data such as this allows horse farm managers to select pastures that can be grazed without additional management (pastures 6 and 7), pastures that need improved management to reduce tall fescue (paddock 10), and pastures that likely need total renovation (paddock 12),

Use of Sentinel Farms to Monitor Seasonal Ergovaline Concentrations

Ergovaline is known to vary throughout the year and typically produces a spike in the spring in conjunction with seed production and a secondary, smaller spike in the fall coinciding with fall growth (Figure 2). However, in recent years the monitoring of sentinel farms has shown that the fall spike can plateau and remain high for months. Climatic conditions in years where ergovaline levels have plateaued in the fall have had warm, dry falls followed by consistent precipitation and mild early winter conditions.

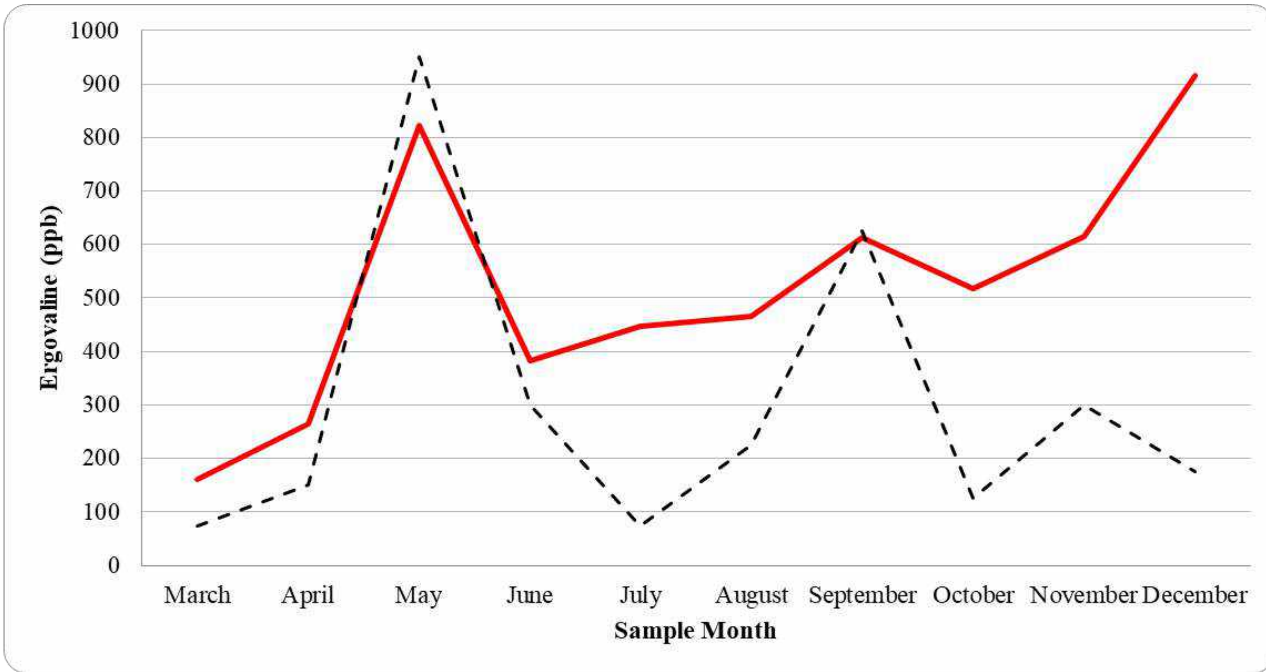

Figure 2. Seasonal variation of ergovaline concentration.

Figure 2 presents data from a single pasture in 2007 (dotted black line), showing the "normal" ergovaline concentrations across the year including a significant spring spike and a smaller fall spike. The red line represents data from many farms that were part of the UK Horse Pasture Evaluation Program in 2023. With an exceptionally dry fall and mild early winter, ergovaline concentrations remained high and even increased from October through the end of the year. Mares due to foal in January would be at their most susceptible stage during November/December (last 30-60 days of gestation) and the risk of complications such as prolonged gestation and dystocia, low or no milk production and thickened, retained placenta, would be greatly increased (Boosinger et al., 1995).

Discussion

Other research focusing on toxic plants in grasslands and rangelands have also shown the benefits of evaluation of the whole system when considering the impact of toxic plants. Pfister et al. (2002) stressed the importance of recognizing the factors that contribute to livestock poisoning, such as environmental conditions, changes in plant composition and animal behaviour. Holechek (2002) found that "poor" range management was not always corelated with livestock losses to poisonous plants and that management of such plants is more complex than just improved overall management. Finally, Krueger and Sharp (1978) found that precipitation and temperature can also influence plant growth, which in turn affects the distribution and palatability of toxic plants. Livestock managers need to adapt their management strategies based on a range of factors including weather, species composition, and animal behaviour. The UK Horse Pasture Evaluation Program has demonstrated a method of forage evaluation and sentinel farm monitoring that helps to inform horse farm managers of the relative risk posed by each pasture using the following categories: very low, low, significant, high, and very high. This allows them to make more informed decisions and can serve as a model for other evaluation methods in grasslands and rangelands.

In conclusion, reducing risk by monitoring species composition and toxin concentration has proven effective with tall fescue and this or similar methods have potential application for managing non-lethal toxic plants on rangelands and grasslands worldwide.

Acknowledgements
The authors of this paper would like to thank the numerous students that have assisted in data collection and the horse farms that have been part of the UK Horse Pasture Evaluation Program and supported on-going research at the University of Kentucky. We also want to thank USDA-ARS-FAPRU unit in Lexington, KY for providing supplemental funding for the graduate students who have worked on the project.

Key words: northern Australia; heat load; calf loss; pasture utilisation; body condition

Abstract

Northern Australia's beef industry annually experiences high heat loads and variable pasture conditions, yet their impact on reproductive wastage remains relatively unquantified. This study analysed retrospective herd data (26,903 cow-production years; 17 herds) to identify predictors of foetal and calf loss (FCL) in northern Australia, integrating climatic, pasture, and animal-level variables. Multilevel logistic regression revealed animal class, lactation status, relative pasture utilisation rate, body condition score and calving period as major factors. Counterintuitively, monthly heat stress indices (CCI) showed no direct association ($p=0.59$), potentially masked by monthly averaging or its effect moderated by other factors contained in the model. These results further underscore the importance of grazing and nutritional management in mitigating reproductive losses in northern beef cattle herds.

Introduction

Approximately 60% of Australia's national cattle herd is in northern Australia, encompassing Queensland, the Northern Territory and the northern regions of Western Australia (Bray et al., 2016). Beef production in a major industry in the region, characterised by extensive grazing on native pastures with limited augmentation with legumes. The breed composition is predominantly Bos indicus, due to its adaptability to the tropical and subtropical climate.

Northern Australia experiences extreme heat and humidity during summer, with temperatures frequently exceeding 35°C and relative humidity levels above 70%(Gaughan et al., 2010). Such conditions pose significant risks of heat stress in livestock, a metabolic state arising when heat accumulation surpasses an animal's capacity for thermoregulation (Brown-Brandl, 2018). Heat stress manifests in reduced feed intake, impaired growth and diminished milk production. The adverse effects of heat stress on reproductive performance (including reduced fertility rates, prolonged calving intervals, and elevated embryonic loss) are well-documented, though research has predominantly focused on dairy production systems (Takahashi, n.d.).

The repercussions of heat stress extend to neonatal health and immunity. Late-gestation heat stress in cows has been linked to reduced circulating immunoglobulin levels and suppressed milk yield (Monteiro et al., 2016). For calves, colostrum intake within the first hours of life is critical for establishing passive immunity, a key determinant of morbidity and mortality reduction in beef herds. Heat stress exacerbates dehydration risk in neonates due to suppressed milk supply, impaired thermoregulatory capacity and reduced suckling behaviour. Compounding this, heat-stressed calves exhibit suppressed immune function, increasing disease susceptibility(Tao et al., 2018).

This work formed part of the broader *Sweet Spot* project, which developed a retrospective dataset to investigate the relationship between pasture utilisation and reproductive performance of beef breeding females in northern Australia. This paper reports the results of an explanatory analysis determining the impacts of pasture and environmental conditions during the month of calving influenced the risk of calf loss. Additionally, parameters associated with beef breeding females and pasture conditions were investigated to assess their impact on losses between confirmed pregnancy and weaning.

Methods

A retrospective animal performance dataset was constructed by collating herd records from participating properties using a standardised data template. This template captured individual animal identifiers (e.g., electronic and visual ID, breed, location), management group details (e.g., age class, paddock), and muster-event variables such as body condition score (BCS), lactation status, pregnancy status, foetal age, live weight, and dates. To ensure consistency, farm-reported BCS scales were standardised to a 1–5 system, and heterogeneous Excel datasets were merged into a unified format. This enabled longitudinal tracking of individual females across annual production cycles, defined as the interval between consecutive pregnancy-testing musters.

Losses between pregnancy and weaning were assessed using annual pregnancy status (binary: 1 = pregnant, 0 = not) and lactation status. Using an assumed gestation length of 285 days, the month of conception and expected calving month were estimated based on foetal age and the date of pregnancy testing, pregnancies were assigned to an annual production year, with a September 1 cutoff for conception. Advanced pregnancies detected post-September were attributed to the subsequent cycle. Lactation status classified females as lactating or non-lactating. Calf loss occurred when a female confirmed pregnant in year t was non-lactating post-calving in year $t+1$, with successful rearing requiring lactation confirmation.

Climatic conditions during the month of expected calving were characterised using historical data sourced from SILO (https://www.longpaddock.qld.gov.au/silo/). To quantify heat stress risk, the Temperature Humidity Index (THI) and Comprehensive Climate Index (CCI) were calculated for each site. For each site, maximum daily index values were then summarised by mean and median and the proportion of days exceeding established heat stress thresholds.

Pasture dynamics were modelled for the annual growth cycle (1 October – 30 September) across 60 paddocks in northern Australia as part of the *Sweet Spot* project. The GRASP model (Rickert et al. 2000) was applied to simulate pasture growth and utilisation, integrating gridded historical climate data from SILO (https://www.longpaddock.qld.gov.au/silo/) supplemented with site-specific rainfall records where available. Modelled pasture growth was calibrated against ground-truthed measurements, including satellite-derived green ground cover and paddock-level Total Standing Dry Matter (TSDM). To assess pasture conditions during critical reproductive phases, modelled outputs were averaged across three temporal windows: (1) the month of expected calving, (2) the two preceding months and (3) the three-month post-calving period.

Statistical analyses were conducted using R (R Core Team 2024) to evaluate the relationship between pasture and animal parameters and foetal and calf loss. Mixed logistic regression analyses were performed with animal as the unit of analysis with animal within station and year specified as random effects. A forward stepwise modelling approach was applied. Continuous variables were assessed for linear or non-linear trends, and interactions were explored and only biologically plausible interactions retained. Results are reported as adjusted means with standard errors, reflecting adjustments for all model terms.

Results

The starting dataset contained 26,903 rows of data representing a production year for an individual cow. On average, each individual cow contributed 1.76 (95% CI, 1.74-1.77) animal-production years of data for which a valid foetal or calf loss was ascribed. Seventeen herds contributed information to the analytical dataset with a median of 1085 (interquartile range, 500 - 2387) FCL outcomes relating to an individual herd.

The final multilevel model, accounting for hierarchical data structures, which explained the greatest variation in foetal and calf loss contained the fixed effects: animal class (*Heifer, 1st Lactation cow, Mature cow, Aged Cow;* F=8.78, p<0.001), a quadratic polynomial of body condition score (F=3.23, p=0.04), Estimated period of calving (*Jul-Aug, Sep-Oct, Nov-Dec, Jan-Feb, Mar-Apr, May-Jun;* F=1.93, p=0.09), annualised lactation status (*Lactated, Didn't lactate*; F=45.18, *p*<0.001), Pasture utilisation rate relative to recommended safe carrying capacity (continuous; F=24.90, *p*<0.001), average maximum comprehensive climate index for the expected month of calving (continuous; p=0.59) and region category (*NE Qld, South NT, Central NT, North NT;* F=0.93, p=0.48), with a significant interaction between calving period and region (F=4.04, *p*<0.001).

The occurrence of foetal and calf loss was predicted for each factor using the final multilevel model, with predicted probabilities and approximate 95% confidence limits of the mean presented in Figure 1.

Discussion

This paper is one of the few that describes the influence of pasture utilisation and heat load indices in relation to the reproductive performance of free-grazing beef females in northern Australia, specifically foetal and calf loss. However, it is important to acknowledge that the analyses were conducted using a retrospective dataset comprising both research and commercial herd performance data. Consequently, the individual datasets exhibit inherent idiosyncrasies and management practices may have been influenced by trial design and an appropriate level of caution is advised in interpreting the findings presented in this paper.

The final model highlighted the importance of management practices that support the nutritional requirements of pregnant females to maximise reproductive performance. These effects were nuanced by the expected calving period, highlighting the need for tailored nutritional strategies. Notably, pasture utilization rate relative to safe carrying capacity had a strong influence on calf loss, with overstocking leading to increased losses. This finding reinforces the critical role of nutrition in maternal support, particularly through milk and colostrum production. Animal class was a critical determinant. Consistent with previous research findings, heifers were found to exhibit greater calf loss compared to 1st Lactation and mature cows (Fordyce et al., 2022). Heifers generally have higher energy requirements due to the simultaneous demands of growth and lactation, leading to increased competition for nutrients. This heightened demand can result in a negative energy balance, which may negatively impact their reproductive performance. Overall, cows that lactated in the previous reproductive cycle (contributed a weaner) had 3.8 percentage points lower occurrence of calf loss. These findings align with previous research demonstrating that cows with a history of producing calves tend to have improved reproductive efficiency (Fordyce et al., 2022).

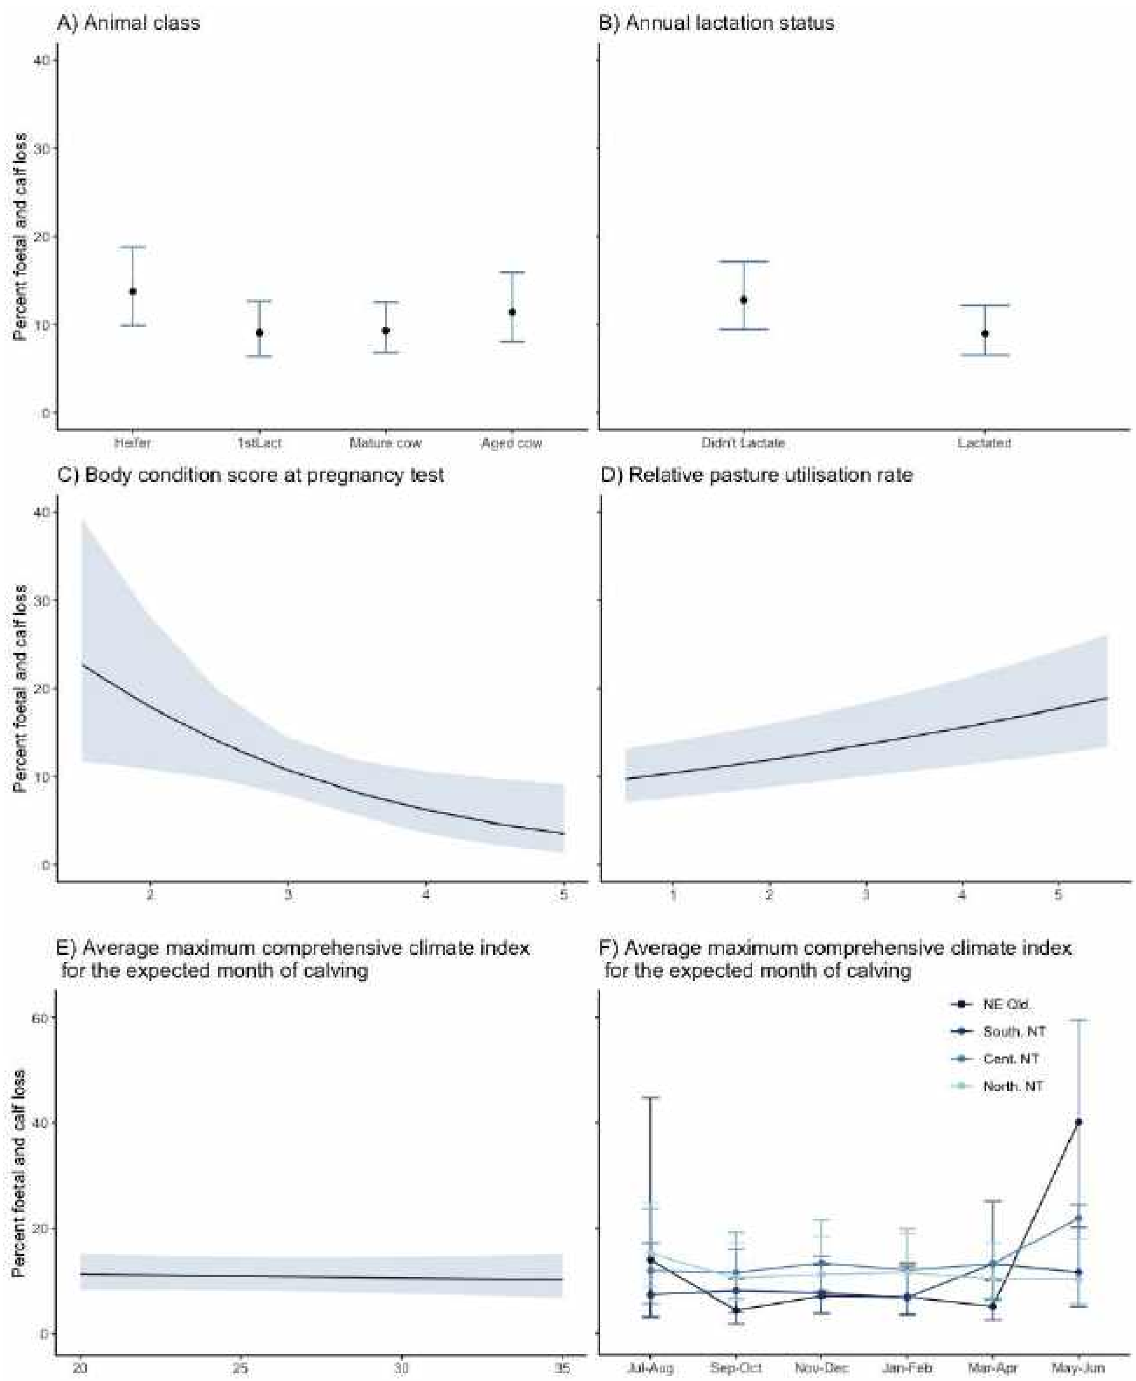

Figure 1: Predicted mean (and 95% confidence limits) occurrence calf mortality across levels of risk factors and their significant interactions identified in the final multilevel logistic regression model. Predictions are based on estimated marginal means adjusted for all variables in the model. Subfigures represent individual risk factor effects or interactions: A) animal class; B) annual lactation status; C) body condition score; D) relative pasture utilisation rate E) average maximum CCI during expected month of calving and interaction between predicting calving period and region.

Counterintuitively, heat stress indices during calving months showed no significant association with calf loss. This absence of a direct relationship may reflect limitations in the resolution of the dataset: monthly averaged CCI values could obscure short-term, acute heat stress events critical to neonatal survival. Alternatively, heat stress impacts may be indirectly mediated through correlated variables in the model, such as calving period, which encapsulates seasonal shifts in both climatic extremes and pasture conditions. Future research should integrate finer-scale heat stress metrics and direct physiological markers (e.g., colostrum IgG levels / calf vigor / actual birth events) when assessing the effects of heat stress on extensively managed beef females.

Rumination as a measure of heat tolerance: a case study in rangeland beef in northern Australia

Chang, AZ[1]; Colusso, PI[1], Williams, TM[1]; Trotter, MG[1]

[1] Institute for Future Farming Systems, School of Health, Medical, and Applied Sciences, Central Queensland University, Rockhampton, Queensland, Australia, 4701

Key words: beef cattle, climate change, heat stress, rumination

Abstract

Climate change poses significant challenges to both productivity and welfare in extensive beef production systems. The identification of heat tolerant individuals is essential for developing resilient herds capable of withstanding increasing temperatures and prolonged periods of heat. The ability to capture relevant phenotypic data for incorporation into genomic evaluation programs, however, remains a significant limitation in extensive environments. This study reports on the use of sensor-based rumination detection to assess individual responses to increasing heat. Thirty-eight cows were equipped with accelerometer ear tags to monitor individual rumination responses to increasing heat during baseline and heat stress periods. The results highlight the potential of a sensor-based rumination detection system to identify heat tolerant individuals in extensive beef systems.

Introduction

Rising global temperatures and the increasing frequency of extreme weather events associated with climate change pose significant challenges to livestock production systems (Godde et al., 2021). In cattle, increased heat is associated with reduced feed intake (Brown-Brandl, 2008), compromised reproductive performance (Dash et al., 2016), reduced growth rates (Lees et al., 2019), and increased mortality rates (Lees et al., 2019). The implantation of strategies to develop heat tolerant herds is essential to ensure the resilience and sustainability of the extensive beef industry in the face of climate change induced pressures – one such strategy is through genomic selection.

A heat tolerance breeding value was initially developed for dairy cattle in 2017 in order to identify individuals that are capable of maintaining a higher milk, fat, and protein yields in hot and humid conditions (Nguyen et al., 2016; Osei-Amponsah et al., 2023). In contrast, developing an analogous breeding value for heat tolerance in extensive grazing systems presents significant challenges, primarily due to the difficulty in collecting relevant phenotypic data due to paddock size and limited animal monitoring and interaction.

Sensor systems offer a promising solution by enabling the continuous collection of behavioural data, supporting phenotype capture in extensive systems. One promising phenotype that is worth exploring is rumination time. Rumination is strongly correlated with a cow's productivity and overall welfare, serving as an indicator of both health and physiological status (Paudyal, 2021).

The integration of sensor systems to monitor rumination behaviour continuously in extensive environments offers an opportunity to generate high resolution phenotypic data that can be used to inform genomic investigations. This study highlights how variations in individual rumination response to heat stress in extensive beef cattle systems can be utilised to support the development of genomic estimated breeding values (GEBVs) for heat tolerance.

Methods

Animal management

This study was conducted at Belmont Research Station (23°13′S, 150°24′ E), 26km north of Rockhampton, Queensland, Australia in November to December 2023. A total of 38 multiparous cows (tropically adapted *Bos taurus*) were grazed in a 65.2 ha paddock. The paddock consisted primarily of alluvial plains, with areas of eucalypt and Brigalow forests. Grass species included spear grass, kangaroo grass, and Queensland blue grass.

Accelerometer ear tags and rumination model

The experimental animals were fitted with Axivity AX3 accelerometer devices (Axivity Ltd., Newcastle, United Kingdom) mounted on modified Allflex Maxi Female ear tags (Allflex Australia Pty Ltd., Murarrie, Australia). The accelerometers recorded data at a sampling frequency of 12.5Hz. Raw accelerometer data was retrieved using the AX3/AX6 OMGUI Configuration and Analysis Tool (Open Movement, Newcastle, United Kingdom). A total of 240 features were generated from the raw data using a mixed model epoch approach (Chang et al., 2022b). A machine learning model for rumination detection was subsequently developed for each animal using the methodology described by Chang et al. (2022a). The individualised rumination models were then applied to calculate daily rumination time across the experimental period.

Weather data

Weather data was obtained from the Bureau of Meteorology station at Rockhampton Aero (site number: 039083), located approximately 16km from the research site. Dry bulb temperature and relative humidity were captured at one minute intervals. The temperature-humidity index (THI) was then calculated at one minute intervals and subsequently summarised to a daily value. The THI was calculated using the formula described in Mader et al. (2006):

$$THI = 0.8 \times T + RH \times (T - 14.4) + 46.4$$

Where

T = dry bulb temperature (ºC)

RH = relative humidity, expressed in decimal form

Statistical analysis

A linear mixed effects model was generated in R using the ‘nlme’ package to evaluate the relationship between rumination time and mean daily THI (Pinheiro et al., 2020). Mean daily THI was a fixed effect, while individual animals were included as a random effect to account for repeated measures (Fogarty et al., 2020). The analysis aimed to establish baseline rumination levels and identify the threshold at which a significant change in rumination time was observed relative to mean daily THI. The proportion of change in rumination time was quantified by comparing the average rumination time before and after the critical THI threshold.

Results

A significant decrease in rumination time was observed when the mean daily THI exceeded 66 (Fig. 1).

Baseline rumination time varied between animals (range: 22.7% – 41.9%). When the mean daily THI reached the critical threshold, rumination decreased across all animals, with a proportionate change ranging from 35.8% to 73.8% (Fig 2).

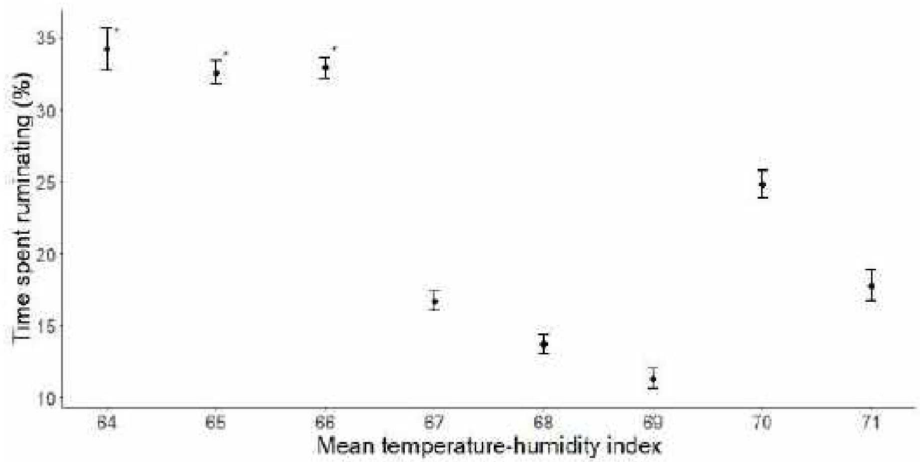

Fig 1. Time spent ruminating vs. mean temperature-humidity index. Significant differences in rumination time between groups are denoted by asterisks (P < 0.05).

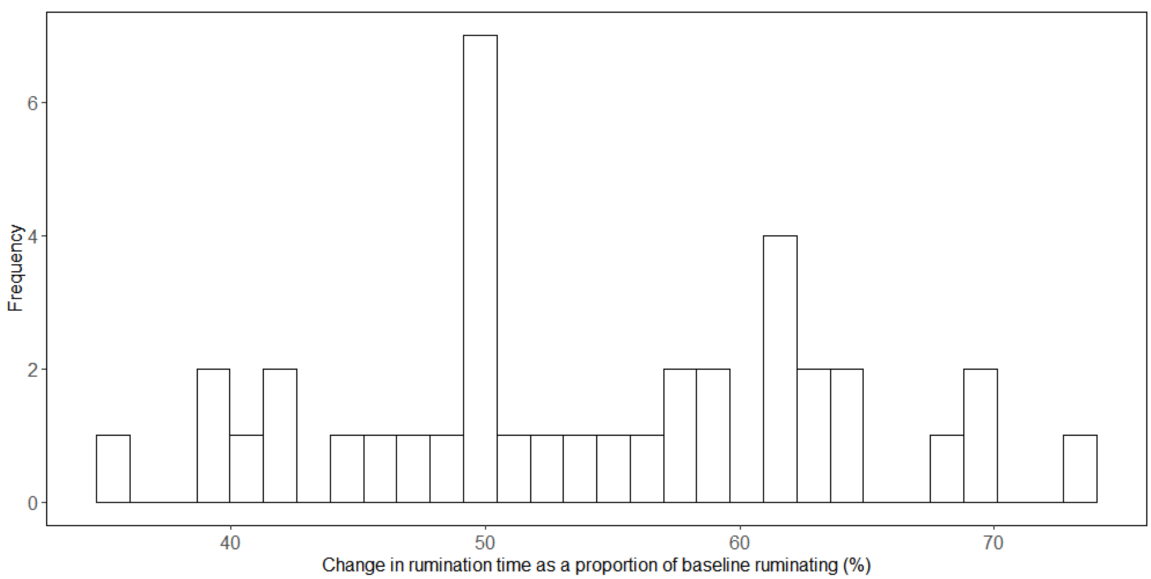

Fig 2. Frequency of the change in rumination time as a proportion of baseline rumination (mean daily THI ≤66).

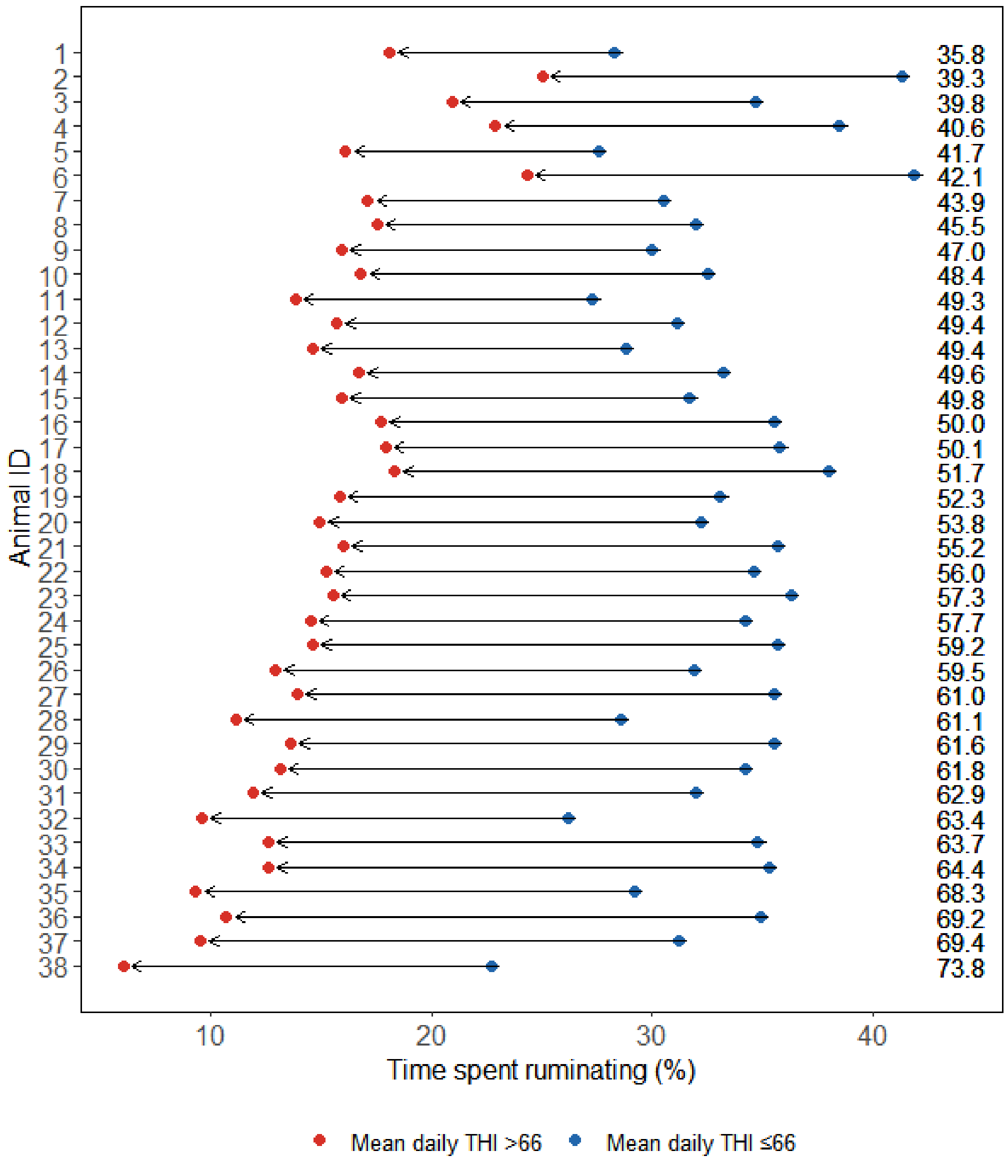

Fig 3. Time spent ruminating by individual experimental animals below and over the critical mean daily temperature-humidity index (THI) threshold. Labels refer to the change in rumination time as a proportion of baseline rumination (mean daily THI ≤66).

Discussion

The findings of this study support existing literature indicating that rumination decreases with increasing heat (Soriani et al., 2013; Moretti et al., 2017; Antanaitis et al., 2024). When exposed to increased heat, humidity, and solar load, cattle engage in various behavioural and physiological strategies to maintain thermoregulation, including reducing rumination (Soriani et al., 2013). Despite the variability in baseline rumination time and the degree of reduction, the decrease in rumination across all animals when the mean THI threshold reaches 66 underscores the potential of rumination as a reliable indicator of heat stress in extensively grazed cattle.

The degree of rumination decrease varied considerably between animals, potentially reflecting differences in individual heat tolerance. These results highlight the opportunity to use rumination data in genomic evaluations to identify heat tolerant individuals. Integrating this data into targeted breeding programs could enhance herd resilience to heat stress, contributing to improved productivity and welfare under increasingly challenging climatic conditions.

Further research is required to validate the inclusion of rumination data as a phenotype for developing GEBVs for heat tolerance. The methods outlined in this study provide a framework for generating high resolution phenotypic data in reference populations, enabling the identification of genetic markers associated with heat tolerance. This could in turn facilitate the selection of individuals with superior heat tolerance, ultimately enhancing the productivity, welfare, and sustainability of extensive grazing systems in the context of climate change.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Maternal productivity for the rangelands

Pitchford, WS

Davies Livestock Research Centre, Adelaide University, Roseworthy Campus, SA 5371 Australia

Key words: Beef, body condition score, reproduction.

Abstract

Given pastoralists in arid regions have little control over season conditions and cannot easily manage stocking rate or supplementary feeding, the biggest lever of cow productivity is through genetics. Weaning rate which is a function of maximising calves born and minimising calf loss is the biggest driver of profit. Conception rate in heifers is related to joining weight and growth during joining. In cows, condition score is the key predictor. The EBV of greatest importance for reproduction is days to calving. EBVs for other traits like growth, calving ease, temperament and recently cow condition are important also. Cows in the greatest condition which show the greatest resilience are likely to have eaten more when feed was available rather than being metabolically more efficient.

Introduction

This paper reviews 35 years of research on beef cattle primarily led by the author. Although not conducted on rangelands per se, there are important insights for rangeland producers. The rangelands that I am focused on are Australia's arid zone - as defined by annual rainfall <250mm. An example of this region is Alice Springs, which has a mean annual rainfall of 285mm, but with huge variation as the median is 126mm, decile 1 6mm and decile 9 804mm (BOM 2024). The median rainfall is 90% in the summer half of the year (October-March), with winter rainfall being a greater proportion in areas to the south.

In the southern rangeland production systems described, little to no nutritional supplementation occurs.. The possible exception is hay fed to young cattle around the time of weaning. Feed supply is primarily only managed in extreme conditions and through stocking rate. Thus, once pasture management is optimised, one of the few strategic levers producers have for productivity improvements is through genetics, which mostly occurs through bull purchases. Given the region of focus is of very low humidity, the focus is on *Bos taurus* cattle. Factors associated with maternal productivity have been reviewed by Walmsley et al. (2018)

Genetic progress in Angus cattle

During the 35 years that this review relates, Angus cattle have changed significantly (Angus Australia 2024) – exemplified by a substantial increase in growth; 119kg for 600d weight and 102kg for mature cow weight. Birth weight has only increased by 4kg so there has been some improvement in calving ease. Favourable changes in other traits include: mature cow body condition, days to calving, docility, eye muscle area and intramuscular fat. However, there has been negligible change in carcass fat depth. Given that feed costs in the rangelands are low, the greater size of cows does not represent a major cost unless pasture utilisation levels are very high. All other traits have improved in favourable directions. Although Angus breed genetics have improved significantly, commercial cattle breeders struggle to compare breeds due to breed societies controlling the databases. There is a current project running Angus, Charolais, Hereford, Shorthorn and Wagyu cattle head to head. This is tremendous but expensive relative to the approach reported by Pitchford et al. (2021).

Feed efficiency

Feed efficiency can be defined in many ways. A common method in feedlots is to focus on the cost of gain with the measure being feed conversion (feed eaten / weight gain, Koch et al. 1963). Productivity is typically measured as output per unit input. In growing beef cattle, weight gain varies more than feed intake, so both measures are maximised by the fastest growing cattle.

In an attempt to overcome the problems of ratios, Koch et al. (1963) introduced the concept of residual or net feed intake (NFI). This has become a major focus of many groups around the world. However, Pitchford et al. (2018) demonstrated that when feed is limited, there is negligible variation in NFI. The implication of this is that there is negligible variation in maintenance requirements and so genetic improvement is not possible.Additionally, Pitchford et al. (2018) reported that variation in NFI under favourable feed conditions is associated with fatness. The implication of this is that variation in NFI must be through appetite rather than efficiency *per se*. The application of this work to the rangelands is that rather than select for animals with low NFI and supposed greater efficiency, it is likely that the best animals are those that eat more when feed is available, build up condition and then are more resilient during times if feed shortage.

Accioly et al. (2018) reported the performance of lines of Angus cattle divergent for fatness or NFI from the Beef CRC Maternal Productivity project (Pitchford et al. 2014). While all cattle gained and lost condition throughout the annual production cycle of feed availability and lactation status, the High-Fat and High-NFI lines were always fatter than the Low-Fat and Low-NFI lines respectively. The impact of this during times of feed shortage was that the leaner lines were always the ones to trigger supplementary feeding. Specifically, calculations based on the data in the Accioly paper estimate that if cows lose condition at a rapid rate (1 condition score/month), then a cow with an extra 1 mm rib fat EBV would take 7.5 days longer to reach the same supplementary feeding threshold. Maintenance of healthy body condition is a crucial trait in the rangelands so selection for increased condition is likely important.

Body composition

Following the work demonstrating the relationship between fatness and cow resilience, there has been an increased emphasis of commercial producers selecting bulls with above average fat EBVs. The result of this is increased fatness of both slaughter and breeding cattle. While this is advantageous for grass-finished steers (Deland et al. 2018), it leads to greater cost of gain and lower meat yields for feedlot-finished steers.

Pitchford (2023) examined the relationship between mature cow body condition and carcass EBVs for growth, muscle and fat. It was demonstrated that approximately ¾ of the genetic variation in cow condition is independent of carcass composition traits. Fat and muscle measured in heifers at yearling and pre-calving were highly correlated (De Faveri et al. 2018). Fat and muscle measured in cows across lactations were also highly genetically correlated. However, the correlation between maiden pre-calving and weaning measures was much lower. Thus, rangeland producers wanting to select bulls that breed more resilient cows should focus on the mature body condition EBV rather than on carcass EBVs.

While genetic selection for growth has resulted in significantly bigger cows, Hebart et al. (2024) have shown that in current commercial cows at 4.5 years of age and adjusted to a condition score 3 (scale 1-5), the average weight was around 550kg.

Productivity and profitability

In the Beef CRC Maternal Productivity project, Hebart et al. (2018) reported nutrition and genetics effects on productivity differences and Anderton et al. (2018) reported the effects on profitability. Variation in maternal productivity defined as weight of calf weaned per unit feed intake by the cow and calf, was associated with feed intake (50%), weaning rate (37%) and only 9% due to the weight of the calf. In the rangelands with cheaper feed, weaning rate will be the strongest profit driver (McCosker et al. 2010).

Anderton et al. (2018) reported that the Low-Fat lines were more profitable than the High-Fat lines. However, the design of the project (Pitchford et al. 2018) was that when one line (always the Low-Fat line) triggered the need for supplementary feed (a single animal dropping below condition score 2, Graham 1985), both lines would be fed (Accioly et al. 2018). The idea was that treating them the same was important for design but with the benefit of hindsight this may not have been wise. The impact of the design was that the High-Fat lines were fed more and maintained in a greater condition score, so there was greater investment in feed than necessary. In rangeland conditions where there is not this level of control, it is likely that those that maintain greater body condition are more resilient, more productive and more profitable.

Reproduction

Pitchford et al. (2022) reported results from the "Black Baldy" trial run with Hereford's Australia. The cattle were run in large mobs in northern Tasmania. While the environment is very different to the rangeland focus herein, they were run in large mobs and at high stocking rates and so provide a model for what could happen in other commercial herds. As expected, attainment of puberty in heifers prior to joining at 13-15 months was associated with the sire scrotal circumference EBV which reflects age at puberty in yearling bulls. However, this only had a weak association with weaning rate. As expected, the EBV with the strongest association with weaning rate was days to calving, a measure of the time taken from joining to calving. In naturally mated mobs, some of the variation in days to calving is associated with gestation length, but much more is associated with post-partum anoestrus and associated time to conception. The relationship was 8% more calves weaned in two joinings per day variation in the EBV. Similar results were found in the Beef CRC data (unpublished).

To address potential bias in conclusions for commercial producers coming from the Beef CRC data, a recent project on productivity of over 14,000 heifers on commercial properties has been conducted (Hebart et al. 2024). There are some key outcomes that have relevance for rangeland systems. A high aim could be to achieve 80% conception rate within two cycles (6-week joining). The two biggest factors affecting this are joining weight and during joining weight gain. If during joining gain is low, then heifers should be >350kg. However, if heifers are rapidly (>1kg/d) gaining during joining then much lighter weights will suffice. In the rangelands following a rain event, it is likely that cattle will be gaining rapidly so conception could occur at quite light weights (<300kg). As expected, conception rates of cows was most closely associated with condition score. Those with low condition due to high milk production or low feed intake will be most at risk of not conceiving.

Heterosis

Estimated from a genomic analysis, the heterosis effect in the Hereford x Angus crosses in the Black Baldy trial was 4% for pre-joining weight, 1% for pre-joining height, 6% for P8 fat and 13% for proportion pubertal (Pitchford et al. 2021). This demonstrates the value of heterosis or hybrid vigour for contributing to resilience.

Pitchford et al. (1993) reported heterosis effects on growth and reproduction in Brahman x Hereford crosses. The effect on growth was large on high-quality pasture (21%), but much less on low-quality pasture (1%). The conclusion was that the mechanism of heterosis was to increase appetite rather than metabolic efficiency as the effect can only be seen when the additional appetite was satisfied (high-quality pasture). This conclusion both guided and supported the same conclusion about the causes of biological variation in NFI (Pitchford et al. 2018). In the Brahman x Hereford crosses, the heterosis effect was large (39%) for weaning rate (Pitchford et al. 1993).

Conclusions

Given pastoralists in arid regions have little control over season conditions and cannot easily manage stocking rate or supplementary feeding, the biggest lever of cow productivity is through genetics. It is very likely that conclusions about genetic variation reported in Angus cattle in Mediterranean and Temperate grazing systems does provide valuable insights for the arid rangelands. However, the lack of multi-breed and commercial rangeland data in current genetic evaluation systems is limiting genetic progress for the rangelands. Genomics offers a significant opportunity to address this shortfall.

Emissions management in grazing

Trade-offs between farm profit and greenhouse gas emission reduction

Pham-Kieu, M[1]; Harrison, M[1]; Ives, S[1]; Badgery, W[2].

Key words: enteric methane emissions; soil carbon sequestration; multiple mitigation strategies; programming model.

Abstract

To develop sustainable sheep production, there is a need to stack multiple mitigation interventions on the one land parcel, such as grazing management associated with soil organic carbon (SOC) accrual and feed additives for enteric methane reduction. The study, thus, aimed to investigate trade-offs between farm profit and greenhouse gas (GHG) emission reduction associated with those interventions.

We used soil carbon data measured in a long-term field experiment in New South Wales and data of net emissions (associated with using different feed additives) on two sheep farms (440 ha and 3786 ha), representative for small-scale and larger-scale farms. Then, a mixed-binary nonlinear programming model was applied to identify combinations of grazing management and feed additives to maximise farm profit and minimise net GHG emissions.

The results of both farms indicated that the most appropriate grazing management and feed additives varied depending on farmer's objective was profit or emission reduction or both. If profit was key goal, combination of multi paddock-fast rotation-high stocking rate and 1% walnut shell biochar would be adopted. In contrast, 15 paddock-slow rotation-low stocking rate and flexible grazing stacking with 0.2% Bovaer would be considered to minimise net emissions. If the objective was to maximise profit and minimise net emissions simultaneously, results of adopting multiple grazing management varied depending on farm size. The small-scale farm tended to adopt 15 paddock-slow rotation-low stocking rate and flexible grazing, while the larger-scale farm implemented 15 paddock-fast rotation-high stocking rate and flexible grazing. Furthermore, carbon price was a driver of farmer's decisions on mitigation interventions. The larger-scale farm would change to adopt 15 paddock-slow rotation-low stocking rate and flexible grazing when carbon price was equal or more than $AU50/tonne CO_2-equivalent. Thus, policies and legislative process relevant to increases in carbon price should be considered.

Introduction

There is a need to adopt mitigations for sustainable production that balance economic viability with environmental responsibility. Farm management relevant to soil carbon (Meyer et al. 2018) and feed additives (Gerber et al. 2015) are key for GHG emission reduction. While each mitigation has its strengths, combinations of grazing and feed management may provide greater benefits by enhancing emission reduction, improving soil health and boosting farm profitability. This study aims to determine what combination of feed additives and grazing management results in the lowest net farm GHG emissions while maximising profit.

Methods

In terms of data source, measured data of soi carbon sequestration was from a field experiment (Simmons, pers. comment.) at the Orange Agricultural Institute, New South Wales, Australia; while simulated data of sheep production (sheep productivity, feed volume, sheep age, total GHG emissions and emission intensity) were calculated through GrassGro software and SB-GAF tool. Farm characteristics (revenues of selling sheep and wool, land management cost, selling cost, stock management cost, pasture cost, supplement cost, and fixed costs) was collected though two real commercial sheep farms, 430 ha and 3786 ha. Consistent with Pham-Kieu et al. (2024), we extrapolated experimental data to the farm scale and combined with sheep production, then a invoked programming modelling approach.

We developed three mixed-binary nonlinear programming models to identify optimal combinations of grazing treatments – feed additives, grazing area allocation, the number of sheep sold and their age. These models aimed to maximize farm profit, minimize net GHG emissions, or achieve a balance between the two objectives. While the models differed in their objective functions, they shared a similar set of constraints. We assumed that farmers would maintain consistent grazing and feed management practices over a six-year period for a single sheep flock. Then the models were formulated below:

<table>
<tr><td></td><td>Model I</td><td>Model II</td><td>Model III</td></tr>
<tr><td>Objective function</td><td>Max
Sheep profit</td><td>Min
Net GHG emissions</td><td>Max
Profit = Sheep profit + environmental income</td></tr>
<tr><td>Subject to all constraints</td><td colspan="3">- Constraints of SOC accrual
- Constraints of sheep productivity and enteric methane reduction
- Constraint of total GHG emissions
- Constraints of stocking rate and sheep numbers
- Constraints of revenue and production costs</td></tr>
</table>

Results

Optimal grazing and feed management

When profit was prioritised on two farms (Model I), they would raise more sheep (approximately 1.5 times larger than those of Model II), achieved higher sheep profit and released higher emission intensity (Fig.1). While 15 paddock-fast rotation-high stocking rate was dominated on larger farm, there was a split between grazing area subject to this treatment and 30 paddock-fast rotation-high stocking rate on small farm (Fig.2). Despite generating greater profit, large farm had an emission intensity of approximately 0.6 tCO2-e/DSE higher than small farm. In contrast, if the primary goal was to reduce GHG emissions, higher emission reduction and lower profit were realised with flexible grazing and 15 paddock-slow rotation-low stocking rate. For trade-off between profit and emissions, similar adoption was considered on small farm, while combination of 15 paddock-fast rotation-high stocking rate and flexible grazing was adopted on large farm. Such grazing regimes led to higher emission intensity (about 0.4 tCO2-e/DSE higher) and lower environmental income (around $AU3/DSE less) compared with small farm. 1% biochar was used to maximise profit, while 0.2% Bovaer was considered to minimise net emissions or achieve both goals on 2 farms.

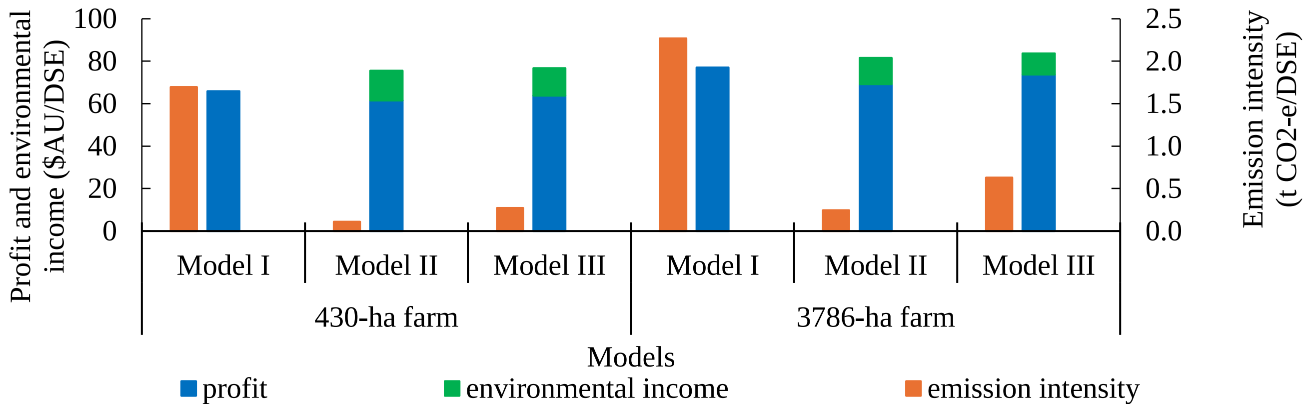

Fig. 1. Farm profit and emission intensity over 10-year simulation for three models subject to adoption of grazing treatments and feed additives

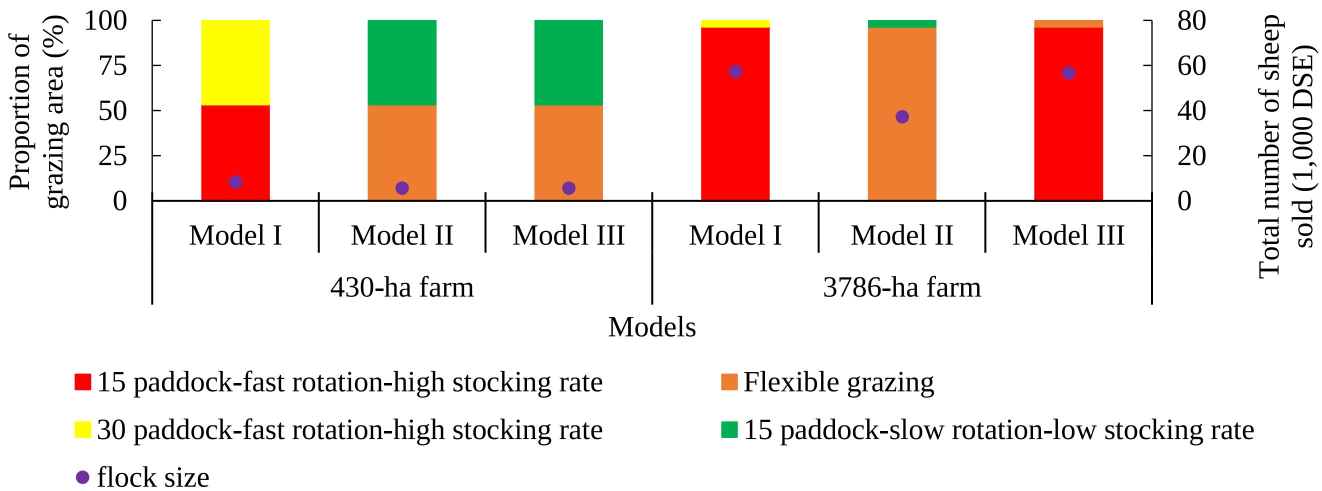

Fig. 2. Grazing management scenarios examined in the study and simulated number of sheep sold.

Impacts of carbon price on farm decision-making

When carbon price increased, small-scale farmer tended to sell sheep at early age, but did not alter their decisions on adopting grazing and feed management. In contrast, large-scale farmer adjusted their grazing management, shifting from 15 paddock-fast rotation-high stocking rate to 15 paddock-slow rotation-low stocking rate with flexible grazing dominated the grazing area, although they did not change feed management or the timing of sheep sales.

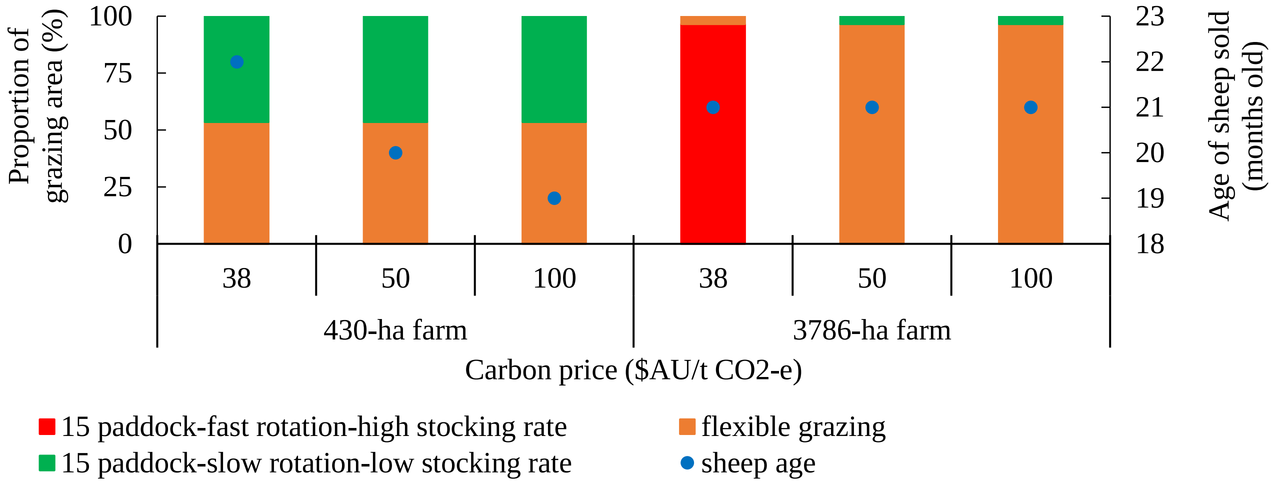

Fig. 3. Impacts of carbon price on grazing area allocation and emission intensity on farms.

Discussion

Align with Beauchemin et al. (2022), we found that combinations of grazing and feed management varied depending on farmer's objectives, even though these combinations bring greater results in emission reduction than any single management (Fujisaki et al. 2018; Harrison 2021). Fast rotation-high stocking rate with 1% biochar was most conducive to profit-aim, while flexible grazing and slow rotation-low stocking rate with 0.2% Bovaer was more conducive to emission-aim. Fast rotation-high stocking rate, though preferred for profit, is detrimental to SOC in the long term as it would negatively impacts on pasture productivity, decreasing above- and below-ground biomass and reducing SOC (Bilotto et al. 2023). In contrast, flexible grazing or slow rotation-low stocking rate (Rouquette 2015; Badgery et al. 2017) can reduce grazing pressure, promote forage growth, and increase both above and below-ground biomass, contributing to greater SOC accrual. Although multiple paddock systems can optimise pasture use and promote environmental sustainability (Jorns et al. 2023), the 30-paddock system was not preferable on large farm due to its high costs and substantial infrastructure requirements. For feed additives, biochar was preferable for profitability due to its ability to improve animal productivity (Mirheidari et al. 2019) and its lower cost compared with other feed additives, wheares Bovaer was more effective in reducing enteric methane emissions (Martínez-Fernández et al. 2014). Asparagopsis was excluded from all models due to its high cost.

Consistent with Pham-Kieu et al. (2024), our results indicated that trade-offs between profit and emission reduction was context-dependent, varying across farm size. Large-scale farmer tended to favour grazing treatments with lower infrastructure cost since they focus on optimising efficiency and minimising infrastructure investment to reduce overall production costs. Small-scale farmer, however, split the adoption of low- and high-cost treatments, likely due to higher potential for environmental income. As farmers would alter management relating to mitigation when potential profit was greater than their current activities, increased carbon price may attract more participants to join carbon credit markets and mitigate net emissions on their farms. However, the extent of these changes may depend on farm size, as large-scale farmer is likely to be responsive with price fluctuation. This could be due to their greater capacity to absorb risks, access to resource, or more substantial economic incentives. In contrast, the small farm may have limited financial resources and less flexibility to make major changes unless the financial benefit is clearly significant. Hence, future policies and legislation should thus consider mechanism to increase carbon prices and create opportunities to realise economic, environmental, social and cultural co-benefits associated with carbon farming practices.

Key words: food systems; grazing lands; rangelands; socio-ecological systems; sustainability

Abstract

Ruminant livestock production is among the most controversial land uses and sectors of our global food system today. It also may be the most consequential, impacting half the land on earth, supporting over one billion people directly, and contributing significant greenhouse gas emissions. This sector must be part of food systems transformation to support nature, tackle climate change, and improve human wellbeing. However, the environmental, economic, and social context and outcomes from these systems varies enormously. Silver bullet solutions or misapplication of scientific findings can lead to trade-offs and inefficiencies. We developed case studies from a range of biomes, production system types, socio-political and economic contexts around the world. We then did a comparative qualitative analysis to identify patterns in contextual factors that enable or create barriers to implementation of a range of management practices, and can be used to inform policy or other interventions. In this paper, we describe the contextual factors that influence uptake of different practices in three rangeland-based case studies which we chose to exemplify the three major production system types, and a cross-section of climatic and socio-economic settings – Eastern Africa, the Tibetan Plateau of China, and the Great Plains of the United States. We highlight that research and resulting policy to improve climate, biodiversity, and human wellbeing outcomes must be better tailored to the unique, often-changing local conditions than they have been in the past.

Introduction

Grazing lands make up over a quarter of ice-free land (FAO 2023) and can provide wildlife habitat, soil carbon stocks, livelihoods and cultural value in addition to livestock production (Sala et al. 2017). Globally, livestock production systems based in grazing lands exist across diverse ecological, economic, social and cultural contexts, (Rivera-Ferre et al. 2016) and outcomes (Poore and Nemecek 2018). To meet calls for greater environmental sustainability in livestock production, there is a need to understand how context – both historical and current – informs potential practice change and related outcomes. Here, we used a case-study approach to identify patterns in: 1) the key contextual factors that influence systems; 2) use of different management practices; and 3) enabling conditions and barriers for change towards improved sustainability. Our aim is to highlight how context can inform effective policy and investments to encourage sustainable livestock practices that maximize benefits and reduce harms for people, climate, and nature.

Methods

We conducted a qualitative, comparative thematic analysis of case studies from diverse livestock production systems and agroecological regions around the world (Kazanski et al. *in review*). Case studies were developed based on region-specific knowledge and experience, published literature, and input from local and regional practitioners or experts in livestock production. The case studies and the comparative analysis enabled us to explore the relative weights of the impacts of contextual factors on current practices and potential to change. Here we focus on rangeland cases from Eastern Africa, the Tibetan Plateau in China, and the cow-calf phase of cattle production in the Great Plains of the United States, which provide a cross-section of common economic/market and ecosystem contexts (Kazanski et al. *in review*). We also focus on the practice categories of agroforestry, animal management, technology and information within these case studies.

Results

Numerous environmental, economic, social and cultural characteristics shape livestock production systems (Kazanski et al. *in review*). The rangeland-based cases explored here highlight the diversity of production systems when all these elements are taken into consideration (Table 1). The case studies are predominantly based in semi-arid to arid rangelands where precipitation is the primary constraint on forage production. In Eastern African systems, livestock and wildlife coexist, introducing conflict and considerations on forage use. In the Great Plains, ranching with sound management can support wildlife by maintaining intactness of grazing lands that could otherwise be converted to crop production or developments that could reduce habitat (Cameron et al. 2014). Management and land tenure also varies: in Eastern Africa, communal grazing is predominant; in the Tibetan Plateau land was historically communally managed but has shifted to more individualized allotments; and in the Great Plains land is individually managed. In both the Eastern African and Tibetan Plateau pastoralist systems, livestock are a primary source of livelihoods (Lind et al. 2020), although tourism is an increasing source in the Tibetan Plateau (Gongbuzeren et al. 2024). Livestock also predominantly support hyper-local markets. In contrast, in the Great Plains, while ranching is core to many livelihoods, ranching families increasingly have additional jobs to diversify incomes (Wulfhorst et al. 2022) and production is linked with intensive row crop farming in service of commercial, national and global markets.

The case studies highlight that livestock production "best" practices depend on context and should not be universally applied. For example, in settings with a history of some tree canopy (e.g. in some systems across Eastern Africa), agroforestry offers benefits like improved feed and nutrition and adaptation to climate change (Balehegn et al. 2015; Balehegn et al. 2017). However, in systems that did not evolve with trees (e.g. the Great Plains or Tibetan Plateau), agroforestry practices could jeopardize biodiversity and ecosystem services (Veldman et al 2015) or fail due to soil and rainfall constraints (Briske et al. 2024). We find that even categories of practices that are generally beneficial tend to have important specific considerations depending on context (e.g. technology and information services and animal management). For example, technical services are identified as a gap/opportunity in both the Tibetan Plateau and Great Plains cases. Yet, agricultural "innovations" might look different across contexts. While ag-tech and innovation is often about robotics, precision agriculture, or new varieties, well established or traditional practices with multiple benefits may be a missed opportunity that could be bridged, e.g., through use of mobile phones with chat or video features for veterinary telehealth. Similarly, while animal management is broadly applicable, the specific goals of genetic selection and breeding, for example, can differ by context. In some cases, breeding aims for larger and faster growing animals (e.g. the commercial systems in the Great Plains). However, these breeds tend to require high nutrition, which may be limiting in low-input extensive rangeland systems. In contrast, animals with smaller mature size can be better adapted to harsh conditions (e.g., poor nutrition, extreme temperatures), and could be increasingly valued across systems as the impacts of climate change intensify. Taking context into consideration when identifying practices or system change to support sustainability is therefore critical.

We also find that the primary barriers and enabling conditions for practice implementation strongly differ by contexts (Table 1). In the analysis, economic and market settings emerged as primary drivers of change: in the Great Plains case study (an example of commercial production in a high-income country), consumer and market demands, regulatory enhancement, investment in technology research and development, and safe-to-fail trials are promising enablers for change. In contrast, in Eastern Africa and the Tibetan Plateau (multipurpose systems in low- and middle-income countries), capacity building and investment in technical assistance, culturally appropriate training on herd management, and climate investments for inputs or technology are more likely to facilitate change. We find the ability to change practices or systems is also often constrained by environmental factors, like precipitation, which is becoming increasingly variable (Sloat et al 2018). Cultural tradition and history also appeared to ossify behaviors, greatly informing future practices and systems, and what change might be possible.

Table 1. Livestock production system case study summaries. Case study details were compiled by regional experts based on the literature and additional expert input as described in a prior study (Kazanski et al. *in review*).

	Eastern Africa	Tibetan Plateau of China	Great Plains of the U.S.
Dominant production systems	**Pastoralism.** Mobile pastoral systems of diversified herds (cattle, sheep, goats). Livestock are multipurpose, providing meat, milk, and blood[1]. Many people and their livestock are located far from urban market centers.	**Pastoralism**. Yak and sheep graze high-altitude pastures for the provision of food, fuel (manure) and socio-cultural purposes. There is a history of communal land and animal management, but this is changing[9].	**Ranching**. Mostly cattle grazed in arid rangelands during cow-calf phase, then fattened/finished on grain. The system is entirely integrated into the global economy with some local and regional market opportunities.
Dominant ecosystem	Tropical and subtropical grasslands, savannas and shrublands	Montane grasslands and shrublands	Temperate grasslands, savannas and shrublands
Environmental context	Degradation of grazing lands, characterised by soil erosion, encroachment of woody	Fragile alpine soils	Climate change impacts threaten economic viability of this system[12, 13].

	species, loss of biodiversity[2].	Increased stocking rates have negative impacts on vegetation and soils[10].	
Economic context	Livestock production is core to community livelihoods[3].	Livestock products are sold into domestic markets; tourism presents opportunities to diversify livelihoods[11].	Global market integration; beef is sold into both domestic and export markets, especially Asia[14]. Profit margins are tight.
Social and cultural context	Deep cultural value of livestock[4, 5]; pastoralism has a 10,000+ year-history in the region[6].	Deep cultural history and tradition	Rural community livelihoods Ranching and cowboy culture are culturally significant
Barriers	Difficult for vulnerable communities and households to take risks on new practices[7].	Little opportunity to improve or diversify production within this ecosystem.	Consumers driven by price Capital improvements are unaffordable
Enabling conditions	Commitment to adapting livestock systems to keep them central to livelihoods[8]	Livestock production and tourism are being explored for further integration and diversified marketing strategies. Government policy is encouraging community-level grazing land management and reaggregation of livestock.	Tax breaks, insurance and subsidies can facilitate practice change

Discussion

The three case studies highlight how context informs current and potential production systems and practices. Economic and market setting, the role of livestock in culture and livelihoods, and ecological setting all interact to inform what might be considered best practices. We also see that environmental constraints, history, and cultural tradition inform what future practices or systems might be possible. It is clear that environmental, economic, and social and cultural elements are key to understanding production systems and opportunities for change. The inclusion of additional perspectives could shift the picture of these systems.

The observation that context is important is not new, but worth emphasizing, particularly to inform policy and investment. In global fora and multilateral policy efforts, there is increasing attention on livestock systems and rangelands (e.g. at recent climate COPs; the upcoming International Year of Rangelands, 2026; and FAO's recent Global Conference on Sustainable Livestock Transformation, 2023). For an equitable and just food system transformation, decision makers must incorporate understanding of context into policy and investment approaches.

Doing this, while considering multiple outcomes from livestock systems for people, climate, and nature, will be critical to crafting policies that maximize benefits and reduce harms (Harrison et al. 2021).

Key words: carbon market; cow-calf; ecosystem modelling; life cycle analysis

Abstract

Managed grazing lands cover ~25% of global land area. Carbon stored in grazing land soils (top 1 m) represent 20% of total global soil organic carbon (SOC) stocks with a potential annual SOC sequestration rate of 0.5 ton C ha^{-1} yr^{-1}. Conversely, grazing animals produce greenhouse gases (GHG). Although the US beef industry has made significant advances in reducing its environmental footprint, extensive grazing operations (e.g., the cow-calf and stocker phases) are responsible for ~ 70% of the GHG emissions from the beef value chain. Multiple stakeholders are interested in the potential effect carbon market participation may have on the financial status of the beef industry and its cascading effects to conservation and climate mitigation. Producers are interested in carbon markets to diversify income sources and drive increased profitability. Financially viable producers support diverse industries, ranging from fertilizer, feed, equipment, and beyond. Conservationists are also interested in carbon markets as a tool to fund the protection of grazing lands to benefit conservation goals. The question remains how extensive grazing operations can engage in carbon markets. We utilized life cycle analysis and an ecosystem model to understand net carbon sequestration at Archbold Biological Station's Buck Island Ranch, a commercial cow-calf grazing operation in Many ranchers are being approached by carbon credits brokers aiming to trade ranch carbon credits in carbon markets. If effective, these markets ensure globally reduced atmospheric greenhouse gas concentrations when buyers pay sellers for reduced emissions or increased sequestration. For Buck Island Ranch to credibly be paid for carbon sequestration, new management reducing emissions or enhancing sequestration is needed, even though the ranch is presently a net carbon sink. Credible carbon markets include the concept of additionality which refers to the need for payments to result in newly avoided emissions or increased sequestration beyond what would have already been occurring without the payment. Emissions could be reduced either from cattle or the environment. Inhibiting cattle methane through feed additives shows promise in the dairy industry (Belanche et al. 2020) and may be useful for pasture-based systems. Increasing soil C stocks is more difficult because many producers are already implementing effective SOC management (Silveira et al. 2024). To have a meaningful impact on climate change, ideally contracts should span at least several decades (Dynarski et al. 2020).

. Life cycle analysis estimated annual average emissions as 11,294 Mg CO2 eq. The ecosystem model estimated annual soil organic carbon sequestration as 12,391 Mg eCO2/year. Sequestration offset emissions with 1,097

metric tons CO2e remaining. A preliminary survey of ranchers' (n=23) interest in carbon markets showed barriers to enrolling in carbon markets were lack of awareness of existing programs, lack of information on programs, and not receiving credit for existing practices. Lastly, we explored the possibility for ranchers to participate in carbon markets considering common program credibility concerns.

Introduction

There is increasing interest in management of grazing lands for carbon sequestration. At the same time, there is also interest in reducing greenhouse gas (GHG) emissions from cattle on grazing lands as 70-80% of the US beef industry's GHG emissions result from the cow-calf phase of the beef life cycle, which is managed on grazing land (Rotz et al. 2019). It is critical to accurately quantify carbon uptake and emissions from grazing lands to manage carbon sequestration and reduce emissions.

Economic incentives through carbon markets are an emerging tool for conservation of grazing lands. Producers are interested in carbon markets to diversify income sources and increase productivity (Silveira et al. 2024). The potential for carbon to affect the financial status of the beef industry through carbon market participation has cascading effects to conservation. Ranching can benefit conservation goals by providing wildlife habitats, connectivity and wildlife corridors, and preserving multiple ecosystem services ranging from water quantity and quality, open space, and recreation. Therefore, maintaining economically viable ranches is an important conservation strategy. However, there is a lack of information about the producer community's interest in these programs and the barriers or incentives to participating.

Understanding baseline ranch-scale carbon emissions and uptake is the first step towards ranch participation in carbon markets. For ranch operations, life cycle assessment (LCA) is a method for evaluating environmental impacts associated with the production of goods (Rotz et al. 2019). Ecosystem process-based models can be used to quantify ecosystem carbon dynamics but these models must be validated (Zhou et al. 2021).

Here we: 1) quantify all carbon emissions from a representative ranch operation with LCA; and 2) utilize a process-based ecosystem model validated with *in-situ* ground measurements to understand ecosystem carbon emissions and uptake. To address the need for producer community interest in carbon markets we conducted a survey.

Methods

This study took place at Archbold Biological Station's Buck Island Ranch, located in south-central Florida, USA, a 4249-ha cow-calf operation with ~3,000 cattle. The ranch contains 1,953 ha of cultivated pastures planted with *Paspalum notatum* and 2,290 ha of semi-native grasslands dominated by a mixture of native grasses (*Andropogon* spp, *Coleataenia* spp, *Axonopus* spp) and *P. notatum*. The climate is subtropical with a mean annual temperature of 22ºC (1998-2021) and mean annual precipitation is 132 cm.

The carbon footprint was calculated by way of LCA employing the Beef EA model (Alltech E-CO_2, Stamford, United Kingdom), a bespoke tool employed in both research and industry. Independently accredited to be compliant with carbon footprint standards globally (ISO, 2018), the model is rooted in the Intergovernmental Panel on Climate Change (IPCC) Guidelines for National Greenhouse Gas Inventories. Emissions modelling follows the IPCC Tier 2 Framework (IPCC, 2006; 2019), however facilitates incorporation of site-specific Tier 3 data when available. This approach enabled detailed account of cows' dietary intake, for example, and incorporation of higher granularity data from an ecosystem model (described below) for estimates of CH_4 and N_2O arising from cows' deposition at pasture.

The system boundary was defined as cradle-to-gate, covering emissions arising in all inputs and processes through the supply chain and on-farm, up to the point at which the product cattle left the ranch. Operations data were collected for the period from 2015 to 2020 and GHG emissions estimated for each of the six calendar years. This included account of all ranch inputs (e.g. fertilizer, lime, pesticide, herbicide, feed use), fuel and electricity use, animal excreta and applications to the land, and enteric fermentation by cattle.

We quantified total ranch emissions in two ways: *Scenario 1*) including enteric methane and calculating direct and indirect N_2O loss and manure CH_4 by LCA Tier 2 method, but not including ecosystem methane; and *Scenario 2*) including enteric methane using LCA approach and including ecosystem methane, N_2O and manure CH_4, all calculated using an ecosystem model (*ecosys*). Not including ecosystem methane as in Scenario 1 is typical of LCA practices that consider this source a process of the natural ecosystems.

The process-based model *ecosys* was utilized (Zhou et al. 2021). This model implements biogeophysical and biogeochemical principles to simulate water, energy, carbon, and nutrient cycles over the soil-plant-atmosphere continuum at hourly time steps. The model estimates photosynthesis, autotrophic and heterotrophic respiration, and soil nitrous oxide emissions and soil emissions caused by field-level responses to environmental forcing and practice data (e.g., manure input and fertilizer). Other model inputs included animal use days for all pastures and fertilizer inputs. The initial soil carbon stock was derived from the gSSURGO database. Data from on-site groundwater wells was incorporated to ensure accuracy of the hydrology of the site, where groundwater typically rises to the surface in the wet season and recedes in the dry season. The model gross primary productivity (GPP), ecosystem respiration (Reco), and ecosystem methane were validated using eddy covariance data comparisons to model estimates. Soil carbon increases were modeled for 1 m depth of soil.

We did not include wetlands, ditches, or woodlands, but focused on pastures as the largest land use on the ranch and the landscape primarily utilized for beef production. Future work will incorporate the entire ranch ecosystem as a third scenario.

Producer Survey

We conducted a survey of beef producers in Florida to determine interest in carbon markets for pasture-based beef production. The survey asked about the incentives and barriers to practicing climate-smart agriculture and participating in carbon markets (Campbell et al. 2019). We obtained a sample of beef producers through the data procurement company DTN. We collected responses using online survey software Qualtrics between June 2023 and October 2024 and offered a $15 Amazon eCard as compensation. This survey was approved by the Archbold Ethics Review Committee, #2023-001.

Results

Throughout the six-year period, total annual emissions for scenario 1, averaged 6,294±1095 (stdev) metric tons CO2eq between 2015 - 2020 (Table 1). This resulted in an emissions intensity value of 20.97 kg CO2 eq/kg of live weight. In scenario 2, annual average emissions were 11,294 metric tons CO2 eq. Emissions intensity was 38.53 kg CO2 eq/kg live weight. Annual emissions were driven by variability in enteric fermentation, fertilizer use, and ecosystem emissions.

Ecosystem Model

The site-level simulations showed that the *ecosys* model captured both the magnitude and seasonal patterns of carbon fluxes measured by an onsite eddy covariance tower (i.e., ecosystem gross primary production (GPP), and ecosystem respiration (Reco)) with R^2 equal to 0.8 and 0.79, for GPP and Reco, respectively. The eddy covariance tower net ecosystem productivity (NEP) was -2.39 ± 0.41 Mg C ha^{-1} yr^{-1}. The *ecosys* model estimated the annual average C sequestration rate was 1.84 Mg C/ha/year. At the ranch scale, the annual increase in SOC was 12,391 metric tons eCO2/year.

Net Carbon Balance at the Ranch Scale

In Scenario 1, the net carbon balance was -6,097 metric tons CO2eq. Net emissions intensity was on average -20.31 kg CO2eq/kg live weight for calves leaving the ranch. In Scenario 2, the annual average sequestration exceeded annual average emissions by 1,097±3026 metric tons CO2eq. This resulted in an average net emissions intensity of as -3.65 kg CO2eq/kg live weight for calves leaving the ranch.

Table 1. Carbon emission and sequestration analysis from Buck Island Ranch from 2015 – 2020. Results are generated with LCA and the process-based ecosystem model *ecosys*. All units are in metric tons CO2eq, except otherwise noted.

Producer Survey

We received a total of 23 survey responses. The results from these respondents are not meant to be representative of all Florida beef producers and are not generalizable. Respondents engaged in climate-smart practices to improve soil condition (n=20), maximize profitability (n=20), and increase yield and/or productivity of the land (n=19). Nearly all respondents (n=20) conducted soil test-based fertilizer applications and rotational grazing (n=19). Barriers to engaging in climate-smart agriculture included lack of or not enough knowledge about practices (n=10, n=9 respectively) and the uncertainty about the impact on farm business (n=8). The primary barriers to participating in carbon markets reported were lack of awareness of and information on existing programs (n=10, n=9 respectively) and no credit for existing practices of past use (n=9). When asked about incentives to participate, payments for past practices (n=14) and no out of pocket program costs (n=14) were top responses.

Discussion

Here we showed that a typical ranch in the humid subtropics, is on average, a net sink of carbon. The modelling approach we employed can be utilized to determine baseline carbon footprints and assess management interventions to mitigate emissions or increase soil carbon sequestration. The model estimate of 1.8 Mg C ha $^{-1}$ yr^{-}

^{1} (1 m depth) was in line with sequestration estimates measured by soil sampling (20 cm depth: 0.9 Mg C ha $^{-1}$ yr^{-1}) and eddy covariance (1.1 -1.4 Mg C ha $^{-1}$ yr^{-1}) (Silveira et al. 2024).

Many ranchers are being approached by carbon credits brokers aiming to trade ranch carbon credits in carbon markets. If effective, these markets ensure globally reduced atmospheric greenhouse gas concentrations when buyers pay sellers for reduced emissions or increased sequestration. For Buck Island Ranch to credibly be paid for carbon sequestration, new management reducing emissions or enhancing sequestration is needed, even though the ranch is presently a net carbon sink. Credible carbon markets include the concept of additionality which refers to the need for payments to result in newly avoided emissions or increased sequestration beyond what would have already been occurring without the payment. Emissions could be reduced either from cattle or the environment. Inhibiting cattle methane through feed additives shows promise in the dairy industry (Belanche et al. 2020) and may be useful for pasture-based systems. Increasing soil C stocks is more difficult because many producers are already implementing effective SOC management (Silveira et al. 2024). To have a meaningful impact on climate change, ideally contracts should span at least several decades (Dynarski et al. 2020).

Producers are interested in these programs but lack information about climate smart practices, carbon markets and the best way to engage. They are concerned about the lack of acknowledgment for the benefits of existing practices and require more information about how participating in carbon markets affects farm business.

Key words: *Mulberry*, Reduced Methane Emission, Sustainable, Livestock, Feeding System

Abstract

Mulberry (*Morus* species; Family: *Moraceace*) leaves are source of highly palatable as well as digestible fodder during summer season and are rich in crude protein content (14.0–34.2%) and macro as well as micro nutrients. These leaves are rich in secondary metabolites known to enhance livestock production including the flavonoids present in mulberry leaves are known to show efficacy in managing fatal livestock diseases such as neonatal calf diarrhea and reducing enteric methane production. Moreover, mulberry species is easy to propagate, and produces high leaf biomass yield and can be grown under vast climatic conditions from arid, semi arid, tropical, subtropical to temperate conditions. Further, mulberry species can be managed as a tree, shrub or hedge and has been found to be compatible to be grown under agro-forestry systems, as high density plantations, as boundary plantations and bund plantations etc. Thus, given the pressing issues of declining livestock productivity, increasing enteric methane emissions, and the prevalence of livestock diseases, harnessing the potential of mulberry species emerges as a sustainable solution which needs promoting cultivation of mulberry species ensuring sustainable livestock feeding systems in India. For cultivation, identification of elite germplasm that are well suited to the various climatic conditions along with higher and uniform leaf biomass yield, high protein as well as nutritional profile, nutraceutical potential (flavanoid rich) and methane reduction potential is required which can be promoted for cultivation among farmers. Thus, there is an urgent need to initiate screening of mulberry species germplasm for identification of superior genotypes of mulberry for ensuring economically viable way to reduce enteric methane emissions and ensuring sustainable livestock feeding systems in India under various agro-climatic zones.

Introduction

In India, livestock plays a key role in sustaining rural economy and nutritional requirements of the rural people. Besides this, livestock sector also contributes 4.11% and 25.6% respectively to total GDP and agriculture GDP of India. The average milk productivity of milk animals in India is significantly lower than in developed countries such as the USA and UK (Intodia, 2017). Sustaining livestock production is crucial for bolstering the rural economy in India, where the livestock population stands at 535.78 million, according to the 20th Livestock Census (2019), reflecting a 4.43% increase since the 2012 census (Singh, 2020). However, low productivity is primarily attributed to a persistent shortage of quality fodder. The rising livestock population exacerbates this demand-supply gap, emphasizing the urgent need for strategies to enhance fodder availability and ensure sustainable livestock production. According to reports, India faces a deficit of 11.24% for green fodder and 23% for dry fodder (Roy et al. 2019). Moreover, feedstuff and fodder that is fed to our livestock is of poor quality especially feed/fodder stuff that is fed during the dry/lean period is poor in crude protein content, digestible nutrients, metabolizable energy, vitamins and macro as well as micro mineral content (Devendra 2011, Simbaya 2020). Because of poor quality of feed, digestibility as well as utilization of nutrients gets reduced and it leads to increased enteric methane emission from livestock, the lesser body weight gain and reduced milk production (Devendra 2011, Simbaya 2020). Therefore, ensuring round the year quality nutritious fodder supply and improving protein availability for livestock during lean period is need of the hour to ensure fodder security, reduce enteric methane emission from livestock via inhibiting the growth of methanogenic bacteria and ciliates inside gut and sustain livestock productivity. Under such case, tree fodder leaves are sustainable option for ensuring round the year quality fodder supply and to address dry season protein and nutrients deficiency for livestock and reduce enteric methane emissions (Jetana et al. 2010, Chibinga et al. 2012). Therefore a literature review was carried out to shortlist important fodder tree species to identify tree species that are easy to grow as well as widely distributed; protein, macro micro nutrient as well as secondary metabolite rich to ensure round the year quality fodder supply, reduce enteric methane emissions and enhance livestock productivity.

Methods

Literature review was carried out using relevant sources, including peer-reviewed journals, government reports, institutional publications, and databases like Scopus, Web of Science, and Google Scholar to identify important fodder tree species that are easy to grow as well as widely distributed; protein, macro micro nutrient as well as secondary metabolite rich to ensure round the year quality fodder supply, reduce enteric methane emissions and enhance livestock productivity. Based on the literature review, mulberry species was found to be the potential fodder species to fulfil above mentioned concerns. Thereafter, ICAR-IGFRI, Jhansi, India started collection of mulberry species germplasm via exploration in Himalayan zone as well procurement from various research organizations from India covering various agro-climatic zones for evaluation and selection of high yielding and nutritionally rich genotypes of mulberry for semi arid and temperate conditions.

Results

Mulberry (*Morus* species) belonging to family Moraceae are potential fast growing fodder tree species that are found growing under various agro-climatic zones from arid, semi arid, tropical, subtropical to temperate conditions. Mulberry leaves contain higher crude protein content (14 – 35%) than the traditional forages; are rich in macro as well as micro nutrients (Ca, P, K, Na, Mg, Fe, Zn, Mn, B, Cu, Mo); are highly palatable as well as highly digestible (75–85%); available during during summer season and rich in secondary metabolites especially mulberry leaf flavonoid that enhance livestock production (yield and quality), reduce enteric methane production via inhibiting the growth of methanogenic bacteria and ciliates inside gut and are also utilized in livestock disease management like neonatal calf diarrhea (Bi et al. 2017, Hassan et al. 2020). Moreover, mulberry leaf supplementation to dairy animals has been proved to enhance milk yield and quality (protein, fat content) (Datta et al. 2002, Venkatesh et al. 2015). Supplementation of livestock feed with 5–10% of mulberry silage have been reported to improve rumen micro-biota, fermentation, and enhance the production of fiber-digesting, propionic acid synthesizing and milk fat enhancing microorganisms leading to the improvement in milk yield in dairy animals (Li et al. 2020). Secondary metabolites especially mulberry leaf flavanoids present in mulberry leaf have been reported to enhance milk production improve health and manage serious disease like neonatal calf diarrhea (Gonzalez et al. 2010, Bi et al. 2017, Li et al. 2020). Further, mulberry leaves can be easily converted into hay, silage, leaf meal etc. thereby can also be stored for feeding the livestock during fodder scarcity. Another advantage with mulberry species is that they are fast growing, easy to propagate, and produces high leaf biomass yield of 25-30 t/ha depending upon the species, harvest cycle and plant density (Venkatesh et al. 2015). Moreover, mulberry species can be grown in various forms such as tree, shrub, hedges etc. and being perennial, deep rooted tree species they are less susceptible to changing climatic and weather conditions. Huge genetic variation in mulberry species germplasm with respect to the growth, leaf yield, and fodder quality traits, secondary metabolites (flavanoid content) as well as biochemical, methane reduction potential, ensiling traits; physiological, phenological, agro-morphological traits etc. has been reported (Taikader and Kamble 2009, Kandylis et al. 2009, Gonzalez et al. 2010, Doss et al. 2012, Suresh et al. 2017, Yu et al. 2018, Hassan et al. 2020, Krishna et al. 2020). This genetic diversity among mulberry species germplasm have a huge potential to be exploited for identification of elite germplasm of mulberry species for mitigating enteric methane emissions and ensuring sustainable livestock feeding systems across various agro-climatic zones in India.

However, despite being a potential species for ensuring fodder security, mitigating enteric methane emissions and enhance livestock productivity, mulberry has not been utilized quality fodder production in the country and limited attention to *Mulberry* has been given by livestock and fodder researchers. Therefore, ICAR-Indian Grassland and Fodder Research Institute, Jhansi have initiated the research work on these aspects and collected a diverse collection (73 collections) of mulberry germplasm at IGFRI, Jhansi belonging to the five species (*Morus alba*, *M. latifolia*, *M. indica*, *M. laevigata* and *M. bombycis*). These collections are being evaluated under semi-arid and temperate conditions for fodder yield as well as quality traits and during initial observations under nursery conditions huge variations for growth, morphological, biochemical and fodder traits have been observed in *M. alba* germplasm. The germplasm revealed wide variations for height (81.67 to 200 cm), diameter (8.70 to 15.56 mm), and number of leaves per plant (39.33 to 189.33), total chlorophyll content (0.90 to 1.93 mg/g of fresh weight), and total carotenoid content (24.60 to 88.20 µg/g of fresh weight). Furthermore, significant variation was observed in qualitative morphological traits of leaves. Leaves were either homophyllous or heterophyllous; leaf lobation varied from being unlobed, bilobed, trilobed & tetra-lobed, leaf apex varied from acute or narrowly acute to acuminate; leaf margin was either crenate or crenulate; leaf base was either cordate or truncate or combination of both. These variations can be linked to yield and quality traits, enabling indirect selection.

Given these findings, there is a pressing need to initiate an extensive evaluation of mulberry germplasm collections to identify and screen out promising genotypes suitable for ensuring sustainable livestock feeding system in India.

Discussion

Mulberry species are potential affordable as well as scalable option for ensuring fodder security, mitigating enteric methane emissions and enhance livestock productivity in India. Therefore, there is need to collect diverse germplasm of mulberry species and evaluate it across various agro-climatic zones in India for screening out promising genotypes for fodder yield as well as quality traits and reducing enteric methane production to ensure sustainable livestock feeding system in India.

Abstract

Silvipastoral systems, which integrate trees, forage, and grazing livestock on the same land, have gained importance because of their potential for carbon storage and for improving farmers' livelihoods. A study conducted in the subtropical region of the northwestern Himalayas along the elevation gradient (Zone I: <600 m amsl and 600-1200 m amsl). In Zone I, five agroforestry systems were identified: agrisilviculture, agrisilvihorticulture, agrisilvipastoral, pastoralsilviculture, and silvipastoral, whereas Zone II represents six agroforestry systems (agrisilviculture, agrisilvihorticulture, agrisilvipastoral, pastoralsilviculture, and silvipastoral). The pastoral-based agroforestry systems were specifically categorized as agrisilvipastoral, Pastoral silviculture, and silvipastoral. Six grass species (*Simarouba glauca, Imperata cylindrica, Cercocarpus montanus, Haemonchus contortus, Cymbopogon martini* and *Apluda mutica*) were recorded in both zones under pastoral-based systems, with tree species such as *Bauhinia variegata*, *Terminalia bellerica, Albizia chinensis, Ficus palmata, Grewia optiva, Acacia catechu, Bombax ceiba, Melia azedarach, Toona ciliata, Dalbergia sissoo, Populus deltoides, Leucaena leucocephala,* and *Morus alba*. In Zone I, the Agrisilvihorticulture system had the highest total biomass, followed by silvipastoral, agrisilviculture, agrisilvipastoral, and pastoral silviculture. In Zone II, the order was agrisilvihorticulture > silvipastoral > agrisilviculture > agrisilvipastoral > agihorticulture > pastoral silvicultureHowever, soil carbon stock was the highest in the silvipastoral system, resulting in the highest overall carbon stock in the silvipastoral system, these findings suggest that silvipastoral systems in subtropical regions have significant potential for carbon storage while meeting livestock forage demands, making them a valuable strategy for climate change mitigation in the subtropical western Himalayas

Introduction

Livestock is a key component of the agricultural system in India, and is crucial for the livelihood of rural households (Hemme and Otte 2010). Due to the rise in livestock population, increased forage demand has led to low livestock production (DAHD&F 2021). Forage production in India has always been hampered by the unavailability of sufficient arable land with irrigation facilities and changes in the land-use system. In addition, climate change has affected the productive capacity of land for high-quality forage production. Therefore, a balanced and sustainable land-use system is required to meet the forage demand, climate change mitigation, and livelihood security of rural communities. Incorporating fodder trees with grass/other components of land use is considered a climate-change-resilient land-use system (Mbow et al., 2014). The integration of fodder trees with agricultural crops or grasses is termed agroforestry practice.

In agroforestry, the integration of fodder trees with agricultural crops or grasses is classified into different systems such as Agrisilviculture, Agrisilvihorticulture, Agrisilvipastoral, Pastoralsilviculture, and Silvipastoral systems. By integrating ecological functions with productive agricultural activities, silvopasture systems hold immense promise for confronting the challenges posed by climate change (Lawson et al., 2018; Rosenstock et al., 2019). Silvopasture/pastoralsilviculture systems represent a dynamic fusion of trees, forage, and livestock, meticulously orchestrated to optimize land productivity and ecological resilience (Jose, 2009; Peters et al., 2013). However, the synergies of tree-grass associations need to be explored and exploited by evaluating different fodder tree species with a combination of grass species under different climatic conditions. Furthermore, besides fulfilling fodder demand, agroforestry has been identified as having the greatest potential for carbon sequestration among all land uses (Nair and Garrity, 2012). The global assessment of carbon accumulation in agroforestry varied from 0.29 to 15.2 Mg C ha^{-1} $year^{-1}$ aboveground and 30–300 Mg C ha^{-1} $year^{-1}$ for soils down to 1 m depth (Nair et al. 2009). Based on the areas assessed as suitable for agroforestry interventions, a carbon storage potential of 1.1–2.2 Pg. C have been estimated globally (Albrecht and Kandji, 2003). Therefore, agroforestry is receiving increased attention in global initiatives, such as Reducing Emissions from Deforestation and Forest Degradation (REDD), because of its implication in improving and regulating climate variability (Jose and Bardhan, 2012). While previous studies have highlighted the potential of agroforestry systems for carbon sequestration, the specific contribution of silvopastoral systems in the northwestern Himalayas remains understudied, particularly across agroforestry systems. This study aims to evaluate the biomass and carbon sequestration potential of pastoral-based agroforestry systems across two elevation zones in the northwestern Himalayas, with a focus on silvopastoral systems as a climate-resilient strategy.

Methods

The study was conducted in two elevation zones, Zone I (< 600 m amsl) and Zone II (600-1200 m amsl), in the Nalagarh block of the Solan district of Himachal Pradesh, India. The stratified random sampling technique was used for the selection of the study area at two elevation zones, and then the sample plots were randomly distributed in each elevation zone. The existing agroforestry systems in the selected study area were classified into six types based on the structure (nature and arrangement) and function (role/output) of their components.

A 30 × 10 m^2 sample plot was laid in each agroforestry system. Within each sample plot, two subplots of 10 × 10 m and four subplots of size 50 × 50 cm were marked to observe respectively shrubs and herbage. To estimate agricultural crop biomass, four quadrats of size 2 × 2 m were marked for each system type. The aboveground tree biomass was estimated by a non-destructive method using volume equations developed by FSI (1996). Soil samples were collected from each plot at depths of 0-20 cm using a soil auger. Tree, herb, shrub, crop biomass, and tree carbon stock was calculated using the methods described by Singh and Kumar (2018). (2022). The collected data were statistically analyzed at a 5 percent level of critical difference using the software package "STATISTICS".

Results

Identification of pastoral-based silvopasture systems.

In zone I, the pastoralsilviculture system incorporated timber, fuel, and fodder trees, such as *Terminalia bellerica, Dalberigia sisso, Albizzia chinensis, Bauhinia variegata*, and *Ficus palmata*. Alongside these trees, various grass components, including *Seteria glauca, Imperata cylindrica, Chrysopogon montanus, Heteropogon contortus, Cymbopogan martinii*, and *Apluda mutica* were present. In the agrisilvipastoral system in Zone I, maize, brinjal, okra, rice, blackgram, and tomato were cultivated during the kharif season, whereas wheat, cauliflower, radish, barley, and onion were grown during the rabi season. Along the field bunds Various trees, such as *Cassia fistula,* *Dalbergia sissoo, Terminalia bellerica*, and *Toona ciliata*, were strategically planted in different quantities and arrangements. *Populus deltoides* trees played a significant role in this agroforestry system, being intentionally planted at various densities. Additionally, a mix of grasses, such as *Imperata cylindrica, Heteropogon contortus, Apluda mutica, Cymbopogon martini*, and *Chrysopogon montanus*, adorned the field bunds in assorted combinations.

In zone II, the pastoralsilviculture system comprised six distinct system units, incorporating a range of grasses, such as *Apluda mutica, Seteria glauca, Imperata cylindrica, Chrysopogon montanus, Heteropogon contortus*, and *Cymbopogon martinii*. Alongside these grasses, the system featured tree components, such as *Terminalia bellerica, Bauhinia variegata, Ficus palmata,* and *Albizzia chinensis*. Within the agrisilvipastoral systems in Zone II, farmers cultivate three primary cereal and vegetable crops (maize, rice, and okra) during the Kharif season and wheat, mustard, radish, and barley during the Rabi season. Along the field bunds in these systems, farmers intentionally planted trees, such as *Leucaena leucocephala, Morus alba, Albizzia chinensis, Grewia optiva, Bombax ceiba*, and *Bauhinia variegata*. Grasses such as *Digitaria stricta, Themeda anathera, Imperata cylindrica, Apluda mutica*, and *Cymbopogon martinii* were also cultivated. The pastoralsilviculture includes the trees species like *Grewia optiva, Bauhinia variegata, Ficus palmata, Morus alba, Leucaena leucocephala, Albazzia chinensis*, and *Bombax ceiba* along with *C. martinii, D. stricta, A. mutica, H. contortus, P. maximum*, and *T. anathera* as grass component.

Biomass and soil carbon density

The different types of agroforestry systems and varying elevation zones significantly influenced aboveground, belowground, and total biomass. In elevation zone I, the sequence of total aboveground biomass was highest in agrisilvihorticulture (29.57 t/ha), followed by Silvipastoral (27.97 t/ha) and Agrisilviculture (24.68/ t/ha). Similar trends were observed in Zone II, where Agrisilvihorticulture achieved 11.32 t/ha, followed by Silvipastoral (9.53 t/ha). The maximum belowground biomass in zone I was reported in Agrisilvihorticulture, Agrisilviculture, and Silvipastoral. Conversely, in elevation zone II, the maximum belowground biomass was recorded in the agrosilvihorticulture system, followed by the silvipasture system. The total biomass was found to be the highest in the Agrislivihorticulture system. The soil bulk density at elevation zone I was the highest in pastoral-silviculture, followed by silvipasture. In contrast, in elevation zone II, the highest value was recorded in the slivupasture system, followed by the pastoralsilviculture system. The soil organic carbon was found highest under Silvipastoral system (0.81 %) followed by Pastoral silviculture system (0.78 %).

Discussion

Agroforestry is a key component of climate change mitigation and livelihood security. Various agroforestry systems and their units have been studied in both the elevation zones. In this context, various researchers have recorded the same number of agroforestry systems with their respective units in the midhills of the northwestern Himalayas (Upadhyaya 1997; Goswami 2008). The multipurpose trees were recorded to exist in varied numbers on the bunds of agricultural fields, except for *P. deltoides* trees, which were regularly spaced all around the agricultural field. Trees of *D. sisoo, M. azedarach, C. fistula,* and *S. cumini* were found on bunds of agricultural fields, providing fuelwood, minor timber, and fodder for subsistence**.** Among the existing agroforestry systems, agrisilviculture, agrisilvihorticulture, and agrisilvipasture systems illustrate a greater diversity in their components.

In agroforestry, biomass accumulation and carbon sequestration are influenced by various factors, including climatic conditions, soil characteristics, phenology, and floristic diversity, which mainly occur through the absorption of atmospheric CO_2 during photosynthesis and the transfer of fixed carbon into vegetation, detritus, and soil pools for long-term storage in aboveground and belowground major segments (Baes *et al.* 1977; Nair *et al.* 2010). In the current study, the biomass and carbon stock were highest in agrisilvihorticulture, followed by the silvipasture system at elevation zone II. These findings are consistent with those of Singh (2017) and Bammanahalli (2016) in the subtropical region of Himachal Pradesh. Variations in biomass and carbon production are influenced by plant species diversity and genetic diversity interactions within dominant plant species (Crawford and Rudgers 2012). Goswami *et al.* (2014) found that agrisilvihorticulture and agrihortisilviculture systems produced higher biomass than the silvipasture system, as well as pure agriculture or grassland in the western Himalayan watershed. The higher biomass production observed at elevation zone II could be attributed to a greater number of tree species in the agroforestry systems, closer proximity to plant management practices, and variations in species composition. It is well established that incorporating trees into croplands and pastures enhances both aboveground and belowground carbon sequestration (Palm *et al.* 2004; Haile *et al.* 2008

The soil organic carbon content in the present investigation ranged from 0.66% to 0.81%, with the highest levels recorded in the silvipastoral system, followed by the pastoral silviculture system. Similar organic carbon levels have been reported by various researchers in agroforestry soils of the northwestern Himalayas (Rajput et al., 2015; Prenil, 2014; Singh, 2014; Bhutia, 2017). The higher soil carbon stock observed in silvopastoral systems may be attributed to enhanced organic matter input from tree litter and root exudates, which promote microbial activity and soil aggregation, thereby improving carbon retention. These findings highlight the significant role of agroforestry in climate change mitigation. Among various agroforestry systems, the agrisilviculture system exhibits high potential for carbon sequestration and food security, whereas the pastoral silviculture and silvipastoral systems store the highest soil organic carbon while also meeting the nation's fodder demand.

Therefore, it is concluded that in the midhills of the northwestern Himalayas, agrihortisilviculture followed by silvipastoral and pastoralsilviculture systems have a greater scope for climate change mitigation.

Table 1: Crop combination with tree components by different farmers s in terms of system units at elevation zone I and zone II.

Agroforestry systems	Agriculture/grass component		Tree components
	Kharif	Rabi	
Zone I			
Agrisilviculture	Zea mays (Maize), Capsicum annuum (Chilli), Abelmoschus esculentus (Okra), Solanum lycopersicon (Tomato) Solanum melogena (Brinjal), Oryza stavia (rice), Vigna mungo (Blackgram), Curcuma longa (Turmeric)	Triticum aestivum (Wheat), Hordeum vulgare (Barley), Brassica juncea (Mustard), Allium. cepa (Onion), Brassica oleracea (cauliflower), R. raphanistrum & Brassica juncea	Dalbergia sisso, Bahunia variegata, Bambax ceiba, Toona ciliata, Ficus palmata, Populus deltiodes, Grevia optiva, Morus alba, Melia azedarach,
Agrisilvihorticulture	Zea mays, Capsicum annuum, Abelmoschus esculentus, Solanum Lycopersicon, Solanum melogena, Oryza stavia, Curcuma longa & Vigna mungo	Triticum aestivum, Brassica juncea, Allium Cepa, Brassica oleracea oleracea, R. raphanistrum, Hordeum vulgare	Morus alba, Grewia optiva, Citrus limon, Mangifera indica, Psidium guajava, Melia azedarach & Cassia fistula

Pastoralsilviculture	**Grasses:** Simarounba glauca, Imperata cylindrica, Cercocarpus montanus, Haemonchus contortus, Cymbopogon martini, Apluda mutica, C. martini		Terminalia bellerica, Dalbergia sisoo, Albizia chinensis, Bahunia variegata, Ficus palmata, Grevia optiva, Acacia catechu & Bombax ceiba
Agrisilvipastoral	Zea. mays, Oryza stavia, Abelmoschus esculentus, Solanum melogena, Solanum Lycopersicon, Vigna mungo	Triticum aestivum, Brassica oleracea, R. raphanistrum, Hordeum vulgare, Allium cepa, Brassica juncea	Populus deltoides, Cassia fistula, Dalbergia sissoo, Terminalia bellerica, Toona ciliata, Grevia optiva, Albizia chinensis, Bombax ceiba
	Grasses: Imperata cylindrica, Haemonchus contortus, Apluda mutica, Cercocarpus montanus, Simarounba glauca, Cymbopogon martini		
Silvipastoral	**Grasses:** Cercocarpus montanus, Haemonchus contortus, Imperata cylindrica, Apluda mutica, Simarounba glauca, Cymbopogon martini		Melia azedarach, Terminalia bellerica, Toona ciliata, Bombax ceiba, Dalbergia sissoo, Bahunia variegata, Albizia chinensis
Zone II			
Agrisilviculture	Z. mays, C. annuum, A. esculentus, S. melogena, V. mungo, C. longa, S. lycopersicon C. annuum, A. esculentus	T. aestivum, R. raphanistrum, H. vulgare, B. juncea, A. sativum, H. vulgare, B. oleracea and A. cepa	G. optiva, A. chinensis, L. leucocephala, T. bellerica, M. alba, F. palmata, B. variegata, L. leucocephala, B. ceiba, Z. mauritiana & A. chinensis
Agrisilvihorticulture	Z. mays, C. annuum, A. esculentus, O. sativa, C. longa & S. lycopersicon,	T. aestivum, B. juncea, R. raphanistrum, H. vulgare, A. cepa	G. optiva, A. chinensis, L. leucocephala, C. limon, T. bellerica, M. alba, F. palmata, B. variegata

Abstract

We conducted a large research project to address knowledge gaps relating to how grazing management may affect soil organic carbon (SOC) in the northern Australian rangelands. 2257 soil cores over 908 sites were sampled to a depth of 120 cm, and SOC and other relevant soil parameters were determined at 5 cm intervals using spectroscopy. Additionally, in-situ information on land type, land condition and time-series observations of total biomass, vegetation cover, surface reflectance were collected from satellite sensors. The results showed a positive correlation between SOC and land condition. We integrated these results in a modelling tool which will allow us to identify the greatest opportunities for SOC sequestration in the rangelands and potential scenarios of improved grazing management.

Introduction

Increasing Soil Organic Carbon (SOC) by improving grazing management is being rapidly adopted by the livestock sector as an option for improving soil health and offsetting greenhouse gas emissions. The feasibility of significantly increasing SOC through improved grazing management in semi-arid regions remains less evident (Henry et al 2024, McDonald et al 2023, Bartley 2023). Changes in SOC often occur slowly over long periods, requiring resource intensive long-term monitoring to detect significant trends. Our goal is to develop a tool which integrates soil and vegetation sampling, remote sensing data and modelling to assess the dynamics of SOC in the rangelands. A critical step is to understand and account for the long-term effects of management (especially grazing) and SOC. We used an indirect way to account for grazing management: we assessed Land Condition (LC) and assumed that sites with the same land type (i.e. geomorphology and vegetation) but contrasting LC have had differences in grazing management in recent years. The underlying hypothesis that we tested is that sites with better LC will have higher SOC.

Methods

We sampled soil properties, vegetation type, LC and historical land management across the Australian Agricultural Company (AACo) cattle stations in the northern rangelands. We sampled the variability in land types using land mapping from Queensland and the Northern Territory. We also used a land type classification generated in house using digital soils mapping techniques (e.g. Minasny 2015), combining data inputs from the Landsat sensor including fractional and persistent green cover (JRSRP, 2022), and the Radiometric Grid of Australia (Wilford, 2019). We also identified locations with the same land type but contrasting LC scores across a fence. Additionally, we selected 15 paired sites either side of the fence between the cattle grazed Brunette Station and the Connells Lagoon Conservation reserve, which has been intentionally left unburnt and ungrazed since 1982 (Australian Heritage Database, accessed Dec 2024).

Soil sampling

Soil samples were taken to a depth of 120 cm. Five cores, 10 m apart linearly, were sampled per site in 2022. This was reduced to 3 in 2023 following analysis of the 2022 data (Figure 1). The cores were kept refrigerated at 5°C and transported to a laboratory where they were analysed using the SCANS system (Viscarra Rossel et al 2017). Soil and SOC mass for each 5cm sublayer in each core were calculated following DCCEEW (2024) for spectral modelling. Carbon mass was reported on specified soil masses rather than depth to avoid inaccuracies due to core compression, core recovery and changing bulk density in swelling clays. Results are reported for 3500 and 7000 t soil/ha. These masses represent sampling depths of approximately 30 and 56 cm.

Vegetation and Land Condition

Land condition (LC) is a relative measure of the health of grazing lands and is determined by simultaneously assessing indicators of soil and pasture condition, woodland thickening and the presence of weeds (Future Beef, accessed Dec 2024). Rangeland officers with experience in the AACo grazing lands performed a rapid visual assessment in each sampling site following the specific regional guidelines published by the Northern Territory or Queensland. To account for conditions which were intermediate between the four ABCD classes, the officers rated each site using a 7-class system including: A, A-B, B, B-C, C, C-D and D.

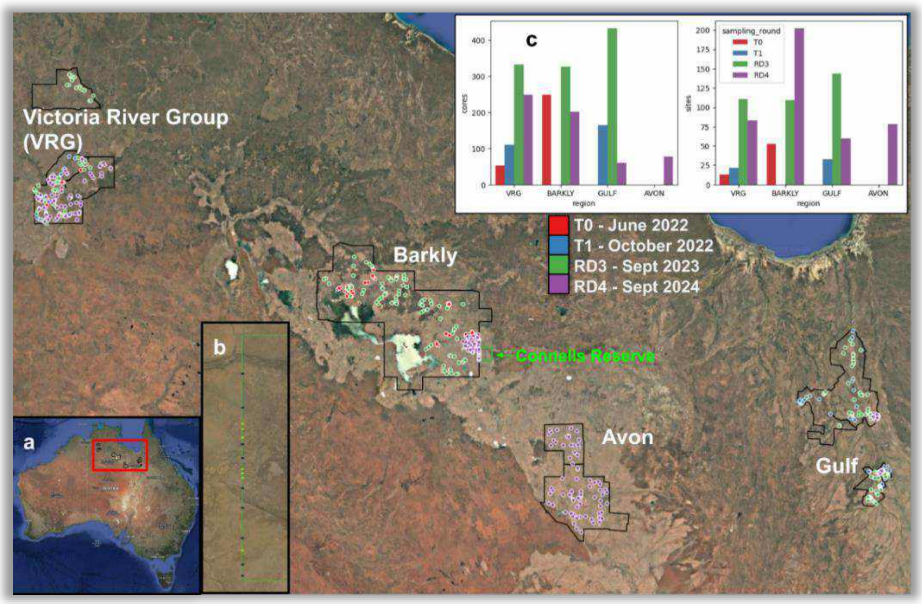

Figure 1: Location of the soil samples collected. Symbol colours correspond to the sampling round as: T0: May/June 2022, (5 cores per site); T1: September 2022, (5 cores per site); RD3: September 2023 (3 cores per site) and RD4: September 2024 (1 core per site). Inset a shows the location of the study area in Australia. Inset b shows the paired sites across the fence dividing Brunette Station (left) from the Connells Conservation Reserve (right). Black and green dots correspond to the clays and rises respectively. Inset c shows the number of cores (left) and the number of sites (right) per region and sampling round.

Landscape carbon model

The landscape carbon tool integrates a series of models with spatial data and spatially referenced databases for model parameters and management events. The key integrated models include a simple pasture growth model, which is coupled with an implementation of the RothC soil carbon model for Australian conditions (Janik et al., 2002, Skjemstad et al., 2004). LC can be incorporated as either a direct multiplier that affects pasture productivity (Net-Primary Productivity) or as a modifier of the soil cover setting in Roth-C. The final calibration of the integrated model is currently in progress utilising the extensive empirical dataset collected through this project. The initialisation of the SOC pools in RothC is taken from soil carbon baseline mapping, for which we employed a multi-layer perceptron (MLP) model (LeCun et al 2015), trained using soil sampling data collected in the project. Inert Organic Carbon could not be directly measured and was therefore estimated based upon the Soil and Landscape Grid of Australia (SLGA) (Wadoux et al 2022) data. The clay fraction is also determined from the trained MLP model outputs for the AACo estate. Where this more specific data is not available, the model can be run using SLGA data.

Results

We collected 2257 soil cores over 908 sites between June 2022 and September 2024 (Figure 1). Of these, 450 cores from 150 sites were taken at locations where Land Condition varied across a fence (75 pairs) and 30 cores (15 pairs) corresponded to paired sites in the Brunette Station – Connells Reserve.

Soil Organic Carbon and Land Condition

SOC mass was positively correlated with Land Condition (a), but the low Pearson's correlation (0.162) indicated that many other factors also determine SOC. Nevertheless, the low p-value from linear regression analysis showed a very low p value, indicating that the probability of finding these results if LC and SOC were not correlated are extremely low. The slope of the regression (1.95) suggests that by every point of improvement in LC (e.g. from C to B condition) results in an average increase in SOC of 0.65 ton C per ha. The 75 paired sites with contrasting LC had a mean difference of SOC of 0.25 ton C/ha (t-test p= 0.11) (b). SOC was, on average, 1.49 ton C/ha higher in the Connells Conservation Reserve (ungrazed) than in Brunette Station (grazed) (c) (t-test p= 0.015). The difference between the grazed and ungrazed SOC was much higher in the rises (mean = 2.53 ton C/ha) than in the clays (mean = 0.58 ton C/ha).

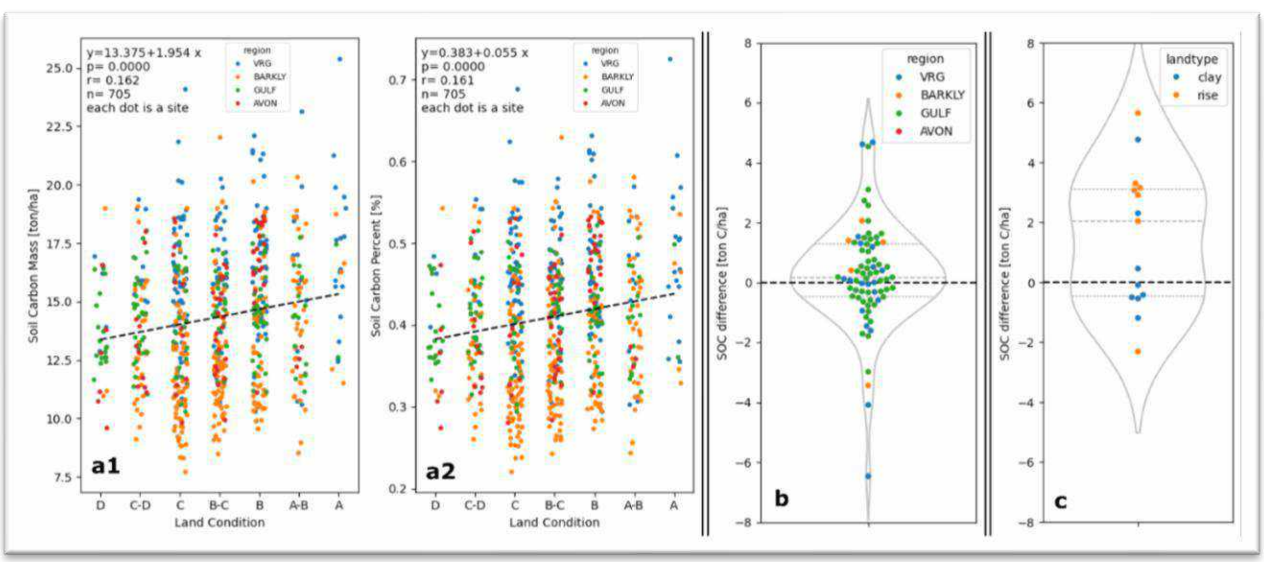

Figure 2: Soil Organic Carbon (SOC) and Land Condition (LC). Panels a1 and a2 show the relationship between SOC and LC over all sites in the study. The black dotted lines show the linear regression between SOC mass (a1) and SOC percent (a2) and LC, where LC was given an ordinal value ranging from 0 (D) to 1 (A). Panel b shows

a swarm plot and violin plot of the difference in SOC mass in the paired sites (n=75). The difference was calculated always as the mass on the better LC side minus the SOC mass in the worse LC side of the fence. Panel c shows the difference in SOC mass for each paired site between the Conells Conservation Area (ungrazed) and the Brunette Station (grazed).

Soil Organic Carbon Baseline and Landscape Carbon modelling

Figure 3a shows the baseline SOC map of the study area. Figure3b shows an example simulation based on preliminary model calibration. The simulation incorporates the time-series climate data, together with site specific soil properties. Two scenarios were simulated: business as usual, and an improved Land Condition. Both scenarios have the same historical data and assumptions, with the improved Land Condition, scenario only differing from 2025 with an assumed uplift in Land Condition. The interannual variation due to climatic variability, influencing both pasture growth and soil carbon decomposition, is obvious. As the scenarios move into a projection from 2025, both scenarios show the same underlying variability due to the cycled climate data, with a gradual build in the soil carbon mass for the improved Land Condition over the 20-year projection period compared to the business-as-usual scenario.

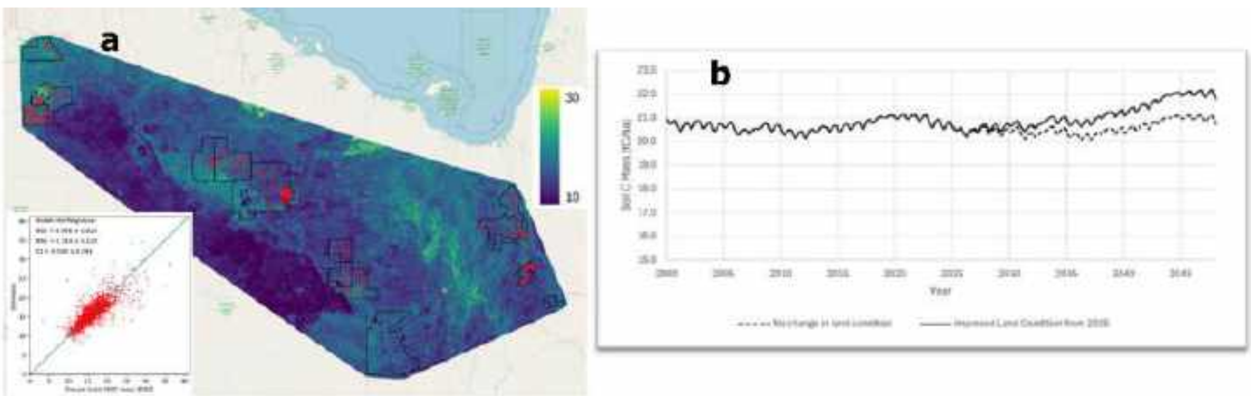

Figure 3: a: Soil Organic Carbon Baseline showing the SOC mass in the top 3500 tons of soil in ton SOC per ha. The red dots show the soil sampling locations. The inset scatterplots show the relationship between the measured SOC and the SOC value from the baseline. b) Example SOC Mass for top 3500t soil mass, historical trend, and projected scenarios from 2025 for a 'No change in Land Condition' and an 'Improved Land Condition scenario'

Discussion

With these comprehensive data we assessed the relationship between SOC and land management in 3 ways. In two of these we used Land Condition as a proxy for grazing management effects on the vegetation and soils with a space-for-time method. We found a noisy but positive and statistically significant relationship between LC and SOC. On average, the difference due to one LC class (e.g. class C vs B) resulted in a difference of 0.65 ton C per ha. When we compared contrasting LC states across a short distance over a cattle fence, however, the differences we found were more modest (0.25 ton C/ha higher on the better LC side). We speculate that LC is indeed a useful indicator of SOC in Australia's northern grazing land, and the experiments of Bray et al (2014) did not have the statistical power to find such results due to a more limited sampling size. As in all space-for-time methods we need to be cautious about the potential pitfalls of the approach. First, the correlation between SOC and LC does not conclusively prove a causal link. Second, these findings do not answer the question: if land condition is improved, how long it will take to see increases in SOC? Other studies suggest that in arid lands this could take at least 5 to 20 years (Bartley et al 2023). Our preliminary simulation results using the integrated model support this, with climatic variability remaining an important driver, with a gradual modest long-term increase in SOC. The results found in the Connells Reserve / Brunette Station fence further support the causal connection, and positive response of SOC to management change. There, the difference in SOC between the excluded and the grazed areas was on average 1.5 ton C/ha. We speculate that the increase in SOC under a better grazing strategy could potentially be even higher (Stanley et al 2024). Even though this study provides the most extensive sampling, and convincing evidence of the potential for SOC sequestration in the Northern Australian Rangelands, the establishment of long-term grazing trials would be invaluable. Using these results we produced a SOC baseline for the wider area under study and a process-based model that allows to simulate Carbon stocks and fluxes over time. Our tool is being refined and will enable us to accurately and affordably estimate soil and vegetation carbon in Australian rangelands.

Carbon sinks in grazing systems

81

XII INTERNATIONAL RANGELAND CONGRESS
AUSTRALIA 2025

Wyoming sagebrush rangeland soils are a weak methane sink

O'Connor, RC[1]; Sannerud, DA[1]; Hamerlynck, EP[1]; Ranches, J[2]; Bohnert, DW[2]; Huber, DP[3].

Key words: Dormant season; Soil carbon fluxes; Soil moisture; Cattle urine; Greenhouse gas

Abstract

Dryland ecosystems cover 41% of Earth's terrestrial surface while providing 60% of the world's food production, and 50% of the world's livestock. Drylands also account for 30% of global carbon while operating as a carbon sink, carbon neutral, or a carbon source depending on the season and availability of soil moisture. Within dryland soils, methanotrophs, methane (CH_4) consuming bacteria, are present and could aid in reducing methane from the atmosphere. However, the influence that methanotrophs have in the overall soil carbon flux of dryland soils is less known. To understand their influence, we established a soil flux experiment in a semi-arid Wyoming sagebrush (*Artemesia tridentata wyomingensis* Nuttall, Beetle & Young) plant community in western North America. We measured *in situ* CO_2 and CH_4 soil fluxes at 30-minute intervals for 16 days during the dormant season. For four days we established a soil flux baseline before adding 200-mL of cattle urine to a subset of plots to observe how cattle might influence soil carbon fluxes. We also added 200-mL of distilled water to the remaining plots as a control. We then measured all plots for an additional 12 days. We found that during the dormant season the sagebrush soils were consistently a weak CH_4 sink, while CO_2 was a weak source, and the addition of cattle urine only augmented those dynamics. We also found a diurnal pattern which coincided with increased surface air temperatures. During the nighttime, both soil CH_4 and CO_2 were carbon sinks, but between 0800 and 1600 hr soil CO_2 fluxes became a carbon source while CH_4 fluxes remained a carbon sink. These results suggest that our semi-arid Wyoming sagebrush rangelands can act as a methane sink even during the dormant season and the strength of the methane sink during the dormant season is based on soil moisture.

Introduction

Even though dryland ecosystems are considered neutral carbon sinks to atmospheric CO_2, dryland soil microbial communities include methanotrophs capable of consuming atmospheric CH_4, making drylands potentially very important in the global carbon cycle. The importance and magnitude of CH_4 consumption in drylands are still uncertain, as our understanding of the underlying mechanisms driving the microbial community activity are unclear (Song et al. 2024). Generally, warm and dry or warm and moist soils provide ideal conditions for methane-oxidizing bacteria to consume the greatest amounts of CH_4, while cold and wet soils reduce CH_4 consumption rates (Wen et al. 2024). Therefore, desert steppe drylands such as North American sagebrush steppe where soils experience prolonged drying regimes (ca. 5 months) coincident with warming temperatures provides potentially a consistent CH_4 sink for atmospheric CH_4.

Atmospheric CH_4 is the second most abundant greenhouse gas in the atmosphere and has more than tripled since preindustrial levels because of anthropogenic activities (Canadell et al. 2021). Globally, livestock account for ~30% of anthropogenic CH_4 emissions (Jackson et al. 2020). Methane emissions from livestock in the United States accounts for 4% of the overall CH_4 emissions in agriculture (Dillion et al. 2021), however it is estimated most of the emissions come from cow-calf production and stockers grazing on lower quality forage in drylands (Vargas et al. 2024). Drylands provide forage for 50% of livestock globally, suggesting soil processes in these drylands are likely impacted by livestock excreta such as urine. Livestock urine provides a high nitrogen deposit in liquid form which is readily available to soil microbes and has the potential to increase microbial activity which would result in higher soil respiration rates as well as higher CH_4 consumption in dryland soils. The objective of this study was to characterize how cattle urine influences soil respiration and methane consumption in the warm late-season plant dormant period of drylands soils. Specifically, we wanted to quantify if cattle urine deposition increased soil methane consumption and soil respiration because of the available nitrogen present in the urine. To address this, we added cattle urine to Wyoming sagebrush steppe soils and repeatedly monitored soil respiration and CH_4 consumption over a 14-day post-urine application period.

Methods

The study was conducted at the USDA-Agricultural Research Service Northern Great Basin Experimental Range (NGBER, 43.471507, -119.691100), located about 70 km west of Burns, OR, USA. The study site is situated in a Wyoming sagebrush (*Artemesia tridentata* subsp. *wyomingensis* Bettle & Young), Sandberg's bluegrass (*Poa secunda* J. Presl.), bluebunch wheatgrass (*Psuedorogenaria spicata* [Pursh] Á. Löve) and Idaho fescue (*Festuca idahoensis* Elmer) plant community at 1397 m asl. The soils at the study site were classed as a Vil-Decantel, Variant-Ratto complex which are well drained and have a duripan at 30-50 cm. Soil texture in the top 10 cm was determined to be a sandy clay loam using the hydrometer method.

We deployed two opaque soil respiration chambers connected to an LI-8250 multiplexer and LI-7810 CH_4 and CO_2 trace gas analyzer (LI-COR Environmental, Lincoln, NE USA). The chambers sat on PVC soil collars that were placed in the interspace between Wyoming sagebrush and native bunchgrasses over bare soil. Soil fluxes were sampled every 2 hrs from 07 September 2022 to 26 September 2022. On 12 September 2022 we applied 200 ml of Angus-Hereford cattle urine to one soil respiration chamber plot, and 200 ml of DI H_2O to the other soil respiration chamber plot. The amount of beef cattle urine applied to each soil respiration chamber plot equates to the average amount released during a urination event by a mature beef cow corrected for the volume of the soil respiration chamber plot (Yamulki et al. 1998, Misselbrook et al. 2016). Cattle urine was collected following FASS approved methodology (Canton et al. 2020).

Results

Even though both chambers were less than 2 m apart we observed the variability in soils in the separation between the two treatments, which was most pronounced in the CH_4 flux. Regardless of this difference we observed that soil CO_2 flux increased the most on September 12 when urine was added to the plot compared to water; incidentally there was also a small precipitation event that occurred the night prior to the urine and water additions (Fig. 1). The influx in available nitrogen from the urine did not alter the flux direction of CH_4, but subsequent precipitation events did increase the CH_4 flux closer to zero, indicating weaker CH4 sink activity. There was a small diurnal pattern observed for the soil CO_2 flux between 0800 hr to 1600 hr, while there was no diurnal pattern captured for the soil CH_4 flux with urine added to the soil, but a potential decrease in CH_4 flux strength where water was added to the soil between 1000 hr and 1600 hr (Fig. 2).

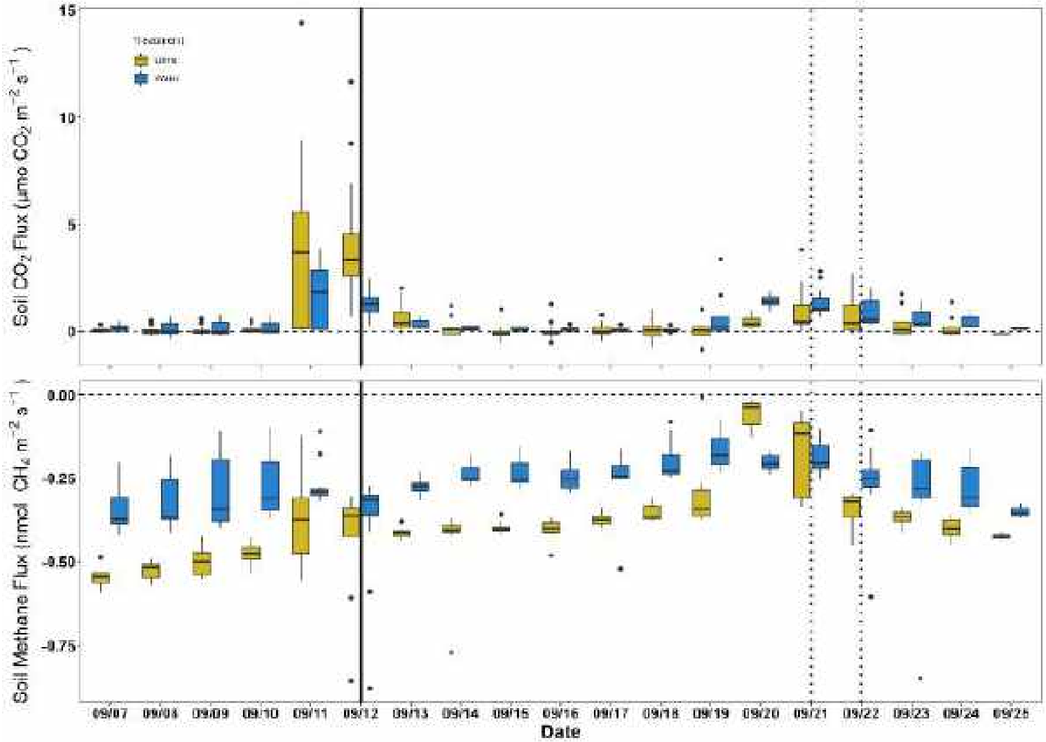

Figure 1. Daily average soil CO_2 (top panel) and CH_4 (bottom panel) fluxes from 07 September – 25 September 2022. Blue boxes are for water addition while yellow boxes are for urine addition. The black vertical bar represents the day water or urine was applied to the plots, and the dotted blue vertical line represents a day when it rained.

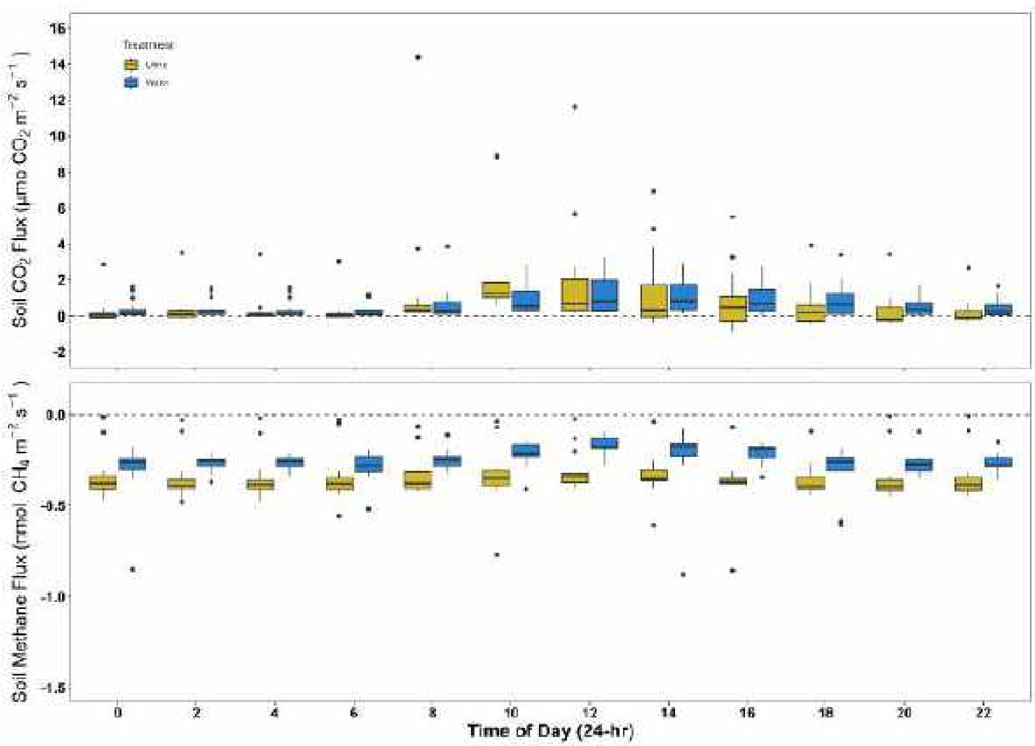

Figure 2. Diurnal soil CO2 (top panel) and CH4 (bottom panel) fluxes averaged across September 12 - September 25, 2022 observations. Blue boxes are for water addition while yellow boxes are for urine addition plots. Data were aggregated during their respective sampling times across the monitoring time.

Discussion

Our data suggests that Wyoming sagebrush steppe rangeland soils act as a weak CH_4 sink in the dormant season regardless of the addition of beef cattle urine or water. However, this soil sink strength is reduced when under moister soil conditions. Additionally, our diurnal data showed that from 10:00 to 16:00 CO_2 efflux increased, regardless of urine or water additions making these soils a weak source of carbon. Over these same periods, CH_4 flux was consistently negative, indicating they acted as a weak methane sink regardless of diurnal variation in soil conditions. Urine deposition possibly increased CH_4 uptake across the study period (Fig. 1), at least in part due to decreased diurnal variation in sink strength (Fig. 2), which likely reflects greater methanotrophic microbial activity. However, this pattern needs to have additional replication to parse out the heterogeneity of soil and the actual effect of cattle urine on the sink strength of CH_4. This project only demonstrates that more research is needed to study CH_4 dynamics in semi-arid Wyoming sagebrush steppe rangeland soil, and that it is critical to determine and how precipitation and livestock activity interact to influence seasonal CH_4 sink strength dynamics, and how these change across seasons and with plant community structure. Our findings and experience will be used to expand this research effort of understanding CO_2 and CH_4 dynamics to a larger spatio-temporal extent with beef cattle grazing in a native Wyoming sagebrush steppe plant community.

Acknowledgements

We want to thank Peter Olsoy for an earlier review of this manuscript. We also want to thank Matheus Ferreira for acquiring the cattle urine following FASS approved methodology.

Abstract

Little is known about soil carbon dynamics and the effects of regenerative grazing practices on sheep ranches in the United States. To address this knowledge gap, we established a soil carbon monitoring program across ten sheep ranches spanning over 1 million hectares of private and federal rangelands in the Western United States. Collectively, these operations manage over 47,000 sheep for meat and wool production. By adopting the Responsible Wool Standard (RWS), these ranches have implemented practices to improve grazing management, land health, and animal and social welfare. From 2020 to 2023, soil carbon levels were measured at a depth of 20 cm. Greenhouse gas emissions, including CO_2, CH_4, and N_2O, were also estimated using the COMET-Farm model at both individual and aggregate levels. Preliminary results indicate that one ranch showed an increase in soil organic carbon (SOC), while SOC levels on the remaining ranches remained relatively stable. COMET-Farm modeling estimates that these ranches have the potential to offset 91,444 metric tons of CO2 equivalents annually. This study provides a crucial baseline for understanding soil carbon dynamics on sheep ranches and highlights the potential of regenerative grazing and conservation practices to enhance carbon sequestration. It emphasizes the role sustainable sheep grazing systems can play in promoting ecological health while maintaining agricultural productivity.

Introduction

Recent efforts have focused on monitoring greenhouse gas (GHG) emissions and strategies to reduce them, with soil carbon sequestration emerging as a key solution. This process occurs when carbon capture through photosynthesis exceeds losses from respiration, transforming ecosystems into carbon sinks. Conservation practices like no-till farming, cover cropping, regenerative grazing, and optimized fertility management (mineral and organic amendments) not only enhance soil carbon but also improve soil health, reduce erosion, and promote sustainability (Havstad et al., 2007; Derner and Schuman, 2007). Rangelands, which cover vast areas, are particularly suited for carbon sequestration while providing critical ecosystem services like food production, water retention, and biodiversity (Follett and Reed, 2010; Davies et al. 2011; Pyke et al. 2015). Interest in sustainable practices among ranchers and farmers has grown due to the environmental concerns associated with livestock production. However, research on soil carbon impacts in sheep production, particularly on U.S. rangelands, remains limited. To address this, we developed a soil carbon monitoring program for sheep ranches in the Shaniko Wool Company Farm Group. These farms implement management practices that are deemed regenerative such as rotational grazing, no-till farming, and riparian restoration. Using field sampling and the USDA's COMET-Farm model, which assesses net GHG emissions, we estimate the carbon budget for individual farms and the group as a whole. We hypothesize that these practices will increase soil organic carbon, supporting the role of regenerative livestock production in sustainable land management.

Methods

The soil carbon monitoring program was conducted across ten ranches within the Shaniko Wool Company farm group. However, this study includes data from only seven farms, as three recently joined the group. Collectively, this group grazes across 2.6 million acres (1.05 million hectares) of private lands, Bureau of Land Management (BLM) allotments, and U.S. Forest Service (USFS) allotments. The USFS lands, located at higher elevations, experience cooler temperatures and greater moisture compared to the lower-elevation, drier BLM and private rangelands. Average annual rainfall ranges between 250mm in the drier areas up to 600mm in the higher elevation allotments. Soil types in the ranches present a very high variability as they are located on different areas, from sandy basins to loams and clayey soils. Altogether, the farm group raises over 47,000 sheep and produces approximately 225,000 kilograms of wool annually. The landscapes span diverse ecosystems, ranging from basin shrub-steppe to high-elevation mixed conifer forests and mountain meadows, reaching elevations of over 2,700 meters above sea level. For carbon monitoring, representative sampling sites were selected on each farm based on factors such as topography, soil characteristics, elevation, gradient, vegetation types, and land use. In total, 236 sampling points were established across the participating farms. At each sampling point, five soil cores were collected using a 2-inch bucket auger and combined into a single composite sample per site. Soil was collected at a depth of: 0–20 cm for all sites. Of the seven ranches evaluated in the project, one was sampled four times (2020, 2021, 2022, and 2023), while the other six were sampled three times (2021, 2022, and 2023). Samples were analyzed at the USDA-ARS Soil Laboratory in Corvallis, OR, USA, for soil organic carbon (SOC) using a LECO CN828 analyzer. Because the study sites are located in semi-arid regions, a preliminary "fizz" test (Lal, 2009; Whitlark, 2011) was performed on all soil samples to detect the presence of carbonates. Reactive samples were further analyzed for calcium carbonate content using a pressure-calcimeter (Fonnesbeck et al., 2013). Additionally, soil pH was measured using both a 1:1 soil-to-water ratio and a 0.01 M $CaCl_2$ solution. Bulk density values were obtained from the USDA Web Soil Survey. Soil carbon stocks were estimated using the following formula:

$$\text{Soil C (kg/ha)} = (\%C \div 100) \times BD\ (g/cm^3) \times D\ (cm) \times 100{,}000$$

where %C is the carbon content, BD is the bulk density, and D is the soil depth.

We used the COMET-Farm model for GHG modeling. Due to model limitations, only BLM public lands and private lands were included while USFS public lands were excluded as the model lacks soil data for forested sites. Operational boundaries were delineated and edited using ArcGIS Pro 2.8.0. To meet model size constraints, large shapefiles were divided into parcels smaller than 1,200 acres and imported into COMET-Farm as SHP files. Projects were limited to fewer than 50 parcels and no more than 200 soil units each. Each ranch was modeled separately for grazing land management, cropland management, and animal agriculture. Emissions from these categories were calculated individually and then combined to estimate total emissions for the operations. Historical (pre-1800s general management), baseline (2000–2020), and animal agriculture data were collected through interviews with land managers and incorporated into the parcels. For grazing lands, data collected included vegetation type (modeled as perennial grass), percent daily utilization, grazing periods, rest days, and management practices like fertilization, irrigation, or burning if applicable. For croplands, data included crop species, planting and harvest dates, tillage intensity, field operations, fertilizer or amendment applications, irrigation events, grazing events, and liming when necessary. For animal agriculture, data collected included class and number of animals, average daily feed, average liveweight, diets, housing, manure management, manure N content, total dry manure produced, and the percentage of pregnant animals.

Each ranch was analyzed separately, as comparisons between ranches were not conducted due to differences in management, history, location, climate, elevation, and soil types. For each ranch, we used a one-way ANOVA to compare the means of soil carbon and nitrogen across its total operations and by lease type (BLM, USFS, and private lands). Normality assumptions were tested by examining residual plots, identifying extreme outliers, and performing a Shapiro-Wilk test. ANOVA and normality analyses were conducted using RStudio (2021.09.0), while regression analyses and plots were generated with SigmaPlot version 15.1.1.26 (2023).

Results

Soil organic carbon

Changes in soil organic carbon (SOC) was not statistically significant ($P>0.05$) on six of the seven ranches (Figure 1a). Ranch D had an increase in SOC between 2021 and 2022 ($P<0.001$) as compared to 2020 and remained stable until 2023.

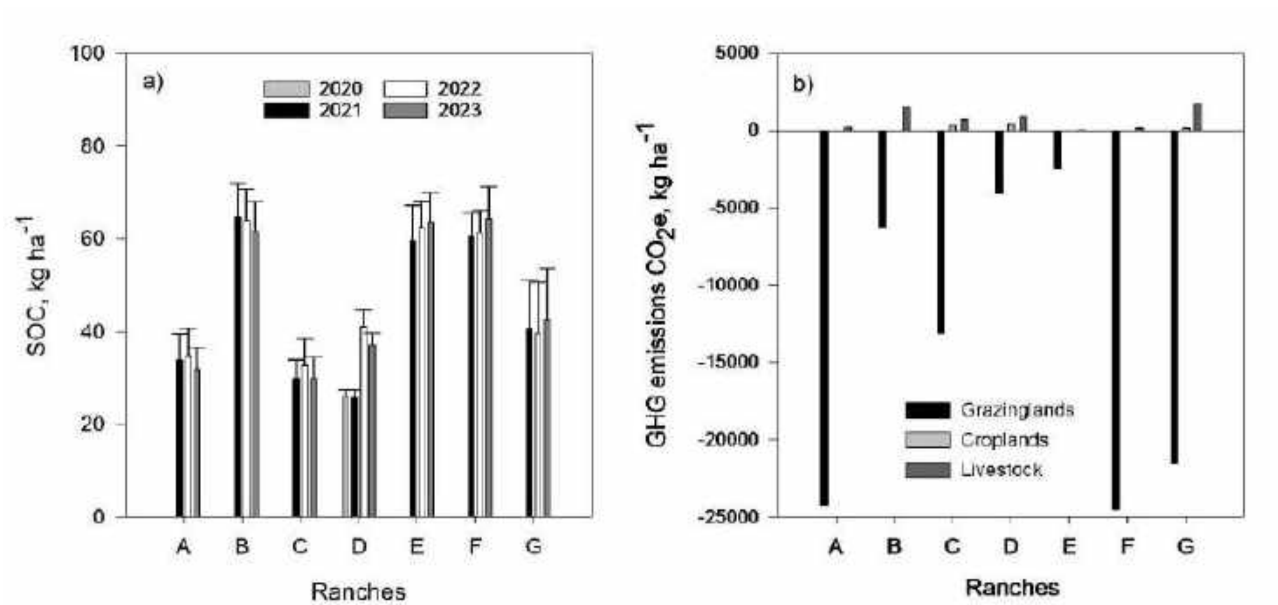

Figure 1. Average soil organic carbon (SOC, t ha^{-1}) change at 0-20cm depth from 2020 to 2023 (a) and GHG emission reduction potential of the ranches (A-G) (b). Bars represent standard error of the mean.

COMET-Farm GHG results

Each one of the ranches presented a large negative emission value in the grazing lands as compared to the smaller positive emissions from the croplands and livestock. The sum of the emissions from the three categories (grazing lands, croplands and livestock emissions) results in a negative emission value for the entire modeled operations. This negative value indicates the potential carbon that can be taken by the soil, demonstrating that all cropland and animal emissions from the ranches can potentially be sequestered by the soil under optimal conditions (Figure 1 b).

Discussion

Among the seven evaluated ranches, only one showed a significant increase in soil organic carbon (SOC) between 2020 and 2023. Three others displayed positive trends in carbon sequestration, while three showed negative trends. Such fluctuations in SOC are expected in the carbon cycle, especially in dry regions where low moisture limits soil organisms responsible for cycling carbon (Burke et al., 2019). In general, we found that soils high in sand content presented lowest soil carbon, as compared to soils with more silt or clay, highlighting the importance of soil texture in carbon sequestration. Particular attention to soil texture needs to be taken in consideration to better understand carbon sequestration and to better advise land managers. As lands with soils higher in clays will have a different potential to bank carbon as compared with drier sandy soils, common in many regions that are grazed. Longer-term sampling is likely needed to better understand SOC dynamics in these ranches.

COMET-Farm™ modeling suggests that, under current management practices, the ranches can act as carbon sinks, potentially offsetting 91,444 CO_2e kg ha^{-1} y^{-1}. However, these estimates assume "optimal" rangeland conditions, such as complete plant cover and average rainfall, meaning the results reflect potential sequestration under ideal circumstances. The analysis included only Bureau of Land Management (BLM) allotments and private lands. U.S. Forest Service (USFS) allotments, covering approximately 247,465 hectares (611,500 acres) of forested soils, were excluded due to limited data. Forested soils on USFS lands generally have higher SOC levels than drier rangeland soils, likely due to greater plant cover. This highlights the potential of agroforestry or silvopastoral systems on USFS lands to maintain higher carbon levels while sustaining livestock.

In summary, maintaining adequate plant cover is essential for increasing and sustaining soil carbon sequestration (Lal, 2004). Regenerative practices—such as adjusting livestock numbers, overseeding rangelands, and planting riparian trees—can create favorable conditions for plants to capture atmospheric carbon (Chen et al., 2009). COMET-Farm modeling is a useful tool to project the impacts of these practices over a ten-year period. At the same time, is important to understand that soil carbon sequestration has a limit or saturation point in which no more carbon can be banked in the soils regardless of carbon inputs. This saturation point is associated to the soil texture, soil structure and the biochemical complexity of the organic compounds (Stewart et al., 2007). Furthermore, maintaining adequate soil carbon levels in the upper layers of the soil can eventually assist to improve the vertical transfer of carbon to the deeper layers of soil as a result of the soil mineral properties, plant and microbial activity, favouring banking (sequestering) the carbon to ensure its permanence in the soil (Dwivedi et al., 2017). While current efforts promote healthy, carbon-sequestering ecosystems, further research is needed to determine when these soils might reach the carbon saturation point and avoid carbon loses.

Key words: soil organic carbon, grazing management, climate change, carbon offsets

Abstract

While the agronomic benefits of organic matter in soils have long been established, debate continues regarding the potential for increasing carbon storage in soils to help combat anthropogenic climate change. Of all the world's biomes, rangelands have arguably the highest expectations, and the greatest uncertainty, for soil organic carbon (SOC) sequestration, i.e. removing carbon dioxide from the atmosphere via photosynthesis and securely storing the assimilated carbon in soil. Our review of evidence for persistent increases in SOC stocks following implementation of new management strategies showed significant methodological limitations and inconsistencies in reported outcomes. A major challenge is that detection and attribution of management impacts are difficult in low productivity, high diversity rangelands where 90% or more of sampled differences in SOC stocks may be determined by climate and soil factors. Caution is needed in interpreting results, but strategies with more consistent evidence for SOC sequestration include over-sowing forage legumes into grass pastures, conversion from cropping to permanent pasture and avoiding prolonged high grazing intensity. Our analysis did not find evidence for significant, persistent increases in SOC stocks with the implementation of other livestock management options (e.g. rotational grazing). We conclude from the available evidence that the potential for SOC sequestration in rangelands is likely modest. However, uncertainty is high, and we recommend research priorities to improve data and understanding of SOC in rangelands for production and environmental benefits.

Introduction

The mass of carbon (C) in soils is very large, estimated at three times that in the atmosphere, and 80% of the total C stored in terrestrial ecosystems (IPCC 2023). Of this C pool, the organic component is more responsive to management than inorganic C, and 25−75% of soil organic carbon (SOC) has been lost globally since 1850 largely through inappropriate agricultural practices (Sanderman et al. 2017). There is strong interest in the prospects for improved management to restore SOC in degraded lands for agricultural productivity, ecosystem services and food security benefits and increasingly as a climate change mitigation strategy since permanent increase in SOC storage (i.e., sequestration) represents a net removal of CO_2 via photosynthesis from the atmosphere (Bossio et al. 2020). Rangeland, as the most extensive biome, spanning 79.5 M sq km (ILRI et al. 2021), and holding a third of global soil organic matter (SOM), theoretically represents a substantial climate change mitigation potential, but there is considerable uncertainty in the achievable SOC sequestration.

The value of SOM for soil condition and functionality is well-established from centuries of agronomic research but how long-term increase in SOC in stable forms is affected by different pasture and grazing management practices is less well-understood (Rumpel et al. 2023, Salley and Brown 2023). To mitigate climate change by offsetting greenhouse gas (GHG) emissions, C sequestration must meet internationally recognised integrity standards for C removals, including additionality (whether management activities go beyond business-as-usual), evidence-base (scientific evidence linking human activity and SOC sequestration), permanence (persistence of stored SOC), and quantification (accurate, conservative measurement or modelling of SOC stock changes) (Dupla et al. 2024). Uncertainty is high for rangelands, due to their diversity and generally limited data. Here we present: (i) an overview of data and evidence for management-induced SOC sequestration in global rangelands; (ii) a case-study of management impacts on SOC sequestration in Australia's rangelands; and (iii) recommendations for research to reduce uncertainty for agriculture and climate policy.

Methods

Scope: The review covered published papers and reports on field trials, soil sampling surveys, and credible modelling studies with SOC data for grazed rangelands. For the global overview we did not undertake a new comprehensive literature search but drew on published reviews, meta-analyses and recent papers (e.g., Reinhart et al. 2021, Sanderson et al. 2020, Salley and Brown 2023). For the Australian case study, we expanded on recent reviews of the impacts of management on SOC stock changes in Australian rangelands (McDonald et al. 2023, Henry et al. 2024) to summarise the sequestration potential of strategies for: (i) grazing management; (ii) pasture improvement; and (iii) land conversion.

Data selection and analysis: Studies on SOC storage in rangelands have used a range of methods for experimental design, SOC quantification and management interventions. Based on recent scientific understanding and measurement protocols (Batjes et al. 2024, Zhang et al. 2024), a set of criteria was developed to select SOC stock change data and management strategies for evaluation (Table 1). Overall, few publications provided adequate information to reliably assess data quality and enable valid comparisons. Inconsistencies between studies affected the strength of evidence and were used to identify data and knowledge needs in rangeland systems.

Results

Global review: Our review revealed that few studies had credible data able to meet minimum requirements for quantifying the impacts on SOC *sequestration* of management strategies appropriate for implementation in rangeland production systems. The impacts reported for similar strategies were marked by inconsistencies in the magnitude (and, in some cases, direction) of SOC stock change, but there was some evidence of robust trends in response: (i) no clear effects of various rotational grazing practices; (ii) positive effects when more productive species were over-sown into grass pastures; (iii) negative impacts of prolonged high grazing intensity on SOC stocks; (iv) positive impacts of conversion from crop production to permanent pasture; (v) limited potential for SOC sequestration, and probable adverse impacts on ecosystem services, of conversion of grasslands to forest (Briske et al. 2024).

Table 1. Summary of criteria used to select credible SOC sequestration data from publications reviewed for analysis, and constraints for rangeland monitoring.

Criterion	Data requirement	Rangeland context
Consistent with SOC sequestration definition	SOC stock change relative to initial or baseline reference	Few long-term trials with SOC and bulk density measured (baseline, project) across the diversity of rangeland soils, climate, production systems
Baseline	SOC stocks under business-as-usual management.	Representative initial SOC stock measurements, preferably dynamic baseline monitored over multi-decadal periods, accounting for variance and climate
Management strategy	Details of baseline and new management	Poor/no data limits the evidence-based attribution and comparisons for SOC change due to new management
Measurement (in-field; lab. or proximal sensors)	Depth ≥30 cm; bulk density; sampling protocols; variance	Vast areas, high spatial and temporal variability and low Net Primary Production (NPP) mean small/slow rates of change that are hard to detect and costly to monitor
Measure – model approaches	Calibrated and verified models	Few data across rangelands for calibration; model representation of C and N dynamics often inadequate
Monitoring periods	Monitor at 5-10 year intervals for decades/ centuries (>10 years)	Dominant impacts of rainfall and soil type, high risks of reversal under low/unreliable rainfall mean detection and attribution of change need longer monitoring

Australian rangeland study: The Australian rangelands cover around 75% of the continental area, with a range of management systems across diverse climates, soils and landscapes. Results of the literature review and analysis of data extracted from studies (field trials, surveys or credible simulations) meeting criteria for monitoring SOC stock changes were broadly consistent with the global observations. While data were insufficient to reliably quantify the potential for SOC sequestration under different initial soil conditions (e.g., nutrient status) and management options, some strategies provided indicative values (Table 2). For example, over-sowing native grass pastures with more productive grasses or with forage legumes provided consistent evidence of sequestration (up to 0.1 t C ha^{-1} yr^{-1}; ~0.3 t C ha^{-1} yr^{-1}, respectively), and conversion from cropping to permanent pasture increased SOC stocks (median value ~0.2 t C ha^{-1} yr^{-1}). Conversely, data from long-term studies indicated that implementing rotational or other grazing strategies had negligible persistent impacts on SOC stocks. Across all studies, the permanency of any SOC sequestration could not be assessed.

Table 2. Summary results from Australian rangeland SOC studies quantifying SOC sequestration (0-30 cm depth). (Adapted from Henry et al. 2024.)

Management strategy	Number of studies[1]	Estimation period (yr)	Baseline[2] C (t C ha^{-1})	SOC seq. range (median) (t C ha^{-1} yr^{-1})
Grazing management				
Lower grazing intensity	2	16 –26	13 – 19	0 – 0.09 (0.03)
Destocking or exclosure	7	7 –58	5 – 80	0 – 1.68 (-0.03)
Rotational vs continuous	4	5 –10	5 – 75	-0.11 – 0.01 (0.08)
Pasture improvement				
More productive grasses[3]	5	Various	>10 – 50	0.02 – 0.11 (0.06)
Oversowing with legumes[3]	3	22 – 50	19 – 52	0.27 – 0.45 (0.38)

Discussion

Assessment combining an overview of global studies and analysis of Australian research indicated that the potential for management-induced SOC *sequestration* in rangelands is uncertain, variable and unlikely to contribute substantially to climate change mitigation or income for livestock producers C offsets. Other recent publications have reached similar conclusions (Don et al. 2023, Dupla et al. 2024, Reinhart et al. 2021). The analysis is also consistent with evidence that the dominant drivers of SOM inputs and losses, and of the long-term net SOC stocks, are rainfall, temperature, and the soil properties that determine SOC stabilisation and persistence. The challenges of maintaining and increasing SOC stocks are exacerbated in rangelands by typically infertile soils and high seasonal variations in NPP (Cotrufo and Lavallee 2022). At a property scale, in rangelands the large areas and low and reversible rates of storage make accurate and cost-effective quantification of SOC stocks and stock change a barrier to 'C farming' (Derner et al. 2019, Batjes et al. 2024, Dupla et al. 2024). Measurement uncertainty adds to the difficulty in attributing changes in SOC to implementation of a new practice when management may be responsible for as little as 10% of measured differences between sites (Allen et al. 2013, Salley and Brown 2024). These factors contribute to the lack of consistency in results from published rangeland trials (Sanderson et al. 2020, Henry et al. 2024). Additionally, studies have varied in whether emissions of other GHGs arising from a management change were counted in the estimated climate change mitigation benefit of SOC sequestration and whether standards for integrity of C offsets, particularly additionality and permanence, were adequately established. To improve understanding of the potential for SOC sequestration, investment is needed in long-term trials using best practice experimental design, multi-decadal monitoring of control and treatment sites for SOC stocks to >30cm with sufficient replicates for statistical analysis of spatial and temporal variance supported by site information on historic management, baseline soil condition and initial SOC stocks. Based on our review, we caution against over-expectation for the environmentally and economically achievable quantity of SOC sequestration in rangeland soils. However, while C farming market opportunities are likely modest, there is value in expanding investment in well-designed, long-term field and modelling studies over spatial and temporal scales representative of the diverse rangelands to better quantify the potential for maintaining or increasing SOC stocks and to understand the value for rangeland resilience now and under future climatic conditions.

Enhancing carbon sequestration in drylands through silvopastoral systems

Gonzalez Quintero, R[1]; Notenbaert, A[1]; Vinceti, B[2]; Van Der Hoek, R[1]; Isiaho, G[1]; Herrera Calvo, PM[3]

[1]International Center for Tropical Agriculture (CIAT), [2]Bioversity International, [3]Food and Agriculture Organization of the United Nations (FAO)

Key words: Sustainable land management; Climate change mitigation.

Abstract

Drylands, spanning over 40% of the Earth's surface, sustain two billion people, half the global livestock population, and rich biodiversity. They are crucial carbon reservoirs but are highly susceptible to land degradation, emphasizing the need for sustainable management. Silvopastoral systems (SPS) present a promising approach to balance productivity with environmental gains. However, the carbon sequestration potential of SPS in drylands remains underexplored.

To address this knowledge gap, the FAO, in partnership with the Alliance of Bioversity International and CIAT, has launched a comprehensive global assessment on enhancing carbon sequestration in drylands through SPS. This initiative aims to provide evidence-based strategies for sustainable planning, management, and restoration of drylands. This study encompasses an integrative methodology combining literature reviews, case studies, and scenario modelling to evaluate current carbon reserves and forecast future potential under varying intensification, climatic, and policy contexts. Outputs include a guide to best practices and a robust monitoring framework.

These efforts will culminate in a detailed report offering actionable recommendations for policymakers, government bodies, and institutions. Collaboration with the FAO's Committee on Forestry (COFO) will ensure the development of tailored, country-specific strategies to maximize the sequestration potential of drylands via SPS. Countries will receive targeted support for designing and implementing SPS as tools for Sustainable Land Management, contributing to climate mitigation, resilience, and livelihood enhancement.

This paper highlights the findings so far, emphasizing evidence, best practices, and lessons learned. It underscores the potential of SPS to enhance carbon sequestration while supporting sustainable management and restoration. By focusing on practical strategies for leveraging SPS, it will underpin actionable recommendations to address climate adaptation and mitigation challenges, fostering the rejuvenation of these critical ecosystems and strengthening global resilience against climate change.

Introduction

Drylands cover about 41% of the Earth's surface, according to the Thornthwaite classification, and face increasing pressures from climate change and population growth (Yan et al., 2024). The livestock sector, a significant driver of land degradation, contributes 9% of anthropogenic carbon dioxide (CO_2) emissions globally, largely due to deforestation and land use changes for pasture and feed crops (Mohammed and Naqvi, 2011; Singh et al., 2017). Additionally, livestock account for 35–44% of anthropogenic methane emissions (Yusuf et al., 2012).

Carbon sequestration has emerged as a critical strategy to offset rising atmospheric CO_2 levels. SPS, multifunctional systems combining herbage, shrubs, trees, and grazing animals, present a promising sustainable land management approach. These systems not only boost productivity but also deliver ecosystem and climatic benefits by enhancing carbon storage in biomass and soil organic carbon (Aryal et al., 2019). Compared to open grasslands, SPS are particularly effective in increasing carbon storage and fostering ecosystem resilience (Feliciano et al., 2018).

Globally, SPS cover approximately 450 million hectares, accounting for 28% of agroforestry systems (Nair, 2012). Their adaptability to diverse environmental conditions and socio-economic needs makes them valuable tools for climate adaptation and sustainable development. These systems integrate diverse practices, such as grazing under tree cover, live fences, and protein banks, enabling tailored applications across regions.

This study explores the potential of SPS to enhance carbon sequestration in drylands. It aims to provide evidence-based strategies for sustainable planning, management, and restoration while addressing knowledge gaps. By evaluating current reserves and forecasting future potential, the study offers the evidence-base for designing actionable recommendations to support global climate resilience and sustainable land stewardship.

Methods

A systematic review was conducted following the methodology of Tranfield et al. (2003), comprising three stages: planning, conducting, and reporting. Studies were screened based on abstracts, full texts, and additional literature identified through snowballing methods.

To identify studies on the carbon sequestration potential of silvopastoral systems in drylands, the following search strings were used: ("silvopastoral*" OR "silvo-pastoral*" OR "agrosilvopastoral*" OR ("grazing*" AND "tree*") OR ("agroforest*" AND "livestock") OR ("pasture*" AND "tree*")) AND ("dryland*" OR "arid" OR "semi-arid" OR "desert") AND ("carbon*" OR "greenhouse gas emission*" OR "GHG*" OR "mitigation"). Boolean operators combined terms to refine searches.

Searches included published journals, bibliographic databases, conference proceedings, industry trials, and grey literature. Key sources included ScienceDirect, Web of Science, Dimensions Research, Google Scholar, and ResearchGate. Grey literature was further identified through manual reference checks, Google Scholar's cited-in function, and targeted searches. Duplicate records were manually removed.

Inclusion criteria required studies to provide quantitative carbon sequestration data for above-ground, below-ground biomass, or soil organic carbon in silvopastoral systems within drylands (annual rainfall <900mm) or areas classified as Hyper-arid, Arid, Semi-arid, or Dry sub-humid (AI <0.65) (Zomer et al., 2022). Publications needed to be recent (2003–2023), peer-reviewed, or reliable grey literature with English-language abstracts. Populist publications and inaccessible records were excluded.

Studies underwent a three-tier screening process—title, abstract, and full text—to ensure only the highest quality evidence informed the review.

Results

The systematic review has so far analysed 62 publications, highlighting diverse SPS arrangements and their contributions to carbon sequestration. Dispersed trees and shrubs in pastures were the most frequently studied arrangement, followed by grazing in timber systems, traditional SPS[10], and live fences. (Ibrahim et al., 2005; Nahed-Toral et al., 2013). These configurations vary in their structure and functionality, yet all contribute to carbon storage in above-ground biomass, below-ground biomass, and soil organic carbon. The adaptability of these arrangements allows them to thrive in diverse ecological conditions while addressing local socio-economic needs.

Dispersed trees and shrubs in pastures demonstrated a broad capacity for carbon sequestration, with total carbon stock values ranging from 60 to 183 Mg C/ha. This variation in carbon stocks is influenced by multiple factors, including soil properties, climate, tree species composition, and grazing intensity.

These systems truly bolster above-ground biomass, which ranged from 9 to 47 Mg C/ha across SPS arrangements, with grazing in timber systems often contributing to the higher end of this spectrum. Below-ground biomass, a critical component of carbon storage in SPS, ranged from 5 to 66 Mg C/ha, with traditional SPS and live fences providing notable contributions to below-ground carbon pools.

Soil organic carbon, often the largest carbon pool in SPS, ranged from 13 to 195 Mg C/ha, with systems integrating trees and shrubs, such as dispersed configurations and live fences, showing high values. Annual carbon accumulation spanned from 0.3 to 8 Mg C/ha/year, with live fences and grazing in timber arrangements contributing to dynamic carbon cycling. CO_2 sequestration rates across all arrangements were substantial, averaging approximately 1 Mg CO_2 eq/ha/year, with some systems, particularly those with denser tree components, peaking at 3.5 Mg CO_2 eq/ha/year.

Discussion

This study highlights the critical role of SPS in addressing global challenges such as climate change, land degradation, and food security. By integrating trees, shrubs, herbaceous vegetation and livestock, SPS create multifunctional ecosystems that deliver environmental and socio-economic benefits. Beyond their capacity for carbon sequestration, SPS contribute to biodiversity conservation, soil health, and water quality, making them essential components of sustainable land management strategies. Furthermore, SPS adoption has shown to improve livestock productivity by reducing heat stress, improving water availability and enhancing feed quality, contributing to higher milk yields and weight gains and reducing greenhouse gas emissions (López-Santiago et al., 2024; Rivera et al., 2024)

A critical insight from this research is the versatility of SPS configurations in achieving region-specific goals. Dispersed trees and shrubs in pastures, grazing in timber systems, and live fences are adaptable arrangements capable of thriving across diverse ecological conditions while increasing carbon storage. These variations influence carbon sequestration potential, with humid environments typically storing more carbon due to increased biomass productivity, while arid regions depend on drought-resistant species for below-ground carbon accumulation (López-Santiago et al., 2019). The influence of soil type is also critical, as finer-textured soils retain more organic carbon, whereas sandy soils require additional organic inputs to enhance sequestration potential. Additionally, moderate grazing supports soil structure and nutrient cycling, making SPS viable under varying grazing intensities (Howlett et al., 2011).

There are, however, several barriers to widespread adoption of SPS adoption. Financial constraints, limited technical knowledge, unsuitability of land to host trees, incompatible livestock management practices and land tenure issues impede their scalability. Addressing these requires targeted policies, adapted financial tools (such as

[10] Traditional silvopastoral systems integrate native trees, shrubs, and pastures with grazing livestock, often following low-input management techniques and natural regeneration. Unlike intensive SPS, traditional systems rely more on native vegetation, less on external inputs, and foster a balance between production and ecosystem services.

subsidies and low-interest loans), market-based incentives like carbon credit programs, and capacity-building initiatives tailored to local needs. Bessi et al. (2024) emphasized the importance of integrating SPS into national policies to maximize their impact on both environmental restoration and socio-economic development.

In conclusion, silvopastoral systems exemplify the convergence of ecological restoration, integrated climate mitigation and adaptation, and agricultural productivity enhancement. By integrating carbon sequestration with food security and ecosystem restoration, SPS offer a viable solution for mitigating climate change and fostering socio-economic resilience. Their strategic implementation, particularly in dryland regions, will play a pivotal role in global sustainable development efforts.

Long-term impacts of rabbit and cattle grazing on carbon sequestration in arid rangelands

Bastin, G[1]; Paul, K[2]; Piper, M[2]; Forrester, D[2]; England, J[3]; Pasut, C[4]

[1] Retired, Alice Springs, NT, 0870, Australia; [2] CSIRO Environment, PO Box 1700, Canberra, ACT, 2601, Australia; [3] CSIRO Environment, Private Bag 10, Clayton South, Vic, 3169, Australia; [4] CSIRO Agriculture and Food, Locked Bag 2, Kaurna Country, Glen Osmond, SA, 5064, Australia.

Key words: above-ground biomass; woody cover; trees and shrubs; remote sensing

Abstract

One of the claimed multifunctional characteristics of degraded pastoral landscapes is their ability to sequester carbon in woody biomass. But what is the actual potential for this, and at what rate may this occur over time? Due to slow growth rates, intermittent droughts, and heterogeneous landscapes, it may require many years of data collection from across multiple site locations to answer such questions. For an arid calcareous landscape in central Australia that had been degraded through overgrazing by cattle and rabbits, we used multiple, disparate, data sources to estimate change in above-ground woody biomass over 40 years. From a very low density of live trees and shrubs in 1981, regeneration occurred in 1-ha plots when protected from grazing by rabbits and large herbivores (‘rabbit-exclosed’). There was lesser regeneration in adjacent plots that excluded only cattle grazing (‘cattle-exclosed’) and minimal establishment in control plots that were grazed. Hyper-spatial satellite images available from Google Earth were classified to estimate multi-temporal woody canopy cover for each plot between 2004 and 2023. Plot-based above-ground biomass (AGB, dry weight) of live trees and shrubs was estimated from the density and cover data using allometric functions from studies conducted elsewhere. Finally, AGB was accurately estimated in all plots in late 2022 using ground-based allometry data. AGB increased by 1.92 tonnes / ha within the rabbit-exclosed plots between 1981 and 2022, with lesser increases on the cattle-exclosed and control plots (0.69 and 0.63 tonnes / ha, respectively). Although maximum AGB after 40 years was still small (1.97±0.303 tonnes / ha), separate analysis of satellite data has shown that woody canopy cover elsewhere in this recovering landscape has reached ~50%, equivalent to ~4 tonnes / ha AGB. Such woody thickening can potentially reduce herbage growth and adversely impact beef production, bringing to focus the multifunctional balance between pastoralism and carbon sequestration.

Introduction

Altered grazing management to facilitate carbon sequestration, above- and below-ground, is progressively being implemented in parts of the Australian rangelands, both demonstrating their multifunctional value (Stringer et al. 2012) and providing an additional income stream for pastoralists (Hacker and McDonald 2021). The potential to sequester carbon may be greatest where formerly productive landscapes have been degraded through loss of perennial vegetation and erosion (Baumber et al. 2020, Henry et al. 2024).

Owen Springs pastoral lease near Alice Springs, Northern Territory (NT), is an exemplar of variably degraded rangeland in arid central Australia. The area has a summer-dominant mean annual rainfall of ~280 mm but with high interannual variability (minimum, 67 mm; maximum, 782 mm; 84-year record, Alice Springs Airport). The lease was first stocked in 1873 with grazing by cattle continuing until 2002 when the lease was resumed and all cattle and feral horses removed. Part of the lease became the Old Man Plains (OMP) research station (522 km^2) which was progressively restocked from 2005 at between three and six animal equivalents (AE) / km^2. Prior to that, cattle grazing pressure on calcareous shrubby grasslands, the most preferred pastoral land type, was estimated at ~12 AE / km^2 (Bastin et al. 2023). Feral horses (unknown number) and rabbits (densities as high as 20 / spotlight km, Foran et al. 1985) added to total grazing pressure. This sustained grazing pressure, particularly during drought, had caused extensive degradation (Pickup and Chewings 1994, see also Fig. 4 in Bastin et al. 2023) including widespread death of browsed shrubs (Fig. 1), a phenomenon previously described by Friedel (1985). High rabbit densities are especially pernicious during drought because rabbits will ringbark stems in their search for water. They will then browse seedlings that may germinate following high rainfall preventing the successful regeneration of woody vegetation.

Figure 1. Extensive shrub death on an OMP calcareous shrubby grassland associated with cattle and rabbit browsing. The 1982 photo also shows a rabbit warren in the foreground and part of a netted rabbit exclosure. Photo: Barney Foran, CSIRO.

The continuing security on present-day OMP of replicated rabbit- and cattle-proof exclosures constructed in 1981 and archived tree- and shrub-density data from that time (Foran et al. 1985) have provided the opportunity to retrospectively monitor change in woody biomass over the past four decades. In this paper, we combine multiple, disparate, data sources to estimate change in above-ground woody biomass since the early 1980s.

Methods

Three 1-ha plots (netted to exclude rabbits, fenced to exclude cattle and open to all grazing) were replicated at six sites in 1981 on calcareous shrubby grasslands approximately ~40 km south west of Alice Springs. The density of shrubs and trees (dead, mature or juvenile) was collected annually in four belt transects (10 m by 50 m) at each plot between 1982 and 1988 (see Foran et al. 1985 for further detail).

Individual stem diameters (at 10 cm) and crown area (as an ellipse) were measured for all trees and shrubs within all exclosures in October 2022. The same data were collected in adjacent 1-ha grazed plots (which may have been different to the original 'controls' as their precise locations were unknown). Health scores of the canopy and stem wood for all individuals were also recorded (Piper, pers. comment). Above-ground biomass (AGB, kg dry weight per individual) was calculated using the generalised shrub allometry of Paul et al. (2016). Plot-level canopy cover was calculated by summing the individual crown areas corrected for health divided by the plot area. Individual AGBs corrected for health were summed and divided by plot area to calculate plot-level AGB. These data were combined with those collected from another 430 sites in the Australian rangelands to develop generalised stand-level canopy cover – AGB relationships (by structural vegetation class) (Pasut, pers. comment) with the shrub equation used to calculate plot-level AGB (tonnes / ha) for the OMP sites in years where canopy cover was estimated using remote sensing.

Publicly available, high spatial-resolution satellite images available between 2004 and 2023 on Google Earth were saved as red-green-blue (RGB) composites with a nominal pixel size of 0.25 m for each site area. Twenty classes were generated for each site-time using ISO Cluster unsupervised classification. Those classes best representing identifiable tree and shrub canopies, plus associated shadow, were grouped to estimate multi-temporal percent canopy cover. Plot-level AGB was then estimated as above.

Results

From a notional low level of woody biomass in the 1980s*, AGB increased by a factor of 12 (cattle-exclosed) to 75 (grazed) by the early 2000s. The rabbit-exclosed treatment had consistently higher biomass, followed by cattle-exclosed (Fig. 2). Remotely-sensed estimates of AGB in 2021 and 2023 were higher for all treatments than the more accurate estimates in late 2022 using ground-based allometry data.

Assuming a consistent increase in AGB between 2004 and 2023, linear regressions fitted to the data suggested an annual increase of 34 kg / ha for the rabbit-exclosed plots ($R^2 = 0.77$, $P<0.01$), 21 kg / ha for the cattle exclosed treatment ($R^2 = 0.21$, ns) and 17 kg / ha for grazed plots ($R^2 = 0.28$, ns).

Discussion

The field-measured AGB of trees and shrubs in 2022 was low compared with other studies in the arid rangelands (e.g. Williams et al. 2023, Pasut, pers. comment). Nevertheless, the other data sources used here indicate that woody AGB started from a very low base on degraded land in the 1980s and may have accumulated at an annual rate of up to 34 kg / ha from the early 2000s onwards. The 'grazed' rate of 17 kg / ha / year extrapolates to an annual AGB accumulation of ~288 tonnes between 2004 and 2023 for the 169 km^2 of calcareous shrubby grassland on OMP. We acknowledge these increases are small and may have large estimation errors due to limited spatial sampling and no validation of the remote sensing analyses.

Initial establishment and growth of seedlings was only successful within rabbit exclosures (Foran et al. 1985, and 1988 data in Fig. 2). Successful regeneration of shrubs in cattle-exclosed and grazed plots probably dates from about 1996 when the rabbit population was substantially reduced, and subsequently maintained at a low level, through rabbit haemorrhagic disease (Edwards et al. 2002). Exceptional rainfall in 2000-2001 combined with destocking promoted vegetation growth (Bastin et al. 2023) and likely facilitated further successful shrub establishment. Thereafter, resumed grazing at a more conservative stocking rate combined with periodic spelling, and further years of above-average rainfall help to explain the gradual increase in remotely-sensed canopy cover and derived AGB.

* There was an initial low density of mature shrubs (predominantly Acacia kempeana, see Table 3 in Foran et al. 1985) and individuals were given a notional AGB of 35 kg (dry weight). Juvenile shrubs were similarly allocated a biomass of 1 kg each.

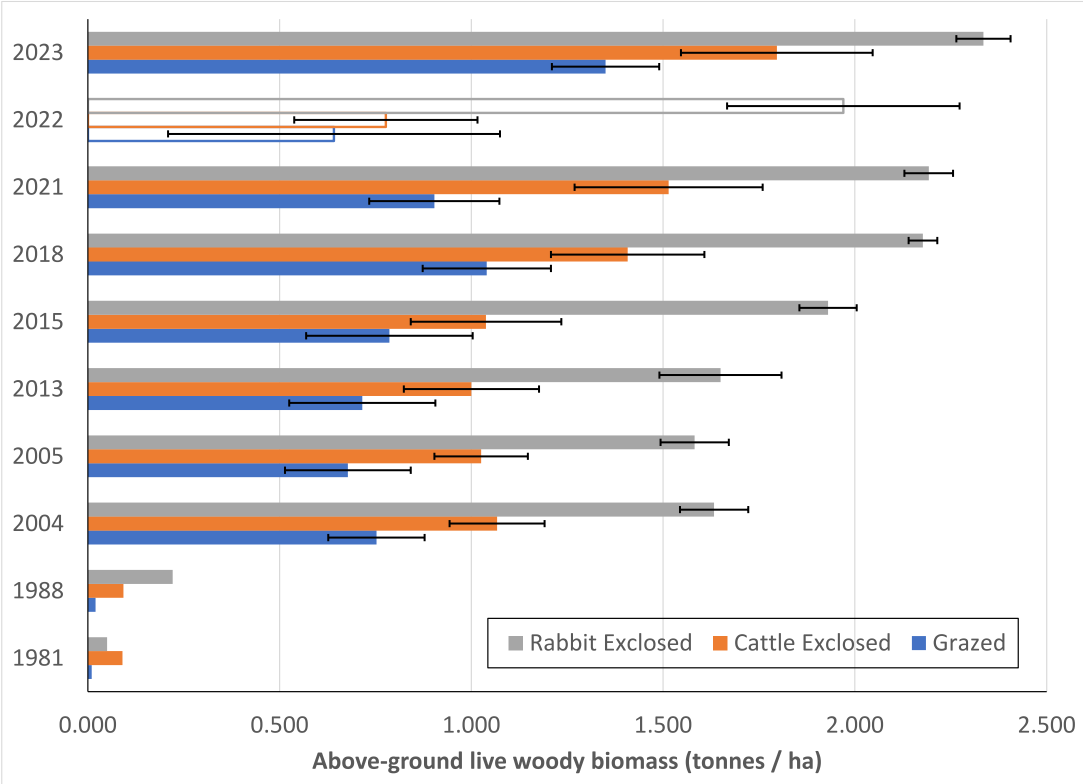

Figure 2. Estimated mean above-ground biomass of trees and shrubs for grazed, and rabbit- and cattle-exclosed treatments at six sites on Old Man Plains between 1981 and 2023. The standard error of each mean from 2004 onwards is also shown. Solid columns between 2004 and 2023 show remote sensing-based estimates with the open columns representing the 2022 field data.

The monitored increase in AGB, excluding the 2022 field data, is indicative rather than absolute due to the assumed relationship between density and AGB in the 1980s and probable errors associated with image processing in accurately discriminating canopy cover. The notional AGB of 35 kg assigned to each of the very few mature *A. kempeana* was based on the mean dry weight of 254 similar individuals harvested in a neighbouring paddock in 2012 (Bastin 2014). The density of juvenile shrubs in the rabbit-exclosed treatment increased through the 1980s but we argue their contribution to woody AGB was minimal regardless of their assigned small biomass value. The RGB images saved from Google Earth had reduced radiometric resolution compared with their source data. Further, we did not radiometrically calibrate the multi-temporal images to correct for different sensors, and sun-angle and atmospheric effects. Woody canopies were best discriminated when there was good spectral contrast between their grey-green foliage and the background soil and a senescent herbage layer; actively growing (green) pasture confounded successful classification. Despite these limitations, the Google Earth images did provide a free and convenient method for retrospectively monitoring change in canopy cover.

Regeneration of trees and shrubs across this calcareous landscape varies according to the nature and severity of past degradation (Stafford Smith and Pickup 1990). Woody canopy cover in some areas has reached ~50%, equivalent to ~4 tonnes / ha AGB. Such woody thickening can potentially reduce herbage growth and adversely impact beef production, without substantially contributing to carbon sequestration. This brings to focus a probable imbalance between the multifunctional values of continued successful pastoralism and meaningful long-term removal of carbon dioxide from the atmosphere.

Know your numbers: Soil carbon sequestration has potential to support carbon neutral red meat and wool production in semi-arid rangelands

Rigg, JL[1]; Newey, L[1]; Hackney, B[1]; Baldry, S[1]; McDonald, SE[2]; Orgill, SE[1]

Key words: Greenhouse gas emissions (GHGe); soil organic carbon (SOC); carbon neutrality; grazing management

Abstract

There is growing global pressure for agriculture, in particular red meat production, to reduce net greenhouse gas emissions (GHGe). A greenhouse gas (GHG) estimate is useful to benchmark and measure emissions and is useful to inform strategies to reduce or offset farm emissions. The average annual net farm emissions for two extensively grazed rangelands properties (Property A and B) in the semi-arid rangelands of southeastern Australia were calculated using the Primary Industries Climate Challenges Centre (PICCC) Greenhouse Gas Accounting Framework (GAF) tools over 5 years. Property A is 19,794 ha, has an average annual rainfall (AAR) of 390 mm and grazes cattle, sheep and goats for red meat production. Property B is 11,831 ha, has an AAR of 290 mm and grazes cattle and sheep for red meat and wool production. The average annual net farm emissions were 2,233 t CO_2-e/farm for Property A and 1,078 t CO_2-e/farm for Property B. As expected, in these low input systems, methane from livestock was the largest source of emissions for both enterprises.

Carbon neutrality within a farm business can be achieved when GHGe are balanced by carbon sequestered in soil and vegetation on farm. Soil is an important and large store of carbon in the landscape. Using Property A as an example, our calculations demonstrate that even a conservative increase in SOC through grazing management could increase SOC concentration by 0.05 % (e.g. from 0.53 to 0.58 % SOC; 0 to 100 cm) over a 25-year period (one of two permanence periods under the Carbon Credits (Carbon Farming Initiative) Act 2011). Calculated at property scale, this equalled 18,497 t CO_2-e per year sequestered in soil which could offset the average annual emissions produced.

Introduction

Greenhouse gases (GHG) are gases in the earth's atmosphere that trap heat. GHG reported under the Australian National GHG Inventory (National inventory report) include carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) and other gases. There is currently very little documented evidence of emissions profiles of rangelands grazing enterprises in Australia. A farm carbon account is useful to benchmark and understand farm emissions, by accounting for sources and sinks of GHG within a farm business. The Australian red meat industry (in particular, MLA) has set the target to be carbon neutral by 2030 (CN2030). To achieve the goal of carbon neutral by 2030 producers must be able to reliably quantify and benchmark GHGe, as well as carbon stored and sequestered in trees and soils. By benchmarking GHG emissions, producers can then determine strategies to reduce emissions and identify opportunities to sequester more carbon in soil or trees. This study aimed to benchmark GHGe over five years for two extensive grazing properties in the semi-arid rangelands of southeastern Australia and identify the potential to offset emissions via soil carbon sequestration.

Methods

A whole farm carbon account and an annual average GHGe estimate (total tonnes of CO_2-e per property) was calculated for two extensive semiarid rangelands properties in New South Wales Australia using the Primary Industries Climate Challenges Centre (PICCC) Greenhouse Gas Accounting Framework (GAF) tool (specifically the SB-GAF and Go-GAF tools, developed by the University of Melbourne). A five-year baseline (~2018-2022) was calculated, as would be typical for a soil carbon project under the following methodology: Carbon Credits (Carbon Farming Initiative - Estimation of Soil Organic Carbon Sequestration using Measurement and Models) Methodology Determination 2021 (referred to as 'the Method'). Emissions intensity (i.e, the amount of CO_2-e per kilogram of product) was also calculated for each property and each commodity. Property A is 19,794 ha, has an average annual rainfall (AAR) of 390 mm and grazes cattle, sheep and goats for red meat production. Property B is 11,831 ha, has an AAR of 290 mm and grazes cattle and sheep for red meat and wool production.

Results

Annual net farm emissions & annual emissions intensity

The average annual net farm emissions for Property A were 2,233 t CO_2-e/farm, ranging across the five years from 1,776 t CO_2-e (2019-20 FY) to 4,396 t CO_2-e/property (2022-23 FY) (Figure 1). The average annual net farm emissions for Property B were 1,078 t CO_2-e/property ranging from 528 t CO_2-e (2018-19 FY) to 1,335 t CO_2-e/farm (2021-22 FY) (Figure 2). Not surprisingly, methane from livestock was the largest source of emissions for both farms. Emissions intensity varied over the five-year period and varied by farm enterprise (Table 1).

Discussion

Globally, we are seeing a growing expectation that agriculture, amongst other industries, should work to reduce its net emissions. This is a whole of supply chain effort and red meat businesses have a part to play.

Soil is an important and large store of carbon in the landscape. There are well known benefits of increasing soil organic carbon (SOC) for agricultural productivity and landscape function. In the rangelands, well-managed grazing animals are important tools in the landscape to build soil organic matter (the driver or the first step towards accumulating SOC) by stimulating plant growth, influencing plant composition, herbage mass and ground cover, nutrient redistribution, and breaking down vegetation and litter through trampling (McDonald et al., 2023, Orgill et al. 2017, Waters et al. 2015). Gray et al (2021) estimated a carbon sequestration rate of 0.17 t C/ha/yr in the 0 to 30 cm soil layer (over 20 years) in the Western Division of NSW if a relative increase of 10 % groundcover could be achieved. However, increasing and sustaining SOC through management in Australian rangelands can be a challenge (Henry et al. 2024). Therefore, management practices which focus on livestock productivity, pasture biomass and composition, and ground cover promotion will support producers to improve their overall emissions intensity, and protect and potentially build soil carbon in Australian rangeland landscapes.

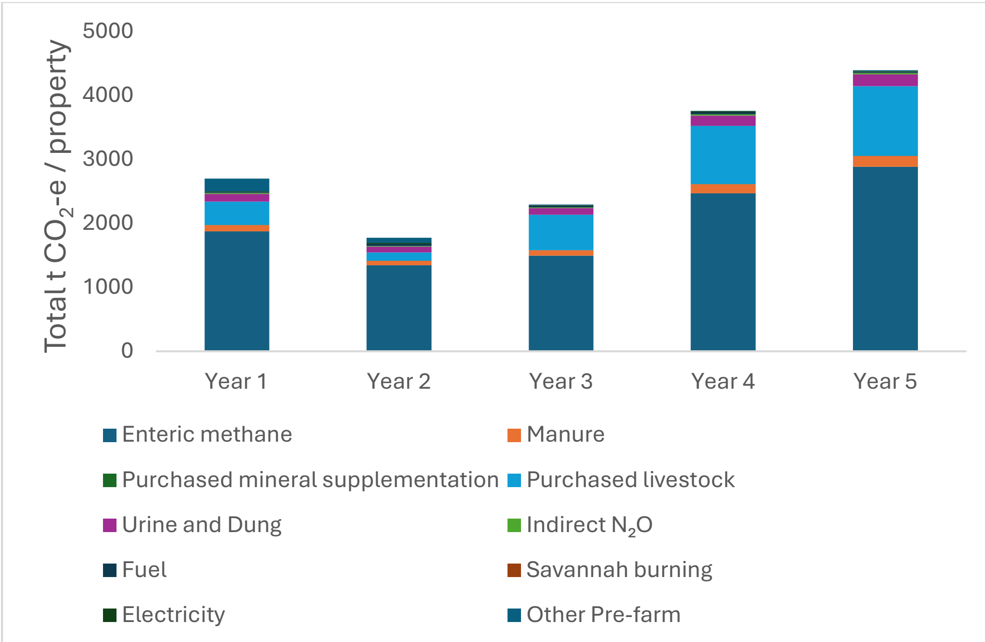

Figure 1. Annual net farm emissions (total t CO_2-e/ property) for Property A. Total emissions are the sum of all livestock enterprises on Property A including Sheep and Beef (SB-GAF) and Goat (Go-GAF). Year 1 was the start of June 2018 to end of May 2019, year 2 was the start of June 2019 to the end of May 2020, year 3 was the start of June 2020 to the end of May 2021, year 4 was the start of June 2021 to the end of May 2022 and year 5 was June 2022 to May 2023. Electricity, fuel and diesel were apportioned to each enterprise (therefore, not double counted). The category 'other Pre-farm' includes fertiliser, purchased feed, herbicides and pesticides lime and livestock away on agistment.

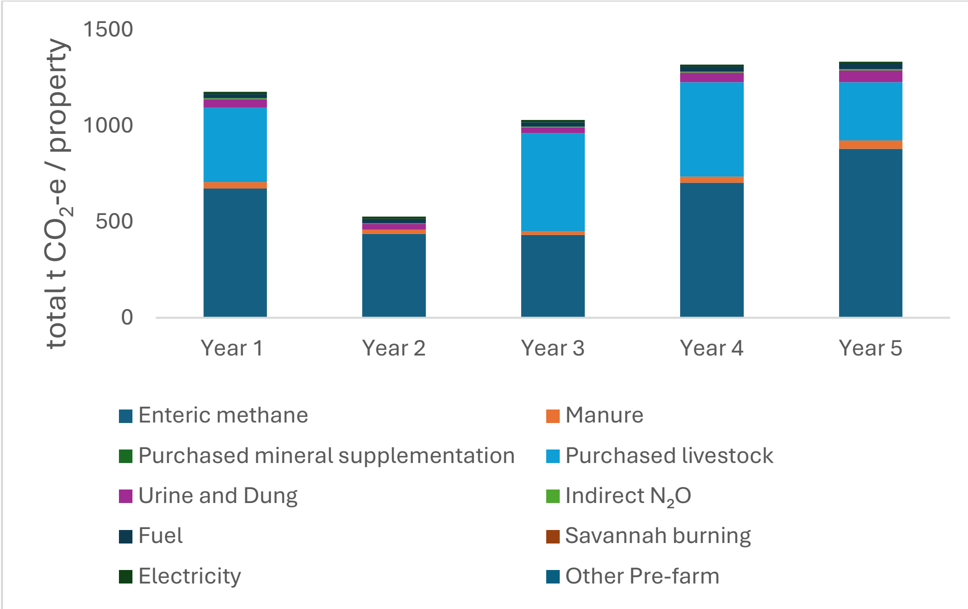

Figure 2. Annual net farm emissions (total t CO_2-e/ property) for Property B. Total emissions are the sum of all livestock enterprises on Property B including Sheep and Beef (SB-GAF). Year 1 was the 2017-18 financial year (FY), year 2 was the 2018-19 FY, year 3 was the 2019-20 FY, year 4 was the 2020-21 FY and year 5 was the 2021-2022 FY. Electricity, fuel and diesel were apportioned to each enterprise (therefore, not double counted). The category 'other Pre-farm' includes fertiliser, purchased feed, herbicides and pesticides, lime and livestock away on agistment.

Table 1. Emissions Intensity (kg CO_2-e / kg live weight (LW)) for Beef, Sheep and Goat enterprises for Property A and for Beef, Sheep and Wool enterprises on Property B over the 5-year period. The year 3 result for beef emissions intensity was artificially high (and therefore data not shown) for Property A. Beef emission intensity could not be calculated for years where there were no sales or purchases (year 2 to 4) for Property B.

Property	Enterprise	Emissions Intensity (kg CO_2-e / kg LW)				
		Year 1	Year 2	Year 3	Year 4	Year 5
A	Beef	10.6	9.0	-	29.2	15.8
	Sheep meat	49.2	15.6	16.0	15.4	13.3
	Goat	5.8	45.5	25.2	27.5	6.73
B	Beef	24.5	-	-	-	-
	Sheep meat	8.0	9.1	30.6	10.9	17.2
	Wool	25.9	28.9	95.1	34.7	53.4

Using the Property A case study as an example (average annual net emissions of 2,233 t CO_2-e), even a conservative increase in SOC sequestration could potentially offset the average annual emissions produced by the property. Assumptions and calculations to determine this are as follow:

- Grazing management increasing SOC concentration (SOC % equivalent to g/100 g) by 0.05 % (e.g. increase from 0.53 to 0.58 % SOC) over 100 cm over a 25-year period.
- Assuming a bulk density (BD) of 1.4 g/cm^3
- This equals an annual sequestration rate of 1.03 CO_2-e / ha/ year
- At the property scale, this is equivalent to 18,497 t CO_2-e per year sequestered in soil under 18,000 ha of grazed country.

This hypothetical soil carbon sequestration rate offsets even the highest annual GHGe for the 5-year baseline period. Whilst only carbon sequestration in *planted* trees is included when using the MLA GAF tools, carbon sequestration in regenerating vegetation and soil in rangeland systems may be an important consideration and, in some situations, may outweigh annual GHG emissions for a rangeland enterprise.

Abstract

Effects of three herbivore species, four grazing seasons and three grazing intensity levels on a semi-arid rangeland in an adaptive management system were investigated using a 7-year grazing experiment in the Xilingol region of Inner Mongolia, China. The region experiences a semi-arid climate, with a mean annual temperature of -0.5°C, and a mean annual precipitation of 315 mm, which mainly falls during the plant growing season from May to September. The rangeland is a typical steppe dominated by *Stipa grandis* and *Leymus chinensis*. A rotational grazing management with grazing duration controlled on the basis of grassland residual height was applied to adapt to the inter-annual variation in plant production. The results showed that cattle, sheep and goats had different preferences for plant species, and grazing by these herbivores at moderate grazing intensity drove divergent changes in species composition of vegetation. Grazing in different seasons at moderate intensity affects plant community structure and production mainly through altering the seasonal pattern of plant standing dead and litter, which impacts soil moisture capture and retention, and thus soil nutrient availability for plant growth; and by changing plant nutrient resorption and remobilisation, with autumn grazing having the least plant nutrient resorped in autumn thus negatively affecting plant growth in subsequent spring. Autumn grazing had the biggest adverse effect on plant community structure and production, while winter and early spring grazing promoted plant growth. Grazing intensity and precipitation jointly shape the compensatory growth and ANPP of the rangeland, with the highest ANPP occurring at relatively high grazing intensity and under high precipitation. Our results provide insights into the rangeland vegetation dynamics under different grazing regimes, and suggest that adjusting livestock composition can be used as a tool in rangeland management. Winter and early spring grazing was better than complete animal exclusion for grassland health, and an adaptive grazing management based on residual vegetation height is efficient for coping with the large inter-annual variation in climate and vegetation production in semi-arid rangeland regions. This paper collates and summarises findings from the study.

Introduction

Plant production in arid and semi-arid rangeland areas varies widely across years driven by large inter-annual fluctuation in precipitation. The vast steppes in Inner Mongolia region of Northern China have been used as rangeland for thousands of years to graze livestock (sheep, goats, cattle and horses) using a nomadic system at low grazing intensity. With the privatization of land use rights in the rangeland region and associated reduction in livestock mobility, one of the major challenges in livestock management is to cope with the uncertainties in climate, to provide sustainable livestock production and other ecosystem services. We have proposed a grazing management strategy to set on and off livestock on the rangeland paddocks in the use-right privatized rangeland farms based on vegetation (residual) height, so as to keep the livestock-forage relations balanced and prevent rangeland from degradation. This management adjusts the summer grazing rangeland areas and the animal numbers at the end of plant growing season. It is essential to understand the effects of livestock grazing strategies in this adaptive grazing management system on plant and soil systems, including grazing season, intensity and livestock species for developing and improving rangeland management.

Methods

We conducted three interrelated grazing experiments to examine the effect of three livestock species, four grazing intensity levels and four grazing seasons on plant community composition and production, and soil properties over a 7-year period in a semi-arid rangeland, located in the Maoden farm, 45 km northeast of Xilinhot city, in Inner Mongolia of China (44°10′N, 116°28′E, 1101m asl). The region experiences a semi-arid climate, with a mean annual temperature of -0.5°C, and a mean annual precipitation of 315 mm, which mainly falls during the plant growing season from May to September. The rangeland is a typical steppe on a sandy loam chestnut soil dominated by tall grasses *Stipa grandis* and *Leymus chinensis,* with other important species of *Cleistogenes squarrosa, Carex korshinskyi* and several forbs.

The experimental rangeland was set up in 2016, with 36 paddocks of 50m×50m, to arrange 9 grazing treatments, replicated by 4 blocks. The nine treatments include no-grazing (NG), summer sheep grazing at three intensity levels of light (LG), moderate (MG) and heavy (HG) grazing; summer cattle (Cattle) and goat grazing (Goat) at moderate intensity, and sheep grazing in early spring (Spring), later autumn (Autumn) and winter (Winter). Summer sheep grazing at moderate intensity (MG) was also used when comparing the grazing season or grazing animal species effects (i.e., MG in grazing intensity experiment = 'Summer' grazing in grazing season experiment = 'Sheep' grazing in animal species experiments). The grazing treatment was conducted from 2017 to 2023 inclusive, two-year old Mongolian sheep with an average initial bodyweight of approximately 33 kg were used for grazing treatments. The number of sheep for NG, LG, MG and HG were 0, 3, 6 and 9 respectively. The sheep were set on the grassland in paddocks in summer period of June, July and August each year, and set off when residual vegetation height decreased to about 6 cm at MG. The same sheep grazing days (i.e., sheep unit × grazing days) in the MG treatment was applied for all grazing treatments in grazing season experiment and animal species experiment. Plant species composition and biomass, and animal bodyweight before and after each grazing rotation were determined, soil properties were monitored each year, and animal daily intake was estimated. Potential plant aboveground biomass (AGBp) at peak plant biomass time was determined by setting up three grazing-exclusion cages of 1.2 m length × 1.2 m width × 1.0 m height in each paddock before the start of summer grazing in all the grasslands subject to grazing at different intensities. Grassland aboveground net primary productivity (ANPP) was determined as the sum of herbage accumulation consumed by animals during grazing season and the residual biomass of grassland at the end of grazing season, including the small amount of detached litter produced in the current year. Please refer to Shi et al. (2022, 2023) and Li et al. (2018, 2021, 2022, 2024) and Yan et al. (2024) for the details in grazing management and monitoring. Here we summarize the major findings from these interrelated experiments, and discuss their management implications.

Results

Grazing intensity effects: grazing promoted grassland productivity, and the promotion varied with precipitation, grazing intensity and plant species.

The realised grazing intensity in the experiment was around 20%, 40% or 60% of the ANPP being consumed at LG, MG and HG, with actual stocking rate controlled at 138 ~ 240 sheep grazing days per year at MG over the 7 years. A comparison of the AGBp and ANPP revealed that grazing at LG and MG promoted plant production, that is, generated compensatory growth (ANPP>AGBp), and the promotion was the highest for dominant grass *L. chinensis*; while the promotion at HG occurred only in wet years, and highest promotion was for *C. squarrosa* and annual species. The grazing enhanced nutrient cycling by defoliation and excreta deposition, accelerated decomposition of plant litter with animal dung (Wang et al 2023), and increased nutrient resorption, can be a major mechanism for grazing promotion of ANPP (Zhang et al. 2020).

Grazing season effects: grazing in winter or in early spring improved, while autumn grazing reduced grassland growth, compared to complete exclusion of animals from grassland.

With moderate grazing intensity applied, under which around 40% of ANPP was consumed by animals during the plant growing season, plant community height and aboveground biomass were higher under spring and winter grazing than that under autumn, summer or no- grazing. The divergence in plant community structure was mainly mediated by grazing-induced variation in the seasonal patterns of plant standing dead and litter mass across the grazing season treatments. A high plant standing dead and litter mass benefited soil moisture by enhancing accumulation of snow in winter and reducing soil evaporation during the plant growing season, benefiting plant growth; also, the removal of plant litter before the plant growing season increased the reception of solar radiation, thus improving soil temperature and plant production. Seasonal grazing, especially autumn grazing reduced plant nutrient resorption in autumn, thus negatively affecting plant growth in the coming year (Zhang et al. 2020).

Animal species effects: Forage preference differed among sheep, cattle and goats. Sheep preferred *L. chinensis* and forbs, cattle preferred *S. grandis* and forbs, and goats preferred *C. squarrosa* and *C. korshinskyi* (Li et al. 2018). Consequently, sheep grazing reduced *L. chinensis* and forbs, but increased *S. grandis*; cattle grazing decreased *S.grandis,* but increased *C. korshinskyi* and forbs; goat grazing reduced *C. squarroa* and *C. korshinskyi*, but increased forbs. However, dominant plant species of *L. chinensis* and *S. grandis* were still dominant over the 7-year period though their dominance changed. These results imply that animal species or population structure can be used as a tool to manipulate grassland communities, and the adaptive grazing of all three livestock species at MG to consume 40% of ANPP can sustain the grassland.

Discussion and conclusion

Our results show that adaptive grazing management by removing grazing animals based on grassland residual height can prevent grassland degradation. Grazing intensity and precipitation jointly determine the ANPP or compensatory growth of grazing grassland, and grazing can promote ANPP by accelerating nutrient cycling. Grazing season affects ANPP by changing the seasonal patterns of plant litter mass that modulate soil physical conditions, and by altering the nutrient resorption efficiency differently. Winter or spring grazing is better than no grazing for grassland restoration and improvement. Grazing by different animal species drives divergent changes in plant community, with cattle grazing preferring dominant tall bunch-grasses and leading to better plant diversity then sheep/goat grazing.

The results do not support the policy to have a grazing ban for preventing grassland degradation in the region. Instead, it suggests that light or moderate grazing (consuming up to 40% of ANPP) is beneficial to plant production. In addition, grazing in winter or early spring before plants starting to grow is better than complete animal exclusion for recovery of degraded grassland or prevention of grassland degradation. The reduction of grazing in autumn to allow more resorption of plant nutrient to belowground is important to keep the viability and production of grassland plants in the coming year. These grazing management strategies should be incorporated in grassland management systems.

Our findings suggest encouraging the farmers to raise 'more cattle and less sheep' in the region, as cattle grazing in our adaptive management system can achieve a higher species diversity (Yan et al. 2024) and total ecosystem services (Shi et al. 2023), but with less damage than sheep production. The needle-like fruit of *S.grandis* is a nuisance in sheep grazing system, as it damages sheep skin and throat. Intensive cattle grazing in the early period of the reproductive stage of *S. grandis* is recommended before sheep grazing to prevent its negative effects on sheep production. Plant residual height-based adaptive grazing system with the rotation of different/mixed livestock species are expected to achieve the dual goal of pastoral production and ecosystem sustainability.

Abstract

This study examined the impact of three distinct grazing management strategies on the mineral composition of bulked native herbaceous forages within the sourveld and sweetveld ecosystems of South Africa's Eastern Cape province. The grazing management treatments examined were communal continuous (CC), holistic planned grazing (HPG), and commercial rotational (CR), each implemented across both veld types. Herbaceous forage samples were harvested from transects distributed along the lower, middle, and upper slopes of each site. Bulked, ground herbaceous forages were analysed for macro-elements (K, Ca, Mg, and P) and micro-elements (Fe, Zn, Mn, and Cu). Results highlighted notable differences between sourveld and sweetveld forages, with sourveld exhibiting higher macro-nutrient levels while sweetveld displayed elevated micronutrient concentrations, except for Mn. In sourveld areas, grazing management significantly affected ($P < 0.05$) the concentration of both macro and micro-elements except Zn. Additionally, the year (season) exerted significant effects ($P < 0.05$) on levels of Ca, K, Mg, Cu, Fe, and Zn, though not on P and Mn. Noteworthy interactions were observed, such as the influence of management practice by year by landscape position on P levels, and management by year on Zn and Mn levels. In sweetveld areas, management practices significantly impacted ($P < 0.05$) the levels of Ca, K, Mg, Cu, Zn, and Mn. Overall, grazing management practice and yearly (seasonal) variations emerged as the primary factors influencing forage mineral status. The analysis indicated deficiencies in P and Cu across both veld types, implying insufficient levels to meet ruminant animal requirements. Moreover, other elements potentially displayed marginal to deficient supplies, particularly in areas with continuous grazing. Consequently, supplementation may be necessary in both veld types. Future research could explore animal blood serum mineral levels to devise practical supplementation regimes aimed at averting potential deficiencies.

Introduction

There are two main types of rangeland tenure and usage in South Africa: communal land, which is owned by the government but managed through the chief, and the title deed land, which is mainly private ranching. Two major grazing systems have been practiced, namely continuous grazing (mostly practiced in communal tenure), and rotational grazing (mainly practiced in the commercial ranching and conservation farms). Over the last few decades, holistic planned grazing (HPG) has been introduced in a few commercial farm and communal areas in an attempt to maintain the natural balance between the livestock and rangeland resources for sustaining livestock production and associated values. Recent studies suggest that vast communally used rangelands in South Africa have degraded (Kwaza *et al*. 2020; Mlaza *et al.* 2023) with implications on mineral provision, both in time and space. However, the changes in forage minerals in the communal land in relation to other management (including rotational or HPG) have not been investigated. The objectives of this study were to determine the mineral content of bulked herbaceous forage samples in three grazing systems along a landscape gradient over time.

Methods

The study was conducted in two rangeland types across a precipitation gradient, sweetveld and sourveld in the Eastern Cape, South Africa. Sweetveld sites in Enock Mgijima local municipality experience a relatively dry climate with sourveld sites in Raymond Mhlaba local municipality receiving ~1000mm mean annual rainfall. Three communal - continuous grazing camps (CC), three communal - holistic planned grazing camps (CHPG) and two commercial ranches with rotational grazing (CR) were selected in the sweetveld. In the sourveld, two CC grazing lands, two CR grazing and two commercial ranches with HPG (CRHPG) were selected. Each camp or farm was divided into three major landscape positions (upper, middle and lower), and two 100 m x 10 m permanent plots ~50 m apart for data collection were established in each landscape unit. Forage samples were collected over two years; in the first year, during end of the dry season (sweetveld – 2016; sourveld – 2017), and towards the end of the growing season the following year. Forage samples were taken from ten 0.25 m^2 quadrats per plot, harvested at stubble height, bulked and oven-dried. The samples were milled and mineral elements were analysed using dry ashing (Method 6.1.1) (ALASA, 1998) at Western Cape Department of Agriculture, Enselberg Laboratories, South Africa. The experimental design consisted of nine treatment combinations in each rangeland type (3 camps/farms and 3 landscape positions). Data were analysed separately for the two rangeland types using the Mixed Model procedure of SAS (2007) testing the effects of grazing management, landscape position and seasonal variation.

Results

Effect of grazing management practices on mineral concentration

All forage mineral contents except Zn were significantly influenced by grazing management (Table 1). Forage Ca and P were higher ($P < 0.001$) in CR and CRHPG farms, K ($P < 0.01$) in CR farms and Mg ($P < 0.001$) in CC farms. Of the micro elements, forage Cu and Fe contents were highest in CR farms and Mn had the order of CR > CC > CRHPG farms. In the sweetveld, grazing management significantly influenced ($P < 0.001$) Ca, K and Mg concentrations. Forage Mn, Cu and Zn were highest in CC camps (Table 1).

Table 1: Mineral concentrations of forage samples from three grazing management systems in the sourveld and sweetveld study areas.

Mineral	Sourveld			Sweetveld		
	CC	CRHPG	CR	CC	CHPG	CR
Ca (%)	0.26±0.01^{b}	0.32±0.01^{a}	0.32±0.01^{a}	0.25±0.01^{b}	0.24±0.01^{c}	0.32±0.01^{a}
P (%)	0.06±0.01^{b}	0.11±0.01^{a}	0.13±0.01^{a}	0.11±0.01^{a}	0.10±0.01^{a}	0.11±0.01^{a}
K (%)	0.69±0.04^{b}	0.69±0.04^{b}	0.86±0.04^{a}	0.59±0.04^{b}	0.48±0.04^{c}	0.84±0.04^{a}
Mg (%)	0.13±0.00^{a}	0.08±0.00^{b}	0.10±0.00^{b}	0.10±0.00^{b}	0.08±0.00^{c}	0.12±0.01^{a}
Mn (mgkg^{-1})	169.6±10.9^{b}	58.8±10.9^{c}	229.1±10.9^{a}	50.2±1.62^{a}	43.4±1.62^{b}	46.1±1.99^{ab}
Cu (mgkg^{-1})	2.16±0.12^{b}	2.24±0.12^{b}	2.66±0.12^{a}	2.88±0.09^{a}	2.59±0.09^{a}	2.51±0.11^{a}
Fe (mgkg^{-1})	281.8±27.3^{b}	263.8±27.3^{b}	442.7±27.3^{a}	667.6±44.38^{a}	585.1±44.38^{ab}	499.4±54.4^{b}

Means with different superscripts differ significantly (*P < 0.05*)

Effect of year (season) on mineral concentration
Significant differences (P < 0.0001) in forage mineral concentrations of Ca, K, Mg, Fe, Cu and Zn were found between years in both sourveld and sweetveld. Sourveld forages had lower concentrations in Year 1 (2017) compared to Year 2 (2018) (Table 2). Phosphorus and Mn were not influenced by year, but P showed a significant interaction of management practice x year x landscape position (P<0.05). In the sweetveld, all macro elements (Ca, P, K and Mg) were greatly influenced (P < .0001) by year with higher P, K, Ca and Mg in Year 2 (Table 2)

Table 2: Mean concentration of macro and micro-minerals by year in sweetveld and sourveld forages.

Mineral	Sourveld			Sweetveld		
	Year 1	Year 2	SE	Year 1	Year 2	SE
Ca (%)	0.27	0.33	0.01	0.24	0.30	0.01
P (%)	0.09	0.11	0.01	0.07	0.14	0.05
K (%)	0.56	0.94	0.03	0.43	0.84	0.03
Mg (%)	0.09	0.11	0.00	0.08	0.12	0.04
Mn (mgkg^{-1})	15.05	39.53	1.76	47.70	45.42	1.43
Cu (mgkg^{-1})	1.71	3.00	0.10	1.87	3.46	0.77
Fe (mgkg^{-1})	249.44	409.48	22.26	496.67	671.35	39.14
Zn (mgkg^{-1})	148.94	156.05	8.90	20.26	49.43	1.48

Effect of landscape position on mineral concentration
Landscape position significantly affected (P < 0.001) K, Cu and Zn concentrations in the sweetveld, with higher levels found in the upper slopes. Management and landscape interactions influenced mineral concentrations, with upper slopes of CR farms having higher K, Mg, Cu, Zn and Mn, while CC and CHPG had highest Zn concentrations in the lower slopes, and K, Mg and Mn highest in CHPG middle slopes.

Discussion
Phosphorus concentration was inadequate for grazing animals in both veld types, and across all management systems. This was likely due to the stage of plant maturity, as P levels typically decrease with advancing maturity (Beyene and Mlambo 2012), particularly when forages are harvested in the dry season and towards the end of the rainy season. The slight increase in P content in Year 2 may have been caused by more seed in the forages harvested

towards the end of the growing season. A study by Kwaza (2018) in the sourveld also found inadequate P levels in the forages of the same veld. The deficiency of P in forages of South African rangelands was previously recorded by Drewes *et al*. (1999). Calcium deficiency may be of concern in CHPG camps, as forages should contain at least 0.27 % for beef cattle (NRC, 2000). The K concentration in sourveld forages exceeded the recommended level for grazing animals (McDowell 1996; NRC 2000), a similar finding to that of Kwaza (2018). Magnesium levels were deficient for grazing animals in both veld types, especially in holistic managed camps and farms. Previous studies, such as Drewes *et al*. (1999), noted Mg deficiencies in Eastern Cape rangelands. The deficiency in Mg could be due to soils with higher amounts of K (Prabowo *et al*. 1991). High soil K can compete with Mg for uptake, reducing Mg availability and causing Mg deficiency in forages. Variations in Mg levels in the different management systems could be partially clarified in terms of the proportion of leaf and stem fractions that were collected for mineral analysis, especially during the dry season where a higher proportion was stem. Beyene and Mlambo (2012) found that most grass species generally meet micro-nutrient requirements, but Zn levels in CHPG were inadequate. In the communal rangelands especially where sheep are grazed, supplementation of Zn needs to be kept under review. The levels of forage Zn did not vary by season, unlike Ramirez *et al*. (2001) who reported variations in forage Zn by season.

The concentration of Cu levels in the forages were below the required 6-12 $mgkg^{-1}$ (NRC, 2000) potentially leading to deficiency. This may be due to the high levels of Fe in the soil as the forages had above the recommended levels of Fe for grazing animals (NRC, 2000). Grazing pressure and grazing systems (CC and CHPG) in sweetveld may have contributed to low Cu levels, potentially due to high Fe and Mn levels. Beyene and Mlambo (2012) found elevated Fe concentrations in bulked range forages harvested from a variety of soil types. Complex interactions between soil properties, land management practices, landscape position, grazing intensity, and seasonal changes affect both the soil's mineral content and the plant's ability to absorb and accumulate these nutrients.

Conclusion

It can be concluded that the forages in the two veld types generally meet ruminant mineral requirements, except for P and Cu. Forage Ca, Fe, Mn and Zn are sufficient. However, K and Mg in communal holistic managed rangelands need monitoring. Supplementation may be required, and further studies on animal blood mineral levels are recommended to ensure animals have the right nutrients and to detect potential health issues.

Overgrazing of buffel grass pasture in the Brigalow Belt bioregion of central Queensland, Australia, led to invasion by Indian couch

Thornton, CM[1]; Elledge, AE[1]

[1] Department of the Environment, Tourism, Science, and Innovation, PO Box 3130, Red Hill, Rockhampton, Queensland, 4701, Australia

Key words: *Bothriochloa pertusa*; Brigalow Catchment Study; grazing land management; land condition; safe long-term carrying capacity

Abstract

Overgrazing, or failing to adjust stocking rates to match annual forage production, traps land in a cycle of degradation. From 2015 to 2024, two adjacent catchments in the Brigalow Belt bioregion of central Queensland were grazed by beef cattle. One catchment was stocked at or below the safe long-term carrying capacity. The other was stocked at the recommended stocking rate for newly established buffel grass pasture on recently cleared and developed brigalow land, which made no allowance for pasture productivity decline over time resulting in overgrazing.

The minimum ground cover in the catchment stocked at the safe long-term carrying capacity was 82% and end of dry season pasture biomass was always greater than 780 kg/ha. The proportion of buffel grass in this pasture averaged 93% throughout the study. In comparison, the overgrazed catchment had a minimum ground cover of 72% and end of dry season pasture biomass was as low as 46 kg/ha. At the commencement of this study, 88% of the overgrazed pasture was comprised of purple pigeon, buffel, and Indian couch grasses (54%, 27% and 7%, respectively). However, after 10 years, purple pigeon grass was almost absent and the proportion of buffel and Indian couch grasses in the pasture was 1% and 92%, respectively.

Overgrazing resulted in a decline in biomass, changed species composition, and the loss of the perennial, palatable and productive purple pigeon grass. Although ground cover initially declined as the tussock grasses disappeared, it recovered with Indian couch invasion. Previous research has shown that overgrazing also substantially altered catchment hydrology, with runoff and erosion more than tripling in the first five years. Conceptually, as runoff increases, the amount of rainfall stored in the soil for plant growth decreases, leading to lower ground cover and pasture biomass. Unless an intervention such as a reduction in stocking rate is undertaken, pasture utilisation will continue to exceed pasture production, and land degradation will continue.

Introduction

The Fitzroy Basin, in the Brigalow Belt bioregion of central Queensland, Australia, has been extensively cleared for agriculture. The dominant land use in the catchment is beef cattle grazing, accounting for 25% of the state cattle herd and 11% of the national herd. Land degradation in the Fitzroy Basin has occurred as a result of continuous heavy grazing, just as it has in up to 35% of permanent pastures globally (Thornton and Elledge 2021). Reducing sediment loss from degraded grazing land in the Fitzroy Basin was a priority under the Reef 2050 Water Quality Improvement Plan (The State of Queensland 2018). Under the plan, the effects of hillslope grazing management on land condition and water quality were monitored at the Brigalow Catchment Study. This paper presents the longitudinal changes in ground cover, pasture biomass, and species composition under heavy grazing pressure compared to conservative grazing pressure.

Methods

This study ran from 2014 to 2024 (hydrological years), utilising two catchments of the Brigalow Catchment Study in central Queensland, Australia. The site has a semi-arid, subtropical climate with a long-term (1965 to 2023) average annual rainfall of 643 mm. Rainfall data prior to the commencement of the Brigalow Catchment Study was obtained from SILO (Queensland Government 2019). Soils in both catchments were dominated by Vertosols which supported native brigalow (*Acacia harpophylla*) woodland prior to clearing and development for improved pasture. The first catchment was a long-term conservatively grazed buffel grass (*Cenchrus ciliaris*) catchment of 12.7 ha. The second was a commercially grazed purple pigeon (*Setaria incrassata*) and buffel grass catchment of 12 ha that was subjected to heavy grazing from October 2014 onward. Both catchments were grazed by *Bos indicus* beef cattle breeds. Conservative grazing stocking rates were at or less than the safe long-term carrying capacity of the landscape, being 3.5 ha/adult equivalent animal. Heavy grazing stocking rates were about 2 ha/adult equivalent, which was the recommended stocking rate for newly developed brigalow land with no consideration for a decline in pasture productivity since clearing. Pasture biomass and species composition were estimated using the BOTANAL method of Tothill *et al.* (1978). Ground cover was assessed using VegMachine® (Beutel *et al.* 2019). A comprehensive description of the study and its associated data sets can be found in Thornton and Elledge (2021).

Results

The extreme variability of central Queensland's rainfall was experienced prior to and during this study. From 2010 to 2014, rainfall was above average, including the wettest (2011) and third wettest (2010) years on record at the Brigalow Catchment Study. From 2015 to 2021, rainfall was below average and included the driest year on record (2017). From 2022 to 2024, rainfall alternated between above and below average.

As a result of consistent above average rainfall from 2010 to 2014, both catchments had high biomass at the commencement of the study, with about 7,600 kg/ha in the long-term conservatively grazed catchment (Figure 1) and 6,900 kg/ha in the heavy grazing catchment (Figure 2). Ground cover was 92% in both catchments. Under conservative grazing, pasture biomass and species composition were dominated by buffel grass in all years (Figure 1). Purple pigeon grass was only observed on one occasion, and Indian couch grass (*Bothriochloa pertusa*) was commonly observed but averaged only 3% of total pasture biomass. Pasture biomass under conservative grazing always exceeded that under heavy grazing.

At the commencement of heavy grazing, purple pigeon grass accounted for more than 50% of the pasture biomass while buffel and Indian couch grasses accounted for 27% and 7%, respectively (Figure 2). Within three years, pasture biomass dropped to less than 10% of the starting biomass and averaged 9% for the remainder of the study. Three major shifts in species composition occurred over time: 1) the dominant purple pigeon grass was replaced by buffel grass; 2) buffel grass became co-dominant with Indian couch grass; and 3) Indian couch became the dominant grass (Figure 2).

Under conservative grazing, ground cover averaged 90% (82% to 94%), while under heavy grazing ground cover averaged 87% (72% to 97%). Periods of low ground cover in the heavy grazing catchment were associated with a shift in the dominant tussock grass, from purple pigeon grass to buffel grass, whereas the highest ground cover was during the dominance of Indian couch in the near absence of tussock grasses.

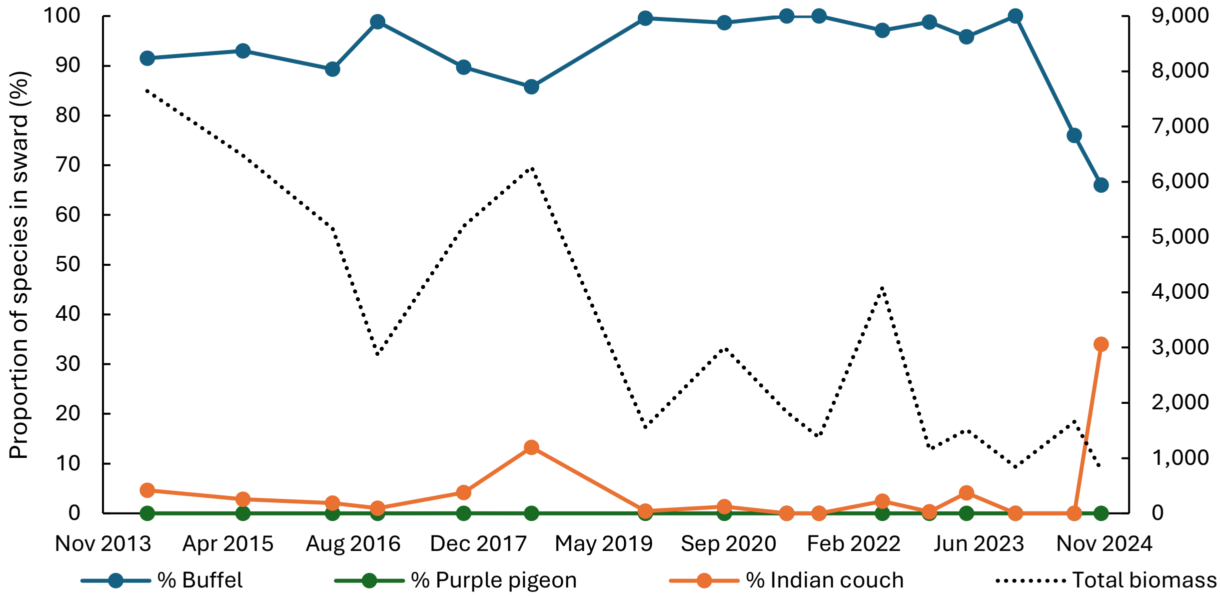

Figure 1. The proportion of buffel grass, Indian couch grass, purple pigeon grass and the total biomass of pasture under conservative grazing.

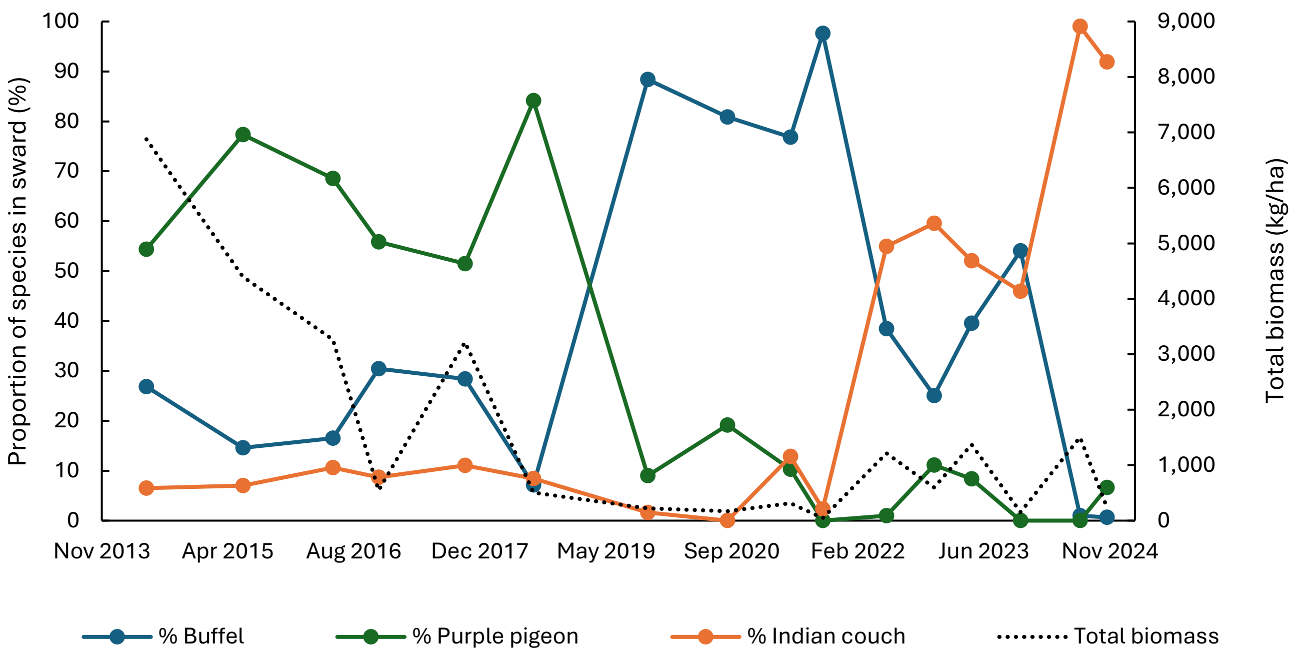

Figure 2. The proportion of buffel grass, Indian couch grass, purple pigeon grass and the total biomass of pasture under heavy grazing.

Discussion

This study was conducted during one of the driest periods in European history. Seven years of below average rainfall is atypical in the observed record, only happening twice since 1890. The previous occurrence was the Federation Drought which totalled an additional 100 mm of rainfall compared to the drought during this study. Drought was a substantial stressor to the pastures, as shown by the decline in yield under conservative grazing well below the 3,000 to 4,000 kg/ha typically seen in that catchment (Radford *et al.* 2007). Failure to lower grazing pressure from 2023 onward likely accounts for the rapid decline in buffel grass, and the corresponding increase in Indian couch due to reduced competition.

The three shifts in species composition under heavy grazing likely occurred because of the cumulative stresses of drought and overgrazing, given that purple pigeon and buffel grasses have contrasting responses to these stressors. Purple pigeon grass is intolerant of continuous heavy grazing and will not survive (Scattini 2008). Conversely, buffel grass is very tolerant of regular grazing and will withstand considerable grazing once established (Skerman and Riveros 1990; Cook 2007). The two species also have quite different rainfall requirements. Purple pigeon grass is considered drought tolerant, but not as much as buffel grass which is considered the most drought tolerant improved pasture species (Cook and Clem 2000; Cook 2007; Scattini 2008). Purple pigeon grass is recommended for regions with annual rainfall greater than about 450 to 500 mm (Skerman and Riveros 1990; NSW Government 2012). In contrast, buffel grass is recommended for regions with annual rainfall greater than about 300 to 350 mm (Humphreys and Partridge 1995; NSW Government 2012). Annual rainfall was marginal for purple pigeon grass in three of the study years, whereas it was only marginal for buffel grass in one year.

The effect of heavy grazing was evident in the declining biomass of all three pasture species over time. While purple pigeon grass was no doubt stressed by record below average rainfall in 2017, it was able to respond to rainfall the following year and maintain a high proportion of the total pasture biomass. However, the combined effects of overgrazing and drought in 2019 to an already stressed plant caused a substantial decline in the proportion of purple pigeon grass in the pasture. The decline of purple pigeon grass likely provided buffel grass a competitive advantage, with buffel grass increasing to average more than 80% of pasture composition until 2021. At this point the proportion of buffel grass in the pasture dropped substantially, prior to a partial recovery, becoming co-dominant with Indian couch grass prior to the dominance of Indian couch grass.

Differences in palatability between purple pigeon and buffel grass may explain differences in initial pasture composition but are unlikely to have had substantial influence on the final pasture composition. Purple pigeon grass is typically considered less palatable than buffel grass, so may have received less grazing pressure, and hence accounted for more of the total pasture biomass during the high biomass period at the start of the study. However, when the proportion of purple pigeon grass in the paddock dropped abruptly in 2019, there was only about 220 kg/ha of feed on offer in a paddock stocked at about 1 ha/adult equivalent, which suggests palatability would have been a substantially lower concern for animals compared to simply finding enough forage to maintain intake.

Interpretation of ground cover without consideration of biomass and species composition provided an incomplete assessment of catchment and pasture condition. The decline in biomass and change in species composition when tussock grasses were dominant was reflected in low ground cover observations. Counterintuitively, the highest ground cover observation of 97% was the final sampling period, which yielded only 230 kg/ha of biomass from a sward containing greater than 90% Indian couch. This suggests that ground cover alone is a poor metric for assessing land condition when Indian couch is the dominant pasture species.

In contrast to changes in pasture composition and cover that occurred under heavy grazing, there was little change in pasture composition and cover under conservative grazing. This demonstrates that drought alone was not responsible for the changes in species composition under heavy grazing, as both catchments were subjected to the came climatic sequence. Heavy grazing was a key driver in the loss of valuable improved pasture species and the subsequent dominance of Indian couch in that catchment. This mechanism was illustrated under conservative grazing in 2024, when failure to lower grazing pressure resulted rapid decline of buffel grass, and a corresponding increase in Indian couch due to reduced competition.

The implications of heavy grazing extend beyond decreased biomass, changed species composition and the dominance of Indian couch in a formerly productive tussock pasture, as all these factors contribute to a decline in beef production (Stokes *et al.* 2023). Furthermore, from 2015 to 2018, heavy grazing more than tripled runoff, peak runoff rate and total suspended solids lost in runoff compared to conservative grazing (Thornton and Elledge 2021). Total nitrogen lost in runoff increased by a factor of 1.6 while total phosphorus loss increased by a factor of 2.6 (Thornton and Elledge 2021). The increased loss of rainfall as runoff and the subsequent loss of nutrients undermines the resilience of pastures to overgrazing and the invasion of Indian couch. Management practice change towards conservative grazing with consideration of safe long-term carrying capacity is essential to halt land degradation and begin improving land condition.

Genetic environment interaction on percent juniper in the diet of goats divergently selected for high or low juniper consumption

Walker, JW[1]; Quadros, DG[2]; Rector, MF[1]

[1] Texas A&M AgriLife Research, San Angelo, Texas 76901, USA; john.walker@ag.tamu.edu [2] University of Arkansas System Division of Agriculture, Little Rock, AR 72204, USA

Key words: restoration ecology; diet preferences; targeted grazing; animal breeding

Abstract

Diet selection by grazing animals is determined by genetic and environmental factors that interact and affect their efficacy for managing vegetation as targeted grazers and developing animals adapted to local grazing environments. The effect of rearing environments on the percentage of dietary juniper (*Juniperus* spp.) of goats, that for 15 years were divergently selected for high (J+) or low (J-) juniper consumption, was investigated using a factorial design 2 × 2 (rearing environment × selection line). Eighty pregnant does from both selection lines were grazed on either juniper-infested (JIR) or juniper-free (JFR) rangelands until their kids were weaned at about 75 days of age. Faecal samples were analysed with faecal near-infrared reflectance spectroscopy to determine the percent juniper in the diet. After weaning, kids from both rearing environments grazed JIR. The J+ does always consumed more ($P < 0.001$) juniper than J- does, demonstrating different maternal role models for kids reared in the JIR environment. The percentage of juniper in J- kid diets (7%) was the same regardless of the rearing environment. However, the rearing environment affected the percentage of juniper in the diet of J+ kids, resulting in a gene-environment interaction (P=0.022). The percentage of juniper in the diet of J+ kids reared in JFR (16%) and JIR (24%) were about two and three times higher than J- kids, respectively, indicating that genetics and the rearing environment contributed about equally to the increase in the percentage of juniper in the J+ kid diets. Regardless of the rearing environment, the J+ kids had a higher percentage of dietary juniper than J- kids (P<0.001). The ability to select animals with specific dietary preferences and proper rearing environments holds promise for targeted grazing strategies to restore degraded rangelands, with potential applications in conservation and ecosystem management.

Introduction

Livestock are valuable ecosystem engineers whose selective grazing habits affect the botanical composition and biodiversity of grazed ecosystems. There is much interest in methods for influencing grazing livestock botanical preferences to manage an ecosystem's trajectory. Diet selection and preference by grazing animals are determined by the genome, gene expression (epigenetics), and complex and variable learning environments of animals, and there is interest in using the variation within breeds to select animals that can utilize poor quality forages high in plant secondary compounds (PSC) that are common in arid environments. Determining to what extent foraging behaviour and diet preferences are genetically and environmentally determined and the interaction of these two factors will aid in selecting animals better suited for use in conservation schemes, whether by employing different breeds or animals from different backgrounds.

Junipers are chemically defended woody plants that have encroached in the western U.S. rangelands. For 15 years, Texas A&M AgriLife Research divergently selected goat populations for increased (J+) or decreased (J-) juniper consumption (Mulim et al., 2024). This study aimed to determine the gene-environment interaction on preference for juniper (*Juniperus ashei* and *J. pinchotii*) by goats from the two selection lines. To accomplish this, J+ and J- does were reared from the end of breeding until weaning on rangelands with or without juniper, and the percentage of juniper in kid diets was compared post-weaning, when goats were grazing in the juniper-infested rangelands (JIR).

Methods

The experiment was conducted following a completely randomized 2 × 2 factorial design (selection lines × rearing environment), and individual animals were replicates. The study was conducted on rangelands in west central Texas, USA. The predominant ecological site for the JIR is a Low Stony Hill in an Oak/Mixed-brush Shortgrass seral state. The JFR is predominantly a Clay Loam ecological site in a Shortgrass Mesquite/Mixed brush Savannah ecological seral state.

Does from the two selection lines were joined to bucks of their respective selection line in separate JIR pastures in the fall of 2021. At the end of the breeding season, 20 does from each line were randomly selected and transported to a JFR, while similar does remained on JIR. Does from the two selection lines in both rearing environments remained in separate pastures until their kids were marked according to their selection line at 30 days of age. Then, they were combined to graze on a common pasture in their respective rearing environments. After weaning, goats from the two selection lines (J+ and J-) and from both rearing treatments (JIR and JFR) grazed common but different JIR pastures for does and kids (Figure 1).

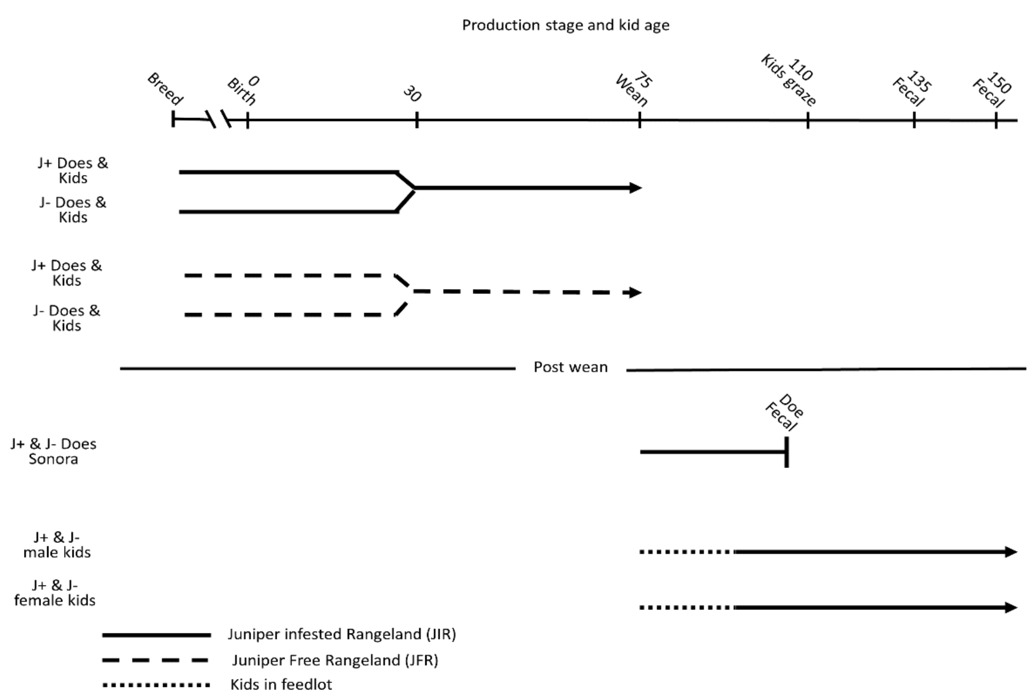

Figure 1. Diagram depicting rearing and grazing environment periods and fecal sample collections for goats divergently selected for high (J+) and low (J-) juniper consumption.

The percent juniper in the diet was determined on faecal samples (fNIR) using near-infrared spectroscopy (Walker et al., 2007). To document that does provide different maternal role models for their offspring faecal samples from does grazing JIR were collected when kids were 30 days old, at weaning, and 30 days post weaning. Post weaning following a 21-day adaptation period, 110-day-old kids from both rearing environments were grazed on JIR. Faecal samples were collected two or three days apart in the same pasture for does and kids, respectively, and averaged before statistical analysis because these samples were considered subsamples. Analysis of variance using the MIXED procedure of SAS 9.4 was used to determine treatment effects and their interactions. Tukey's test was used for mean separation when there were more than 2 means.

Results

When grazing JIR, the J+ does always had a higher percentage of juniper in their diets (P < 0.001) compared to J- does (Table 1). There was no effect of rearing environment (P = 0.488) or rearing environment × selection line interaction (P = 0.096) when does grazed a common pasture.

The percent juniper in the J- kid diets was the same regardless of rearing environment, and J+ kids raised on JFR had twice as much juniper in their diet, while J+ kids raised on JIR had three times as much juniper in their diet compared to J- kids, resulting in a significant selection line x rearing environment interaction (P = 0.022; Figure 2). Regardless of the rearing environment, the J+ kids had a higher percentage of juniper in their diets than J- kids (P < 0.001; Table 2). Compared to males, female kids had a higher percentage of juniper in their diets (P = 0.002).

Table 1. Percentage of juniper in the diet of goat does divergently selected for high (J+) or low (J-) juniper grazing juniper infested rangelands (JIR) or juniper free rangelands (JFR).

Doe treatment	JIR		JIR & JFR
Forage type	JIR	JIR	JIR
Days postpartum	30	75	110
Selection line			
J+	43	67	71
J-	-3	4	26
SEM	NA[1]	13	10
P-value	NA	<0.001	<0.001

[1] Because does grazed different pasture statistical comparisons were not made.

Table 2. The effect of selection line and sex on percentage juniper in the diets of post-weaned kids grazing juniper infested rangelands.

	Selection line		Sex	
	J-	J+	M	F
Juniper (%)	7	19	12	17
SEM	1		1	
P-value	<0.001		0.002	

Discussion

To our knowledge, these two lines of goats are the only livestock that have been selectively bred to change the botanical composition of their diet. The genetic-environment interaction, while often hypothesized (Rook et al., 2004), has little supporting empirical research on free-grazing ruminants. However, the rearing environment did affect the percentage of juniper in the diet of J+ kids, resulting in a genetic-environment interaction. The percentage of juniper in the diet of J+ kids raised in the JFR and JIR environment were about two (16%) and three (24%) times higher than J- kids, respectively, indicating that genetics and the rearing environment contributed about equally to the increase in the percentage of juniper in the J+ kid diets. However, this study cannot explain the cause of the interaction. The rearing environment can cause epigenetic changes that increase an animal's ability to metabolize or eliminate xenobiotics (Zhu et al., 2023), and their ability to learn to sequence meals to mitigate PSC (Villalba et al., 2004). The rearing environment did not affect percentage juniper in the diet of J- kids, indicating that it is limited by their ability to metabolize PSC that act as feeding deterrents (Villalba et al., 2015).

The importance of the genetic influence on diet preference was shown by the higher percent juniper in the diets of J+ compared to J- kids and does regardless of rearing environment. The heritability estimates for the percent juniper in the diet of the goat lines used in this study was 43% (Mulim et al., 2024). Similar to this study in human twin studies the heritable of preference for vegetables that like juniper have a lower preference than other foods is about 45%, and the remaining variation is shared and nonshared environmental (Breen et al., 2006; Fildes et al., 2014). The need to use individual variation in diet preferences within breeds or species to develop animals more aligned with the botanical composition of the rangelands they are grazing has been recognized, and this study demonstrated that there is adequate variation and heritability within breeds to help accomplish this goal.

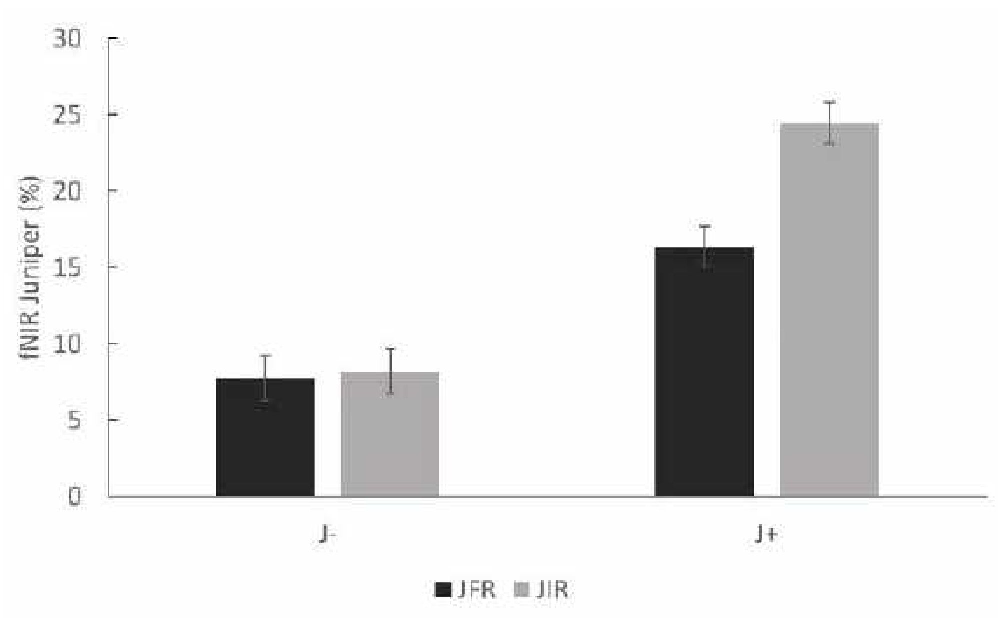

Figure 2. Selection line × rearing environment interaction (P = 0.022) for percent juniper in the diet of weaned kid goats divergently selected for high (J+) and low (J-) juniper consumption and reared on juniper-free rangelands (JFR) or juniper infested-rangelands (JIR) free grazing a JIR.

Key words: grazing intensity; temporal stability; species asynchrony; semi-arid steppe

Abstract

Livestock grazing is a key factor influencing structure, functioning and stability of grassland ecosystems. However, the effects of grazing intensity on the temporal stability of plant community aboveground net primary productivity (ANPP) and the driving mechanisms remain poorly understood in typical steppe ecosystems. In a 6-year experimental study, we investigated how varying grazing intensities (light, moderate, heavy, and no grazing) affect the temporal stability of ANPP in plant communities and functional groups. Our findings revealed that both plant community ANPP and species richness increased significantly under all grazing intensities. Moderate and heavy grazing also led to a significant reduction in the temporal stability of ANPP of community and dominant species. Structural equation modelling further identified species asynchrony as the primary driver of community productivity stability across different grazing intensities in semi-arid grasslands.

Introduction

Grasslands, covering 40% of Earth's terrestrial surface, are critical for biodiversity and livestock production (Wen *et al.* 2011). However, they have suffered significant biodiversity loss, ecosystem degradation, and reduced stability, largely due to livestock grazing (White *et al.* 2000; Shan *et al.* 2011). Grazing alters plant community structure, diversity, and productivity, thereby impacting ecosystem stability (Filazzola *et al.* 2020; Li *et al.* 2022; Sun *et al.* 2023). Maintaining grassland stability is crucial for sustaining ecosystem services, necessitating a better understanding of how grazing influences these systems.

Temporal stability, defined as the consistency of aboveground biomass over time, is vital for sustaining multiple ecosystem functions (Tilman and Clark 2014; White *et al.* 2021). It is influenced by species diversity (Hautier *et al.* 2015), species asynchrony (Hautier *et al.* 2014), and the stability of dominant species (Hillebrand *et al.* 2008). Species diversity enhances stability by promoting species asynchrony, where different species respond differently to environmental variability, buffering productivity fluctuations (Wang and Loreau 2016; Xu *et al.* 2021). Grazing, a widespread land-use practice, impacts grassland stability by altering species richness and asynchrony (Blüthgen *et al.* 2016). Moderate grazing may enhance stability, whereas heavy grazing often reduces it by decreasing species richness (Li *et al.* 2018; Ren *et al.* 2018).

The temperate grasslands of Inner Mongolia, including meadow steppe, typical steppe, and desert steppe, have historically supported traditional grazing due to their unique ecological characteristics (Zhu *et al.* 2023). However, these grasslands have degraded in recent decades due to overgrazing, human activities, and climate change (Bai *et al.* 2015). Overgrazing has led to severe ecosystem degradation in the semi-arid steppe. Understanding how grazing intensity affects productivity stability is critical for developing sustainable grazing management strategies in these regions. In this study, we conducted a six-year field experiment in the Inner Mongolian grasslands to examine how grazing intensity influences productivity stability. Specifically, we addressed two key questions: (1) How do different grazing intensities affect the temporal stability of aboveground net primary productivity (ANPP)? (2) What are the key drivers of temporal stability under different grazing intensities? Our findings aim to clarify the mechanisms regulating productivity stability in semi-arid grasslands and provide a scientific basis for sustainable grazing management in temperate steppes.

Methods

Study site and experimental design

The study was conducted at the Grassland Ecosystem Research Station of Inner Mongolia University, 60 km northeast of Xilinhot city, Inner Mongolia, China (116°31′18″ - 116°32′28″E, 44°15′24″ - 44°15′41″N, 1146 m a.s.l.). In 2016, a grazing experiment was initiated in a level grassland area, with 16 experimental paddocks (0.25 hm^2 each). Four grazing treatments—nil grazing (NG), light grazing (LG), moderate grazing (MG), and heavy grazing (HG)—were randomly assigned, each replicated in four blocks. Grazing intensities were achieved by introducing 0, 3, 6, or 9 sheep to the respective paddocks, using a rotational grazing system. Sheep were introduced in June, July, and August, and after each grazing event, they were removed, leaving a residual grass height of about 6 cm in MG paddocks (approximately 60 g dry matter/m^2). The experiment ran from 2017 to 2022 to assess the long-term effects of grazing intensity on grassland ecosystem structure and function.

Sampling and measurements

Three moving cages of 1.2 m in length, 1.2 m in width, and 1.0 m height were randomly placed in each paddock to protect the grassland from grazing before each animal grazing rotation in June, July, or August. Plant aboveground biomass (AGB) was determined by harvesting (clipping) plant materials species by species from the ground surface at the end of each grazing rotation, both inside and outside each moving cage, using the quadrat of 1 m × 1 m, and then these cages were moved to other places for excluding animal grazing in next rotation. The harvested plant biomass was oven-dried at 65°C for 48 h and weighed.

(1) Aboveground Net Primary Productivity (ANPP): ANPP was determined as the total aboveground biomass produced by plants during the growing season, which included both livestock feed intake during the grazing rotations and the residual plant biomass remaining at the end of the final grazing rotation. The total ANPP for each paddock was measured at the end of each grazing season.

(2) The daily forage intake of grazing sheep (DI): in each grazing rotation was determined as the difference between plant AGB inside (AGB_i) and outside (AGB_g) of the moving cages after each grazing rotation:

$$DI = (ABG_i - ABG_g) \times 2500\ m^2 / N_L / D_g$$

Where DI was in $g \cdot head^{-1} \cdot d^{-1}$; AGB_i and AGB_g were in $g \cdot m^{-2}$; N_L is the number of sheep in grazing, and D_g is the number of grazing days.

(3) Species richness in each paddock was defined as the total number of species detected in the three quadrats.

(4) The temporal stability of ANPP was defined for each paddock as μ/σ (i.e., the inverse of CV), where μ is the temporal mean of community-level ANPP from the paddock over 6 years period and σ is the temporal standard deviation over the same period. Temporal stability is unitless.

(5) The species asynchrony was quantified using the community-wide asynchrony index by species biomass (Loreau and de Mazancourt 2013a).

$$1\text{-}\varphi=1 - \frac{\sigma^2}{\left(\sum_{i=1}^{s}\sigma_i\right)^2}$$

Where φ is species synchrony, and σ^2 is the temporal variance of community aboveground biomass of species i in a community with S species.

Statistical analysis

In this study, we used the Shapiro-Wilk normality test for the normality of variance for each data set. Repeated-measures ANOVAs were performed to test the effects of grazing treatments on ANPP, species richness, stability and asynchrony. One-way ANOVAs with Duncan's multiple range tests were used to determine the significance of difference among the grazing treatments. Structure equation modeling (SEM) was used to estimate the strength of direct and indirect relationships between grazing treatments, species asynchrony, species richness, functional groups stability and community temporal stability.

Results

Effect of grazing on plant community ANPP

Compared to the ANPP of total and function groups in the ungrazed grassland, the total ANPP and the ANPP of subordinate species significantly increased under increasing grazing intensity ($P < 0.05$, Fig. 1a, c). The ANPP of dominant species significantly increased under LG and MG, but not under HG ($P < 0.05$, Fig. 1b).

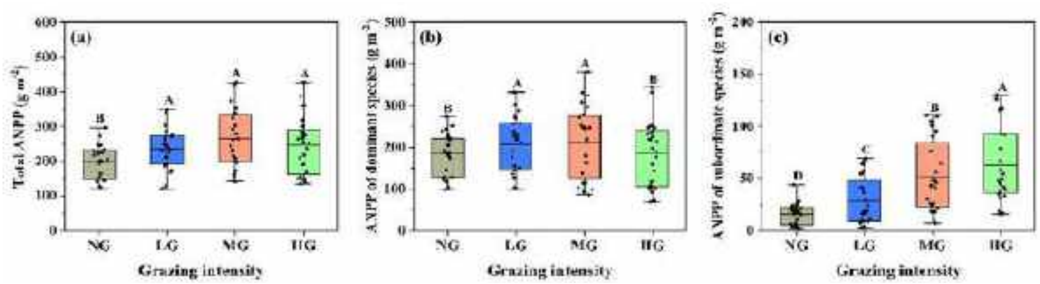

Fig. 1 Effects of different grazing intensity on ANPP of total (a) and function groups (b, c) in a typical steppe grassland. Different uppercase letters indicate significant differences between grazing treatments ($P < 0.05$).

Effects of grazing on temporal stability of ANPP and species asynchrony

Compared with no grazing, the stability of ANPP of community and dominant species significantly decreased under the MG and HG ($P < 0.05$, Fig. 2a, b), and the stability of ANPP of subordinate species significantly increased under moderate grazing ($P < 0.05$, Fig. 2c). Compared with no grazing, the species asynchrony significantly decreased under HG, but the species richness significantly increased under MG and HG ($P < 0.05$, Fig. 2d, e).

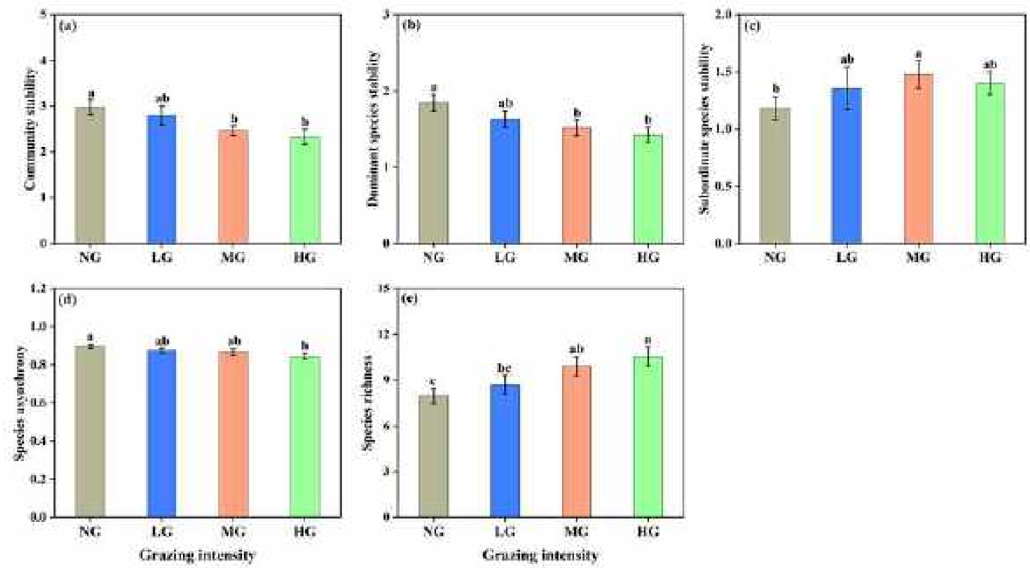

Fig. 2 Effects of different grazing intensity on productivity stability, species asynchrony and species richness in a semi-arid steppe.

Pathways through which grazing intensity influenced community stability

The SEM analysis demonstrated that grazing intensity indirectly reduces temporal stability of community ANPP by reducing dominant species stability and species asynchrony. Additionally, grazing intensity also indirectly reduced community temporal stability through its positive effects on species richness and ANPP. Species asynchrony was the primary factor influencing community temporal stability.

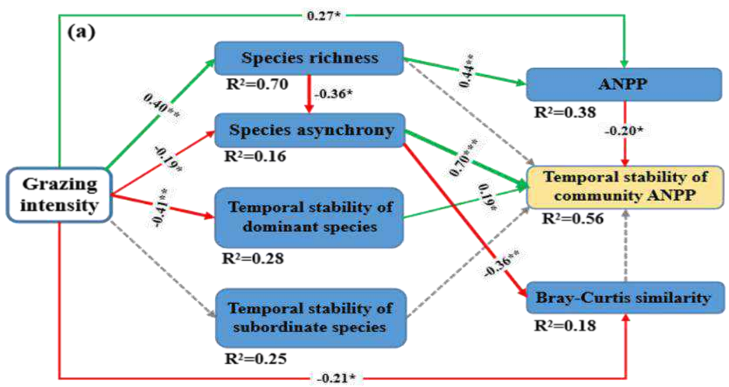

Fig. 3 Structural equation modeling (SEM) depicting the direct and indirect effects of different grazing management on productivity stability in a semi-arid steppe. Red and green arrows indicate negative and positive relationships ($P < 0.05$) respectively, with path coefficients shown on the paths, and dashed gray lines indicating non-significant relationships. Arrow width indicates the strength of the relationship.

Discussion

Our results indicate that grazing intensity increases community ANPP compared to no grazing, primarily due to higher ANPP of subordinate species and, to a lesser extent, dominant species. Previous studies suggest that moderate grazing enhances plant productivity through compensatory growth, while heavy grazing generally reduces productivity (Hilbert *et al.* 1981; Mcnaughton 1983). In our study, however, grassland productivity still increased under heavy grazing, likely for two reasons. First, the grazing intensity may not have been sufficient to cause significant damage, allowing compensatory growth to persist. Second, increased trampling and grazing pressure reduced biomass of dominant species, potentially altering competitive interactions (Sternberg *et al.* 2000).

In alignment with our expectation that livestock grazing can change productivity stability in temperate grassland, our results show that grazing intensity decreased community and dominant species productivity stability. This is consistent with other studies that have shown that community productivity stability decreases with increasing grazing intensity (Qin *et al.* 2019; Han *et al.* 2023). Summer is a season of vigorous plant growth, and grazing activities can alter the competition for resources (i.e., light and nutrients) among vegetation species (Eskelinen *et al.* 2022), resulting in dynamic changes in the plant community and decreased productivity stability. Grazing reduces the dominant species stability, largely owing to selective feeding by livestock. In general, herbivores prioritize tall and palatable plants (Lv *et al.* 2020), dominant species are highly favored by domestic animals owing to their generally larger size and high proportional abundance (Mariotte *et al.* 2013), whereas compensatory growth after ingestion also induces ANPP instability in the community (Zhu *et al.* 2021).

Species asynchrony, arising from differential species responses to environmental conditions, is a common feature of communities (Muraina *et al.* 2021). Our results show that heavy grazing reduces species asynchrony. Under heavy grazing, the relative biomass of annuals and biennials increases, while dominant species like *Leymus chinensis* and *Stipa grandis* decrease, leading to less asynchronous population dynamics. Studies have shown that increased species asynchrony enhances community productivity stability (Tilman and Downing 1994; Loreau and de Mazancourt 2013b; Zhou *et al.* 2019). In line with this, our findings suggest that grazing reduces ecosystem stability mainly by decreasing species asynchrony, rather than by affecting species richness. This negative impact on species asynchrony undermines its stabilizing effect, causing a decline in community stability with increasing grazing intensity (Liang *et al.* 2021). Species asynchrony, but not species diversity, are the main driver influencing community productivity stability in semi-arid grassland grazing ecosystems.

Key words: carry-over effects; native grasslands; forage utilisation

Abstract

Excessive forage utilisation over winter, resulting in short residual sward heights (SH), may compromise spring production of native *Campos* grasslands. To assess the relationship between end-of-winter SH and subsequent spring dry matter (DM) on offer, an experiment was carried out in 2020 and 2021 to describe forage dynamics for swards clipped at 2, 4, 6, 8 and 10 cm as winter residual SH during five sampling dates throughout spring. Each year, 150 homogeneous plots (0.2 x 0.5 m) were arranged in a complete random block design experiment with six replicates (blocks). In both years, residual end-of-winter SH affected spring forage DM on offer but only had a small effect on net DM accumulation. The magnitude and extent of this response differed between years (interaction year* treatment, $p<0.001$). The main climatic difference between years was less rain in 2021 compared to 2020, yet, there was a greater DM on offer and greater net increase in DM accumulation in 2021. Average minimum temperature was greater in 2021 and may account for these year effects. There was little effect of low residual SH at the end of winter on subsequent spring DM production, but the extra DM within the system, by planning to have a greater SH at the end of winter, provided a buffer to render the whole system more weather-resilient.

Introduction

Native *Campos* grasslands are the main nutrition basis for meat and wool production systems in Uruguay, especially for extensive production (Jaurena et al. 2021). Since these pastures are grazed directly all year round and each season provides different amounts of forage dry matter (DM) productivity, with the lowest productivity observed during winter and the highest typically in spring (Orcasberro et al. 2021), it is difficult to properly manage livestock production considering these differences. Thus, it is common to observe excessive forage utilisation in winter, resulting in short residual sward heights (SH) by the end of this season. This shorter initial spring SH may compromise spring forage production.

Stockpiling native grassland forage from a season with a rapid growth rate (such as autumn) in order to be consumed in a season with very little growth (such as winter, when growth is temperature limited - Forde et al. 1975) is a common practice of certain farmers in the Pampa Biome (Jaurena et al. 2021). Thus, during winter, only animal consumption (demand) and virtually no new forage growth (offer) is expected. The question arises as to whether there is any subsequent impact on spring DM production depending on the pasture remaining at the end of winter. The objective of this study was to determine if forage utilisation (final winter SH) of native pastures affects the subsequent dry matter production in the following spring.

Methods

The trial was carried out at “Glencoe” Research Station (INIA Tacuarembó, Uruguay), with average annual rainfalls of 1200 mm, a subtropical humid climate with no dry season, and mean temperatures of the coldest and warmer months being -3 and 18ºC, respectively (Panario & Bidegain, 1997).

Five hectares of native rangelands were stockpiled during autumn from 28th and 25th March on 2020 and 2021, respectively, being intensely grazed before the accumulation period aiming to remove dead material from the summer. This initial autumn stockpiling period aimed to imitate what some farmers do before winter begins.

After the stockpiling period, at the end of the winter (date 0, on 7th and 14th September in 2020 and 2021, respectively), five SH treatments were applied to 150 plots of 0.5 x 0.2 m, with an initial SH of 10±2 cm, by clipping as follows: 2 cm, 4 cm, 6 cm, 8 cm and 10 cm above ground SH. No cattle grazed the site over the duration of the experiment.

Treatments were arranged as a split plot design with assessment date as the main plot and initial SH as subplot treatments, with six replicates each. The dates and treatments were allotted randomly within its corresponding main plot (date) and subplot (SH). The assessment dates (described in Fig. 1) were fixed beforehand and estimated as the summation of degree days (DD) using a base temperature of 8 °C, every 165 DD after the treatment application (date 0).

Forage DM on offer and SH were analysed using a mixed model approach, while simple linear regressions were applied to calculate growth rates (GR). Weather variables between years were analysed using ANOVA. All statistical analysis was performed using Infostat programme (Di Rienzo et al. 2015).

Additionally, GR were calculated as the average DM of each treatment on the final date minus the initial DM value divided by the number of days between sampling.

The DM and SH lab and field evaluations were conducted following the same methods as Cazzuli et al. (2023). Weather data was collected from an automatic station near the trial area.

Table 1. Weather variables during the pre-trial period (stockpiling during autumn and winter) and during the trial (spring) for both years

Weather variable	**2020**	**2021**	**p-value**
	Period: stockpiling pre-trial (autumn-winter)		
Average maximum temperature (°C)	20.6	14.5	< 0.001
Average minimum temperature (°C)	7.4	13.4	< 0.001
Average temperature (°C)	13.7	13.9	0.68
Average rainfall (mm/day)	8.4	4.6	0.10
	Period: trial (spring)		
Average maximum temperature (°C)	26.0	20.3	< 0.001
Average minimum temperature (°C)	10.7	18.9	< 0.001
Average temperature (°C)	18.4	19.6	0.06
Average rainfall (mm/day)	4.6	0.7	> 0.001

Pre-trial dates: 2020 = 28th March 2020 – 7th September 2020 (163 days); 2021 = 25th March 2021 – 14th September 2021 (173 days).
Trial dates: 2020 = 7th September 2020 – 9th December 2020 (93 days); 2021 = 14th September 2021 – 16th December 2021 (93 days).

Results

There was less rain in 2021 compared to 2020 but only during the trial period, and the minimum overnight temperature in spring was much higher in 2021 (Table 1). There were slightly more frosts during the stockpiling period of 2021 compared to the same period of 2020 (53 and 36 frosts for 2021 and 2020, respectively), and no differences between number of frosts during the trial period (5 frosts for both years).

In both years, residual end-of-winter SH affected spring forage DM on offer, but the magnitude and extent of this response differed between years (interaction year * treatment, $p<0.001$) (Fig. 1).

There was a significant year effect (2021 > 2020, $p<0.05$, Table 2) on net DM GR. Even though GR was not affected by treatment, a trend could be observed for greater GR for 10cm in both years.

Final SH reflected initial SH, although there was a trend for 10cm initial sward height to have higher growth rates (double) than all shorter start SHs.

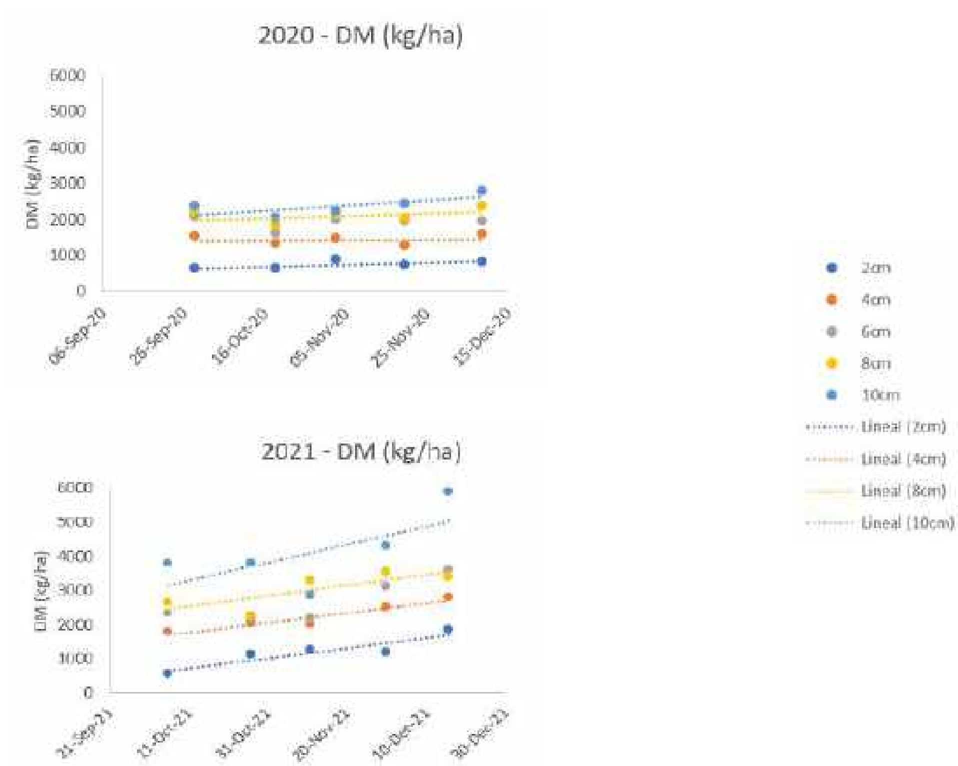

Fig. 1. Dry matter (DM) on offer on each of the 5 sampling dates of a native *Campos* grassland during spring, evaluating either 2, 4, 6, 8, or 10 cm final winter sward heights, for two years. The dotted lines are the regression of DM on offer over time.

Table 2. Daily dry matter (DM) growth rate and sward height (SH) of a native *Campos* grassland during spring, evaluating either 2, 4, 6, 8, or 10 cm final winter SH treatments, for two years.

Treatment SH	Final SH (cm)				Daily DM Growth Rate (kg/ha/day)	
	2020		2021		2020	2021
	Mean	SE	Mean	SE		
2cm	7.1	0.42	9.0	0.98	2.7	18.2
4cm	9.3	0.42	8.6	0.98	1.0	15.6
6cm	9.5	0.42	11.6	0.98	-1.5	18.2
8cm	11.8	0.42	11.5	0.98	3.0	13.9
10cm	13.3	0.42	14.6	0.98	6.2	29.0

Growth rates were calculated as the average DM of each treatment on the final date minus the initial DM value divided by the number of days between sampling. This is why there is a negative value.

Discussion

Residual sward height at the end of the winter affected spring forage-on-offer in both years but there was no effect on net DM accumulation nor on changes in SH (Fig. 1 and Table 2). High utilisation over winter with a low residual SH will have little effect on subsequent spring DM growth but low forage utilisation (high residual SH) may be used as a forage bank if spring DM production is compromised as illustrated in 2020 here. This has important management implications (Claramunt et al. 2018, Orcasberro et al. 2021).

There was a marked year effect, in agreement with Royo Pallarés et al. (2005) who concluded from their 19-year data on similar pastures that there was great inter-annual variability of forage production. On average, these authors found maximum GR of 25 kg/ha/day (between summer and autumn), and minimum GR of 5.5 kg/ha/day (winter months), the latter being above our spring GR data. The values of DM from 2021 were always greater than those from 2020 despite less rain over the period and no difference in the number of frosts in spring. The one difference was that average minimum temperature in 2021 (18.9C) was greater than 2020 (10.7C) and C4 plants are sensitive to minimum temperature to initiate and promote growth (Forde et al. 1975, Ivory & Whiteman, 1978). *Campos* grasslands have a high proportion of C4 plants and this may account for the differences between years in net DM accumulation and SH. Our DM on offer values are similar to the highly variable estimates of the native *Campos* grasslands during spring (e.g. Claramunt et al. 2018 with 1000 and 1500 kg/ha depending on the year, or Orcasberro et al. 2021 with 4147 kg/ha at 11.6 cm and 2910 kg/ha at 6.8 cm).

When analysing production systems as a whole, the higher the pre-drought herbage allowance and herbage accumulation rate, the lower the risk of a negative impact of a drought on the whole system (Modernel et al. 2019). Thus, having a relatively high end-of-winter SH provides a buffer of forage within the system and may have some advantage in not limiting subsequent DM growth over spring. However, the minimum temperature over spring appears to have a major effect on spring DM growth which requires further research in the heterogenous C3 and C4 plant systems such as these.

Implications

Weather conditions play a very significant role on overall forage on offer, even though their interactions are not always thoroughly understood. Minimum temperature in spring appears to be important in the growth response of Campos grasslands.

Nonetheless, there are some principles that apply if the aim is to optimise overall system productivity. Whilst the low residual end-of-winter SH has little effect on net DM accumulation in spring, there is no buffer DM present.

A higher residual SH would make the system more resilient to management strategies and between year variation in temperature and occurrence of frosts. Alternatively, although not statistically different in this study, further research may be warranted to investigate whether the observed trend of greater growth rates with 10cm is a real effect, as this would have implications for recommended end of winter target sward height to maximise spring forage growth and available dry matter.

Acknowledgements
The authors are grateful to all the technical students who co-executed the experiment (Cristian, Leandro, Luciana and Santiago). We would like to thank Saulo Díaz, Diego Dutra, Mauricio Silveira, Alfonso Albornoz and Sebastián Suárez for their invaluable help as well as all Glencoe staff.

Keywords: Fodder, Gaddi Shepherds, Nutritional Composition and Western Himalayas

Abstract

The Gaddi shepherds of the northwestern Himalayan region practice transhumance, migrating their sheep and goats to alpine pastures in summer and lower Shiwalik hills in winter. These animals graze on various vegetation during migration, whose nutritional value remains largely unstudied. Therefore, this study aimed to assess the nutritional quality of key fodder resources (including trees, shrubs, herbs, and grasses) crucial for small ruminant feeding. Gaddi farmers were interviewed using a semi-structured questionnaire to gauge their preferences for these fodder resources. Representative samples 20 most important fodder species (in triplicate) were hand plucked to mimic the diet selection by migratory small ruminants from the Bharmour block of District Chamba and were subjected to nutritional evaluation. The study revealed significant variation in nutritional attributes among the different preferred fodder species. The DM % was highest in *Quercus semecarpifolia* (61.80 ± 0.77) and lowest in *Buddleja crispa* (32.40 ±0.26) [p<0.05]. The CP% (DM basis) was highest in *Indigofera heterantha* (22.03± 0.27) and lowest in *Quercus semecarpifolia* (9.93± 0.17) [p<0.05]. EE % was higher in *Quercus leucotrichophora* (3.26 ±0.20) and lowest in *Morus serrata* (1.33 ± 0.25) [p<0.05]. The CF, NDF, and ADF (%) were greater [p<0.05] in *Quercus semecarpifolia* and lowest in *Trifolium pratense* (37.00 ± 0.31, 53.13 ± 0.39 and 47.66 ± 0.29 vs. 21.23 ± 0.42, 36.13 ± 0.36 and 25.16 ± 0.58, respectively). The TA (%) was found highest in *Populus deltoides* (8.06±0.39) and lowest in *Indigofera heterantha* (2.56 ± 0.30) [p<0.05]. AIA (%) was highest in *Salix alba* (4.66 ± 0.21) and lowest in *Oxyria digyna* (0.66 ± 0.23) [p<0.05]. The NFE (%) was highest in *Festuca arundinacea* (57.13±0.40) and lowest in *Populus deltoides* (43.30 ±0.27) [p<0.05]. Based on farmer preferences and nutritional analysis, the study identified the most preferred species for Gaddi farmers feeding small ruminants in the Bharmour block of District Chamba, including *Desmodium elegens*, *Indigofera heterantha*, *Rubus saxatilis*, *Buddleja crispa*, *Trifolium pratense*, *Festuca arundinacea*, *Salix alba*, *Robinia pseudoacacia*, *Pyrus pashia*, and *Morus serrata*.

Introduction

Himachal Pradesh, located in the North-Western Himalayas of India, is divided into four distinct zones: dry temperate–alpine, moist temperate, sub-temperate, and sub-tropical. The Chamba district, which lies deep within Himachal Pradesh, has a significant tribal population (Rana et al. 2014). Within Chamba, two tribal regions—Pangi and Bharmour—are home to the Gaddi tribe. This tribe primarily resides in the Bharmour and Holi areas of

Chamba district, as well as in parts of Kangra district. In these regions, Gaddi farmers predominantly raise sheep and goats to meet their household nutritional needs. The Gaddis practice transhumance, migrating with their flocks to different parts of the state: they move to the lower Shiwalik hills in winter and to the alpine pastures during the summer. A major challenge for livestock farming in Himachal Pradesh is the seasonal availability of green fodder. While fodder is abundant during the monsoons, it becomes scarce in the winter and peak summer months, prompting nomadic farmers to migrate to find enough nutrition for their animals. This shortage of green fodder has increased the reliance on fodder trees and shrubs during these scarcity periods. A study by Vashist and Pathania (2001) revealed that there was a 59 (%) and 37 (%) shortfalls in dry and green fodder, respectively, in Himachal Pradesh. Due to a lack of research on the nutritional content of both conventional and non-conventional feed used by the Gaddi tribe for their sheep and goats, the present study titled "Exploring the Nutritional Composition of Fodder Resources Utilized by Transhumant Gaddi Shepherds in the Western Himalayas, India" was conducted in the Bharmour block of Chamba district, Himachal Pradesh.

Methods

To evaluate the nutritional content of fodder resources the samples were collected between July-September 2020 from Bharmour region of Himachal Pradesh, which is situated at an elevation of 7,000 feet above sea level. The region is located between 32˚ 11'–33˚ 13' N latitude and 76˚ 22'–76˚ 53' E longitude. The climate is generally temperate, with cool winters characterized by heavy snowfall and temperatures dropping below 0ºC. Summers are pleasant, with temperatures ranging from 15ºC to 25ºC. The mean annual rainfall is 1,500 mm, and the average annual temperature ranges between 3ºC and 30ºC. As per the information received from the gaddi farmers the important fodder species (fodder trees, shrubs, herbs, legumes and grasses) were collected from pastures, farm bunds in Bharmour block by random sampling. The fodder tree species was hand plucked with a mix of all edible parts (leaves, flower, fine stem and pods), while for herbs and other grasses were harvested at about 5cm above the ground level. After harvesting, individual species sample were separated and a total of three composite samples of 1kg each were collected for individual fodder species. Hence in this manner, samples were collected for 20 species consisting of total 60 representative samples.

The collected leaf samples were then dried in hot air oven at temperature 60±5°C until a constant weight was achieved. The dried leaf samples were then crushed in a mechanical grinder fitted with stainless steel blades to form fine powder which was used in the determination of the leaf nutritional composition. The estimation of DM, CP, EE, CF, TA, and NFE was done by employing the methods devised by Association of Official Analytical Chemist (A.O.A.C., 2000). The procedures of (Van Soest et al. 1991) were adopted for the estimation of ADF and NDF. The AIA was also determined. Data analyzed by one way classification as per the procedure suggested by (Gomez and Gomez 1984) wherever the experimental effects exhibited significance per cent level of probability, the critical difference was calculated.

Results

The overall average of DM in fodder tree leaves was 49.58 ± 0.56%. The mean percentage DM was highest in *Quercus semecarpifolia* (61.80 ±0.77) and lowest in *Salix alba* (38.38 ±0.55). The overall mean DM of shrubs was 40.05 ± 0.34% (Table 1). The overall DM (%) in herbs was 38.33 ± 0.21 %. The mean DM (%) was highest in *Rumex nepalensis* (40.13 ± 0.57) and lowest in *Aconogonum molle* (35.70 ± 0.45). The DM % followed a downward trend as *Rumex nepalensis* (40.13 ± 0.57) > *Oxyria digyna* (39.16 ±0.49) > *Aconogonum molle* (35.70 ± 0.45). The overall means of DM (%) in legumes and grasses was 36.63 ± 0.26. The mean DM (%) was greatest in *Festuca arundinacea* (39.16 ± 0.53) and least in *Trifolium pratense* (34.10 ± 0.59). The overall means DM of shrubs was 40.05± 0.34%. The overall DM (%) in herbs was 38.33 ±0.21. The mean DM (%) was highest in *Rumex nepalensis* (40.13 ± 0.57) and lowest in *Aconogonum molle* (35.70 ±0.45) (Table 1).

The mean CP (%) was higher in *Prunus spinosa* (16.53 ± 0.33) and lowest in *Quercus semecarpifolia* (9.93 ± 0.17). The overall mean of CP in leaves of shrubs was 17.49 ±0.70%. The average CP (%) was highest in the leaves of *Indigofera heterantha* (22.03 ± 0.27) and lowest in *Elaeagnus angustifolia* (14.46 ±0.32) (Table 1). The overall mean of CP in herbs was 13.51 ±0.49% where the CP (%) in *Aconogonum molle* was highest (15.20 ± 0.23) and lowest in *Oxyria digyna* (11.86 ±0.42). The overall mean of CP % in legume and grasses was 15.15± 0.32 (Table 1). The findings of the present study revealed that the mean CP (%) was 18.70± 0.41 and 11.60 ±0.31 in the leaves of *Trifolium pratense*, *Festuca arundinacea,* respectively.

The overall means of EE in tree leaves was 2.63± 0.46%. The mean EE (%) was highest in *Quercus leucotrichophora* (3.26 ± 0.20) and lowest in *Morus serrata* (1.33 ± 0.25). The overall means of EE in leaves of shrubs was 3.17 ± 0.40%. The mean EE (%) was highest in *Indigofera heterantha* (3.66 ±0.44) and lowest in *Rubus saxatilis* (2.50 ± 0.21). The overall means of EE in herbs was 1.14±0.46%. The overall means of EE in legumes and grasses was 2.87 ± 0.16%. The mean EE content (%) was greatest in *Trifolium pratense* (2.40 ± 0.30) and least in *Festuca arundinacea* (1.90 ±0.19) (Table 1).

The overall mean CF in tree leaves was 31.62 ±0.35% (Table 1). The mean CF (%) was highest in *Quercus semecarpifolia* (37.00 ±0.31) and lowest in *Robinia pseudoacacia* (25.46 ±0.40). The overall mean of CF in shrubs was 25.38 ± 0.60%. The maximum CF (%) was exhibited by *Desmodium elegans* (28.36 ±0.39) and the minimum in *Buddleja crispa* (22.00 ± 0.28). The total mean of CF in herbs was 22.69 ±1.04%. Mean CF (%) was highest in *Rumex nepalensis* (25.60 ± 0.31) and lowest in *Oxyria digyna* (23.16 ± 0.18). The CF (%) followed a downward trend, as *Rumex nepalensis* (25.60 ±0.31) > *Aconogonum molle* (23.33 ± 0.27) > *Oxyria digyna* (23.16±0.18). The overall mean of CF in legumes and grasses was 22.63 ± 1.40% (Table 1). The mean CF (%) was highest in *Festuca arundinacea* (24.03 ± 0.35) and lowest in *Trifolium pratense* (21.23 ±0.42) (Table 1). The overall mean NDF in tree leaves was 44.22 ±0.73%. The average NDF (%) was highest in *Quercus semecarpifolia* (53.13 ± 0.39) and lowest in *Salix alba* (31.83 ±0.25) (Table 1). The overall means of NDF in shrubs was 40.14 ± 0.30%. The mean NDF (%) was highest in *Desmodium elegans* (43.86 ± 0.33) and minimum in *Buddleja crispa* (40.46 ±0.54). The overall mean of NDF in herbs was 37.61 ± 0.75%. The mean NDF (%) was highest in *Aconogonum molle* (38.40 ± 0.44) and lowest in *Rumex nepalensis* (36.33 ± 0.35). The overall mean of NDF in legumes and grasses was 36.73±0.69%. The mean NDF (%) was highest in *Festuca arundinacea* (37.33 ± 0.42) and lowest in *Trifolium pratense* (36.13 ± 0.36) (Table 1). The overall mean of ADF in tree leaves was 36.13 ± 0.57% (Table 1). The ADF (%) was highest in *Quercus semecarpifolia* (47.66 ±0.29) and lowest in *Salix alba* (23.50 ± 0.37). The overall averages of the ADF in shrubs leaves were 28.60 ± 0.49%. Mean of ADF (%) was highest in *Desmodium elegans* (38.16 ±0.45) and the lowest in *Buddleja crispa* (25.17 ± 0.33). The overall means of ADF in herbs was 27.27 ±0.47%. The mean ADF (%) was highest in *Aconogonum molle* (28.80±0.51) and lowest in *Oxyria digyna* (25.66 ± 0.36) (Table 1). The overall means of ADF in legumes and grasses was 26.43 ± 1.02%. The mean ADF (%) was maximum in *Festuca arundinacea* (27.70 ±0.44) and minimum in *Trifolium pratense* (25.16 ± 0.58).

The overall mean TA content in the tree leaves was 3.98 ± 0.19%. The mean TA (%) was recorded highest in *Populus deltoides* (8.06 ±0.39) > and lowest in *Pyrus pashia* (2.57± 0.24). The mean TA content in shrubs was 4.17±0.70%. The overall mean of TA content (%) in herbs was 4.29 ±0.75. The mean TA (%) was observed highest in *Rumex nepalensis* (5.13± 0.23) and lowest in *Aconogonum molle* (2.80± 0.36) (Table 1). The trend followed in TA content (%) was as follows, i.e. *Rumex nepalensis* (5.13± 0.23) > *Oxyria digyna* (4.93 ± 0.24) > *Aconogonum molle* (2.80 ± 0.36). The overall mean of TA in legumes and grasses was 4.48 ± 0.95%. The mean TA (%) was highest in *Festuca arundinacea* (5.43 ± 0.35) and lowest in *Trifolium pratense* (3.53 ±0.31). The overall mean of AIA in tree leaves was 2.27 ± 0.44%. The mean AIA (%) was highest in *Salix alba* (4.66± 0.21) and lowest in *Quercus leucotrichophora* (0.67 ± 0.28). The overall mean of AIA in shrubs was 2.19 ± 0.25%. The mean of AIA (%) was higher in *Elaeagnus umbellata* (3.33 ± 0.23) and lowest in *Desmodium elegens* (1.50 ± 0.21) (Table 1). The overall mean of AIA in herbs was 2.39 ± 0.91%. The mean AIA (%) was highest in *Rumex nepalensis* (3.76± 0.38) and lowest in *Oxyria digyna* (0.66 ± 0.23). The overall mean of AIA in legumes and grasses was 1.71 ± 0.05%. The mean AIA (%) was highest in *Festuca arundinacea* (1.76 ± 0.24) and lowest in *Trifolium pratense* (1.66 ±0.30) (Table 1). The means of NFE (%) in the different fodder samples are presented in table 1. The overall mean NFE in tree leaves was 48.82 ± 1.13 (Table 1). The mean NFE (%) was recorded highest in *Salix alba* (54.34 ± 0.46) and lowest in *Populus deltoides* (43.30 ± 0.27). The overall mean of NFE in shrubs was 49.78 ± 1.31%. The highest mean NFE was recorded in *Elaeagnus umbellata* (53.23 ± 0.43%) and lowest in *Indigofera heterantha* (45.00 ± 0.23%). The trend in NFE (%) was as follows i.e. *Elaeagnus umbellata* (53.23 ± 0.43) >*Buddleja crispa* (52.23 ± 0.36) > *Elaeagnus angustifolia* (51.46 ± 0.34) > *Rubus saxatilis* (49.83 ± 0.37) > *Desmodium elegans* (46.93 ± 0.13) > *Indigofera heterantha* (45.00 ± 0.23) (Table 1). The overall mean NFE in the herbs was 55.02 ± 0.82%. The *Oxyria digyna* contained highest NFE i.e. 57.10± 0.32% and the minimum NFE content was recorded in *Rumex nepalensis* i.e. 52.40± 0.72%. The overall mean of NFE in legumes and grasses was 55.68± 0.53%. The mean NFE (%) was highest in *Trifolium pratense* (54.23 ± 0.48) and lowest in *Festuca arundinacea* (57.13 ± 0.40) (Table 1).

Discussion and Conclusion

The results obtained in the present study are in agreement with previous studies of (Kumar et al. 2017) who reported that the *Q. leucotrichophora* contained 57.82 to 64.36 (%) of DM. The DM content in this investigation is consistent with that reported by (Azim et al. 2001) who stated that leaves of *Elaeagnus angustifolia* contain 46.7% DM. The DM content recoded in the study are in agreement with the study of (Wangmo, 2018) who stated that *Rumex nepalensis* contains 41.25% DM and *Aconogonum spp.* contained 39.21% DM. (Tomar and Sharma, 2002) reported 15.8 and 18.5% CP in *Salix* and *Robinia*, respectively. Verma, 2020 also reported that leaves of *Quercus leucotrichophora* contained 9.70% CP. Singh et al. 2019 reported that the leaves of *Trifolium* contained 23.98% CP. Verma, 2020 reported that leaves of *Quercus semecarpifolia, Q. leucotrichophara* and *Q. glauca* contained 4.25, 4.13 and 4.23% EE, respectively. (Geng et al. 2020) reported that *Aconogonum molle* 0.97% EE which is lower than the findings of the present study. Verma, 2020 also reported that the leaves of *Quercus leucotrichophora* and *Q. glauca* contained 30.69 and 32.27 (%) CF. Chandra *et al.* 2014 recorded 19.65% CF in the leaves of *Indigofera heterantha*. Results of present study are in agreement with the findings of (Koukolova et al. 2010) reported *Trifolium pratense* contained 18.15% CF. Azim et al. (2001) reported 44.2% NDF in *Robinia pseudoacacia*, which is in agreement with the results of the current study. The findings in the present study are in accordance with results of (Geng et al. 2020) who observed that *Rubus spp.* contained 46.56% NDF. Azim et al. 2001, reported 21% ADF in *Elaeagnus* spp. which is in agreement with the findings of the present study and also reported that the TA in *Populus* spp. and *Robinia pseudoacacia* contained 8.5 and 6.9%. Pandey and Bhatt 2016, also reported that *Rubus spp.* contained 2.97% TA which is in agreement with the findings of the present study. The results in this study are in line with previous study of (Prasanth and Chandran 2017) who reported that *Rubus spp.* contained 0.66% AIA. Verma, 2020 reported that the leaves of *Quercus leucotrichophora, Q. glauca* and *Q. semecarpifolia* contained 50.45, 47.34, and 43.97% NFE, respectively. The findings of the present study are in line with the earlier study of (Koukolova et al. 2010) who recorded *Trifolium pratense* contained 42.66% NFE and (Singh et al. 2019) also reported that 44.41% NFE in *Trifolium.* Bagley et al. 1983, reported 39.50% NFE in *Festuca arundinacea.* Based on both analytical data and field observations, it can be concluded that the CP (%) was highest in shrubs (17.49 ± 1.27) and lowest in tree leaves (12.99 ± 0.72). The highest average CF (%) was found in tree leaves (31.62 ± 0.35), while legumes and grasses had the lowest (22.63 ± 1.40). Moreover, the farmer preferences correspond with the nutritional findings, highlighting the most suitable fodder species for optimal animal nutrition. These results provide valuable insights for improving feeding practices among Gaddi shepherds, ultimately enhancing livestock health and productivity in the region.

Key words: food quality ; meat ; pastoralism ; livestock farming system ; current time history

Abstract

In Southeast France, pastoralism is often highlighted by quality and origin labels as links to the territoriality (or "terroir" identity) of livestock products: pastoral resources partly guarantee the quality of the product, and, in return, pastoral production contributes to the preservation of the land and its know-how. Since the 1990s, this dual relationship has been formalised, constructed and negotiated into normative specifications.

However, climate change seriously threatens the sustainability of Mediterranean rangelands and their farming systems. Livestock farmers and stakeholders are incited to re-question the link between the use of rangelands and quality or origin-linked production. At present, farming practices guaranteed by books of specifications tend to move away from pastoral resources, with potential impacts on the quality of pastoral products and the use of rangelands.

We propose a qualitative and diachronic analysis based on a methodology which intersects with environmental history and livestock farming systems. Through a series of case studies, this paper examines the trajectory of pastoral resources in quality labels in Southeast France since the 1990's, from their prominence in specifications to their reinterrogation. We built farm trajectories based on more than a dozen semi-structured interviews with farmers, supplemented by ten life narratives of other stakeholders. We also analysed current books of specifications and consulted public and private archives.

Quality labels stand out from standard products, particularly because of their seasonality, and represent a key market for pastoral production. They generate significant added value for producers by attracting committed purchases from demanding consumers. Moreover, the use of pasture and rangelands helps to reduce livestock production costs and contributes to sustainable development objectives supported by public policies. Confirming the importance of pastoral resources in quality labels is therefore essential if the sustainability of Mediterranean pastoral livestock farming systems is to be addressed in the long term.

Introduction

Pastoral farming is widespread in Southern France, particularly in Mediterranean and mountainous areas where it can claim very ancient roots and heritage status. These livestock production systems rely partly (or totally) on grazing spontaneous fodder resources (Nozières-Petit et al. 2021), mobilizing diverse environments such as natural pastures, rangelands, and biologically diverse Mediterranean forests. These resources are referred to as pastoral resources. Signs of quality and origin (e.g. geographical indications (GI)) often highlight pastoralism among their commitments (Aubron et al. 2014), especially in conservation areas such as regional or national parks. Indeed, the grazing practices, using spontaneous resources, enhance the unique quality of pastoral meats and cheeses (Martin et al. 2016). In return, GI are also considered to be beneficial for the preservation and management of the environment and natural resources (Milano and Cazella 2021).

In France, public research in agronomy and animal science has played a pivotal role in guiding the transformation of livestock farming systems since the 1960s (Cornu 2018). Pastoral production with a quality label has largely benefited from this scientific and political support (Le Gall 2021).

Since the 1990s, the dual relationship between pastoralism and quality has been formalised, constructed and negotiated into normative specifications with the support of research, and within the framework of both national and European policies. There is therefore an inherent political dimension between quality and environmental issues. However, climate change seriously threatens the sustainability of Mediterranean rangelands and their farming systems (Daliakopoulos et al. 2017). French livestock farmers need to adapt their practices to climate change, but also to others systemic disturbances, like predation. At present, farming practices guaranteed by specifications tend to move away from pastoral resources, with potential impacts on the quality of pastoral products, the use of rangelands and natural pastures, and thus on biodiversity. Through a series of case studies situated in Southeast France, this paper examines the trajectory of pastoral resources in quality labels since the 1990's, from their prominence in specifications to their current reinterrogation.

Methods

We employed a qualitative and diachronic methodology, intersecting socioenvironmental history and livestock farming systems analysis. Our research focuses on three key GI meat case studies (Table 1) for which we conducted 24 semi-structured interviews with farmers, complemented by 22 life narratives of other stakeholders. We also analysed current books of specifications and went through local public and private archives, but also through the national ones. Our methodological framework facilitated the collection of multi-scalar data, encompassing the local evolution of farming practices alongside national historical trends in pastoralism and quality-origin labelling. Our interdisciplinary entry allowed us to build farm trajectories (Moulin et al. 2008), based on five key dimensions: labor/capital allocation, infrastructure and land use, crop management, herd management (including feeding practices), and marketing strategies. These trajectories were supplemented by socio-technical and socio-ecological timelines.

Results

Recognition of the usefulness of pastoral resources by the public authorities and the scientific community

In pastoral meat production, the focus on quality linked to origin emerged quite belatedly. However, in difficult areas, farmers sought a competitive edge early on, leading to the development of the first origin-protected cheeses in pastoral areas, such as Roquefort (1925), Saint-Nectaire (1955), and Laguiole (1956). Initial specification documents were minimal, emphasizing processing practices over breeding as the primary justification for specific quality. At the time, applied agronomic research was carried out in these areas, but it was focused on increasing productivity, particularly in the case of Roquefort (artificial insemination, genetics).

Table 1. Overview of pastoral commitments in PDO and PGI case studies

Geographical indications main case studies	Commitments relating to pastoral resources
PDO Fin Gras du Mézenc (beef)	- Mandatory grazing on natural pastures from June 21st to September 21st - Fattening period with hay from local natural pastures for at least 110 days during winter
PDOs *Charcuteries de Corse* (cured pork product from free-range pigs)	- Pigs growth period (>2 months old) on rangelands (supplement authorised; max 1-2kg/days/pig) - Finishing period under oaks and chestnuts for at least 45 days between October and March
PGI Agneau de Sisteron (lamb)	- Mandatory grazing on pastoral lands for at least 180 days - At least 10ha of rangelands

To implement the link between origin-linked quality and meats, a political and scientific shift beneficial to pastoralism was needed. In the early 1970s, public authorities began acknowledging the unique characteristics of pastoral areas and their livestock systems. Public research was asked to give more attention to the risk of territorial imbalance in development schemes (Cornu, 2021). The 1972 Pastoral Law aimed to maintain pastoralism in mountain areas and recognise its specific technical and social traits, supported by new subsidies in 1973 and 1976. In 1977, a technical journal for sheep farmers devoted a landmark article to "*pastoral ecology*", which was seen as "*a new expression of an ancient tradition*". Meanwhile, French public research on pastoralism was gaining momentum. In 1978, J. Poly, director of the INRA, published a report entitled “*For a more economical and autonomous agriculture*". In 1981, a collective publication about mountains highlighted the economic interest of meat production in maximising the nutritional requirements of grazing livestock. Researchers also proved that rangelands could be managed by adjusting grazing methods and selecting appropriate supplementary feed for hardy breeds. For instance, in the 1970s-80s, the production of quality Corsican cured pork products was linked to feeding pigs chestnuts and acorns, prompting research to sustain free-range farming and develop suitable compound feed.

The shift in scientific views on pastoral resources and the rise of systemic approaches legitimized pastoral systems, offering an alternative to failed agricultural modernization. From the 1990s, livestock farmers leveraged these changes to promote pastoral products through quality and origin signs, still with a strong help of public research.

Pastoral resources: a cornerstone of quality and origin signs

Protected Geographical Indications (PGI) and Protected Designations of Origin (PDO) were recognised by the European Union in 1991-1992. In France, the *Institut National de l'Origine et de la Qualité* (National Institute of Origin and Quality), previously reserved for the wine sector, was given responsibility for GIs in the agri-food sector. This doctrinal change paved the way for the strengthening of pastoral resources as key elements to justify the typicality and territorial anchorage of animal products. Pastoral meat GIs met a strong development during this decade, particularly in the wake of the “Mad Cow crisis”.

The development of food tracers, such as terpenes, enabled a precise correlation between geographical origin and livestock dietary practices on pastures. A study commissioned in 1995 on *Fin Gras du Mézenc* showed that the richness of the flora found in natural pastures was reflected in the meat. These scientific advances met the need for legal and scientific proof of the specific nature and substantial quality of pastoral products.

This emphasis on pastoral resources in the specifications required a cognitive adaptation on the part of those involved in the sector. In the case of *Agneau de Sisteron*, pastoralism *'was a strong choice, it was a precursor to saying that pastoralism is a specific feature of our region, we have to write it down'* (former project manager). In 2001, the stakeholders met with a research centre specialised in pastoralism. After developing a specific indicator, they set a target of 10 hectares of rangelands for pasture in the book of specifications.

An ongoing decline of pastoral resources in livestock farming practices engaged in quality and origin signs
Although pastoral resources were thoroughly negotiated in the specifications, our interviews with farmers tend to assert that these are now being more and more challenged. Firstly, most farmers in the different areas point to the growing uncertainty over grazing resources, linked to climate change. In the *Fin Gras du Mézenc*, cutting dates are increasingly uncertain, and older farmers are concerned about the decline in floral diversity. Droughts and resource uncertainty in Corsica are pushing farmers toward more secure, non-pastoral fodder sources. Since the 1990s, the use of wraps by *Fin Gras du Mézenc* farmers has increased considerably. In Corsica, the use of supplementary feed is gaining pace, making farmers more dependent on price trends and geopolitical hazards (Covid-19, Ukraine…). A Corsican pig farmer explained that *"for me, droughts do not affect me... because we know that we have to feed them anyway. We work with living things, so we can't rely on natural resources"*. Although extreme, these words reveal a profound crack in the logic of quality signs and their link to the "terroir" model. In the same way, the image of the pastoral territories is being turned upside down, leading to painful cognitive divergences in highly patrimonial territories.

Livestock farmers are increasingly adapting their specifications to the current constraints by modifying feed requirements. For instance, after two temporary derogations in 2018 and 2020, the *Taureau de Camargue* PDO reduced the proportion of supplementary feed from local sources in 2022 and dropped the explicit reference to 'rangelands' and 'moorlands' for a more general "pastures". Carefully designed strategies are replaced by short-term adjustments, rational in themselves, but dangerous for the cohesion of the collectives involved.

Discussion and implications
If the decline in the use of pastoral resources within quality or origin labels persists, it could challenge the concept of terroir. Economic pressures could lead farmers to abandon pastoral practices, jeopardizing traditional landscapes and terroir-linked quality. This radical reconsideration could have a strong impact on the typicality of products, potentially undermining their organoleptic qualities and consumer perceptions.

Our observation that pastoral resources are declining in meat livestock farming practices is also evident in other productions, such as dairy products. Between 2016 and 2022, 35 French PDO cheeses requested temporary derogations, all of which concerned the feeding system: 86% requested at least once to reduce the proportion of locally sourced feed, 54% to increase compound feed, 40% to shorten the grazing period (e.g. INAO, pers. comm.). In *Picodon* (PDO cheese), farmers are adapting to climate change mainly by altering grazing areas, purchasing fodder, and housing goats indoors (Loiodice 2024). While traditional pastoral systems offer opportunities to adapt to climate change, these adaptations may come at the expense of farm economic margins and food self-sufficiency (Munoz-Ulecia et al. 2024).

However, the use of pastures and rangelands helps to reduce livestock production costs and contributes to sustainable development objectives supported by public policies (Ickowicz and Moulin 2023). Quality labels represent a significant part of pastoral livestock production in the South of France. The decline of pastoral practices under their specifications could therefore affect the maintenance of open landscapes, but also the pastoral socio-ecological systems. In this respect, although the recent Common Agricultural Policy (2013-2017) has had mixed results, especially in mountain areas (Giannoccaro et al. 2015), public policy has a role to play in reaffirming the importance of pastoral practices.

Our methodology, combining historical and zootechnical analysis, has highlighted the long-term but ever evolving relationship between quality signs and pastoral resources, the related problems that hinder their development and the evolution of socio-technical perceptions among both producers, researchers, and policy makers. As political and scientific paradigm shifts in the 1970s and 1980s advanced pastoralism and led to original and highly valued systems, continuous reassessment of approaches to pastoral practices is crucial to ensure their sustainability amid current challenges. This is true in France, but also in other agricultural systems around the world (Perley 2021). Whatever the odds, confirming the importance of pastoral resources in quality signs and helping producers through their present hardship is therefore essential if the sustainability of Mediterranean pastoral livestock farming systems is to be addressed in the long term.

Meeting global food demand sustainably: Insights from Uruguay´s Campos Ecosystem in South America

Ayala, W; Pereyra[1], F; Rovira, P; Savian, J

National Institute of Agricultural Research of Uruguay (INIA Uruguay), Ruta 8 km 282, Treinta y Tres, Uruguay, CP 33000; [1]PhD student until October 2024, UdelaR, Uruguay

Key words: Grasslands; livestock systems; agri-environmental platform; feed efficiency

Abstract

The Campos ecosystem is in central-eastern Argentina, southern Brazil and Uruguay. It is described as one of the largest areas of native grasslands in temperate-subtropical environments. However, it faces challenges as a food supplier in an increased global food demand. The main threats are the reduction in the area due to competition with cash crops and forestry and climate change effects. Uruguay produces food for 30×10^6 people representing 10 times its own population. Native grasslands are the main feed source for livestock in extensive ecosystems and complement intensive pastures in crop-livestock systems. In this scenario, INIA Uruguay has been evaluating different levels of land use intensification to quantify productive, economic and environmental impacts through a series of long-term experiments (LTE). In a three-year period, four systems were tested, contrasting different levels of intensification in land use combined with different strategies for beef cattle rearing and finishing. Feeding resources included a combination of improved pastures, native grasslands and supplements. The objective of this contribution is to describe productive potential in herbage, crops and livestock production, and identify tools and key results to improve sustainable management practices in terms of achieving 400 kg LW/ha/year. Data obtained showed differences in the productivity obtained in the livestock and agriculture phases. The adjustment of management practices will provide tools to improve productivity and efficiency, minimize risks and identify mitigation and adaptation approaches to sustain future world food demands. Also, science-based information generated by LTE contributes to assisting public policy decision-makers and risk managers aligned to international commitments agreed by Uruguay in relation to the climate change agenda.

Introduction

The grasslands of Rio de la Plata region cover 76 Mha (Soriano et al. 1992), including the Campos ecosystem (approximately 65% of the area), an area that is declining over time (Carvalho et al., 2021), by agriculture and afforestation interventions. The main economic activity in this region is the extensive livestock production based on the use of native grasslands. In Uruguay, the extensive livestock production occupies 10 Mha of productive area. Cattle introduction in Uruguay dates to 1611, when the Spanish colonizer Hernandarias delivered the first herd of cattle (Barrios 2011). After 400 years of intervention, the ecosystem is still recognized for its potential as a food producer, maintaining a high biodiversity of plants, birds and mammals (Bilenca and Miñarro 2004). Because of climate change, the variability in precipitation and frequency of extreme dry and wet events is reported, as well as long-term warming in this region (Malhi et al., 2020). To attend to the increase in food demand, the redesign of systems should include practices focusing on enhancing productivity, animal welfare, system resilience and mitigation of vulnerability, soil health, including carbon sequestration, and reduction of greenhouse gas emissions through management practices (Jaurena et al. 2021).

In 2018, INIA Uruguay developed an agri-environmental platform, including seven long-term experiments (LTE) on the country's main production systems (Leoni et al. 2024). In the eastern region there are three LTE: a) "Sustainable intensification of rice rotations", located in the Paso de la Laguna Experimental Unit of INIA Treinta y Tres since 2012; b) "Extensive sheep production systems on native grasslands, since 2021, and c) "Sustainable intensification of livestock-agricultural systems" since 1995, b and c placed in the Palo a Pique Experimental Unit of INIA Treinta y Tres. The LTE are being designed to respond to problems in current and future scenarios and understand processes and cause-effect relationships. They help assess the impacts of climate variability and management practices on animals, herbage biomass, crop productivity, species diversity, availability of soil resources, quality of water, environmental footprints, and economic outcomes, among other factors. The LTE constitute an efficient research platform for researchers, producers and public policy makers (Leoni et al. 2024). The objective of this paper is to report information about herbage, crop and animal productivity from the LTE nominated as "c": Sustainable intensification of livestock-agricultural systems". This LTE compares four pasture-crop rotation systems with different degrees of land-use intensification during the 2019 – 2022 period for rearing and/or fattening processes in cattle (Pereyra et al. 2022) and identify key decisions to improve systems management.

Methods

A long-term pasture-crop experiment was installed under no-tillage in Palo a Pique experimental unit of INIA Uruguay (S33° 15´ 54´´, W54° 29´28´) in 1995 (Terra and García-Prechak 2001) and reoriented by Rovira et al. (2019). Four rotation systems with different sequences of pastures and crops are being compared (Table 1) and grazed by different beef cattle categories with the general purpose of producing 400 kg/ha/year of liveweight (LW). The experiment lacks synchronic replications, but all phases of the rotations are present each year, including an area of native grasslands in each system, in an area of 150 has. Paddocks varied from 3 to 6 has each.

Table 1. Cropping and pasture sequences of the 4 pasture–crop rotations evaluated (Pereyra et al. 2022).

Rotation	Purpose	Year of rotation					
		Year 1	Year 2	Year 3	Year 4	Year 5	Year 6
CC	Crop/hay	Oat/Sorghum	Black oat/ Soybean	Wheat/Sorghum			
	Grazing	Oat/Sorghum	Ryegrass/Setaria				
SR	Crop /hay	Idem CC	Wheat + P1	P2			
	Grazing	Idem CC	P1	P2			
LR	Crop/hay	Idem CC, SR	Wheat + P1	P2	P3	P4	
	Grazing	Idem CC, SR	P1	P2	P3	P4	
FR	Grazing	Fescue	Fescue	Fescue	Fescue	Fescue	Fescue

P: pasture, followed by pasture age (i.e., P2: second-year pasture). All pastures, including those following the grain/hay crop phase, were available for grazing. Rotation CC: Continuous cropping; SR: Short rotation; LR: Long rotation, and FR: Forage rotation.

The livestock strategy in each system is the following (Pereyra et al. 2022):

a) In the continuous cropping (CC) rotation, rearing calves (180 to 370 kg/an in 12 months), grazing based on a combination of cool and warm annual grasses (oat or ryegrass – sorghum or *Setaria itálica*) plus a native grasslands pasture (33%).

b) In the long rotation (LR), the rearing and finishing of steers (180 to 530 kg/an in 18 months), grazing strategy based on a combination of *Festuca arundinacea*, *Lotus corniculatus* and *Trifolium repens* mixture during 4 years plus a native grasslands pasture (33%).
c) In the short rotation (SR), rearing heifers (150 to 330 kg/an in 12 months) and fattening cows (450 to 520 kg/an in 5 months), grazing strategy based on *Trifolium pratense* and *Holcus lanatus* and/or *Lolium multiflorum* mixture during two years and an oversown pasture of *Festuca arundinacea*, *Lotus corniculatus* and *Trifolium repens* renewed each five years with the same mixture plus a native grasslands pasture (29%).
d) In the forage rotation (FR), finishing steers (260 to 480 kg/an in 12-15 months), grazing strategy based on a pure *Festuca arundinacea* as a permanent pasture plus a native grasslands pasture (26%).

The native grassland is composed mainly of *Paspalum notatum, Axonopus affinis, Cyperus spp., Coelorhachis selloana, Paspalum dilatatum, Stenotaphrum secundatum, Panicum milioides, Cynodon* dactylon, *Setaria geniculata* and *Axonopus argentinus* (Ayala et al. 1993).

Determinations included pasture growth and botanical composition measured once a month in quadrats of 20×50 cm each in 3 exclosure cages per paddock (adapted from Lynch 1947). Pre- and post-grazing biomass was estimated cutting 6 quadrats per paddock (20x50 cm each). Crop production was evaluated at the end of each growing season. Animal LW, stocking rate, heat stress index, water balance and forage utilization were measured once a month.

Results

Climatic conditions determined a deficit in water balance (356 mm/year, on average). Maximum temperature was 41.4°C and the minimum temperature was −5.1°C, with a marked seasonal pattern. Heat stress index was 62.1±8.3, on average, with a maximum of 81 and a minimum of 41, identifying 6.1% of days with medium heat-stress conditions.

The herbage production showed yields of 5.6±4.2 and 6.0±4.5 t DM/ha/yr for native and oversown pastures. The spring deferment applied contributed to increased biomass accumulation. Short-term pastures (2-yr) produced 8.5±6.3 t DM/ha/yr, 16% higher than the results obtained with long-term pastures (4-yr). Cool annual pastures differ in biomass accumulation being annual ryegrass superior over oat (5.0±1.2 and 2.7±2.1 t DM/ha/yr, respectively). Warm annual pasture like Sorghum and *Setaria itálica* have the potential to contribute with 13 and 7 t DM/ha/yr, respectively.

The feed options available in each system are presented in Table 2. Pasture production differs between FR and CC systems, with pasture levels in the CC system being 25% lower than those in the FR system. The LR, SR and CC include legumes in a proportion of 48, 43 and 33% of the total area of the system, respectively. Legume contribution in mixed pastures declines over time, from 39.5 to 4.9% in a four-year pasture in the LR system and from 39.7 to 21.5% in a two-year pasture in the SR system. In CC legume contribution was 8.2%.

Animals received strategic supplementation when pasture was not enough to prevent LW loss, mainly in winter or summer. The utilization of hay was maximum in LR, followed by SR; representing 15 and 12% respectively of the total biomass offered (pasture + hay). The HSGM was an important component, particularly in the LR system. The LW production differed significantly between systems, being greater in CC and SR, compared with LR and FR. The conversion efficiency did not differ significantly between systems ranging between 14.1 to 19.2 kg of feed per kg of LW produced. Rearing categories exhibit greater conversion efficiency than finishing categories.

Forage utilization varied between 50-60%, 55-62% 48-52% and 35-39% for LR, SR, CC and FR, respectively. Mean stocking rate was 614, 600, 575 and 498 kg LW/ha/yr for CC, SR, LR and FR, respectively (Pereyra et al. 2022).

Table 2: Level and type of pasture, supplements, production and efficiency in each system in 'Palo a Pique' long-term experiment in Treinta y Tres, Uruguay (three-year average), adapted from Pereyra et al. (2022).

System	Feeding options (DM, kg/ha/year)					Production	Efficiency
	Pasture	Hay[1]	PC[2]	HSMG[3]	BR[4]	LW (kg/ha/yr)	(kg feed/kg LW)
Continuos Cropping	5206 b	256	21	122	0	426 a	14.1
Short Rotation	5763 a	790	12	169	0	418 a	15.1
Long Rotation	5399 ab	940	20	616	63	369 b	16.1
Forage Rotation	6867 a	138	0	23	166	310 c	19.2
p-value	0.039	--	--	--	--	0.003	ns

[1] Hay: 6.7% crude protein (CP), metabolizable energy (ME): 5.8 MJ/kg DM; [2] Protein concentrate (PC): 46.5% CP, ME = 10.5 MJ/kg DM; [3] High moisture sorghum grain (HMSG): 8.1% CP, ME: 12.6 MJ/kg DM; [4] Balanced ration (BR): 14% CP, ME: 11.7 MJ/kg DM

The range of productivity of different crops varied between 1.20-2.43, 4.12-6.79, 2.20-3.02, and 0.76-4.02 t/ha/yr for Oat, Sorghum, Soybean and Wheat, respectively (Pereyra et al. 2022). In 2021-2022, oat, sorghum and wheat did not produce grain. In the CC system, crops produced less than those that rotate with perennial pastures (SR, LR), being 23, 9 and 16% lower in the years 2019-2020 and 2020-2021 for wheat, sorghum and soybean, respectively.

Implications and Conclusions

The effects of climate determined variations in the availability of feed resources, demanding the use of supplements to minimize animal LW losses. Native grasslands based on their resilience to stress factors played a strategic role in each system. Match feed demand and supply is a crucial process, requiring to be monitored and introduce stocking rate adjustments. From the animal perspective, the occurrence of heat stress conditions demands special solutions to minimize effects. The synergies between agriculture and livestock production provide low-cost solutions.

The objective of achieving 400 kg LW/ha/year was reached by two of the four systems evaluated (Continuous Cropping and Short Rotation). These systems included the highest proportion of rearing stock with a trend to have the best conversion efficiency rates. Systems that include a pasture phase (Short Rotation and Long Rotation) tend to show high crop production. From the results, there are opportunities to improve efficiency in the different systems tested.

Identifying the appropriate spatial and temporal scales to address sustainable management of drylands: a US Tribal lands case study

Washington-Allen, RA[1]; White, CD[1]; Gilbert, W[1]; Emanuel, RE[2]; Louhaichi, M[3]

[1] Dept. of Agriculture, Veterinary, and Rangeland Sciences, University of Nevada-Reno, Reno, Nevada, USA; [2] Nicholas School of the Environment, Duke University, Durham, North Carolina, USA; [3] International Center for Agricultural Research in the Dry Areas (ICARDA), Tunis, Tunisia …

Keywords: Aridity Index (AI), Ecological Resilience, Native Americans, Vulnerability Assessment

Abstract

There are 234 indigenous tribes within 225,365 km^2 of tribally managed drylands within the conterminous United States of America (USA). A national report on the carbon dynamics of US Tribal drylands argued that a knowledge gap existed for these dynamics in drylands because data, publications, and research were nonexistent. However, carbon stocks of Tribal lands have been implicitly studied, and a few explicit studies have used poor experimental design to produce questionable results. We explicitly address the carbon dynamics knowledge gap by defining Tribal dryland extent using the aridity index (AI) and a time series of Moderate Resolution Imaging Spectroradiometer (MODIS) 250-m pixel resolution net primary productivity or NPPM250, g C m-2 yr-1 from 2001 to 2019 of US drylands. We compared the 19-year mean NPP of the rangeland and cropland land uses within the tribal, public, and private land ownerships within their shared ecoregions. We compared the ecological resilience of tribal and non-tribal rangeland's NPP in response to the 2002 global change-type drought. We mapped aridity thresholds associated with land degradation and used the thresholds to identify tribal lands vulnerable to increasing aridity. We conducted these analyses at multiple scales using open-source GIS software, including Google Earth Engine (GEE) and QGIS. We found that Tribal rangeland and cropland land uses had greater productivity than non-tribal drylands. We found that Tribal rangelands had greater ecological resilience in the face of a global change-type drought than non-tribal drylands. However, we also found that with increasing aridity, 86% of the Tribal land area exhibits potential vulnerabilities that include declines in food security, species richness, canopy cover, productivity, and soil fertility. These potential vulnerabilities suggest the need for complementary field and remote sensing studies to determine the integrity of these predictions.

Introduction

Drylands are defined as the 30-year mean aridity index (AI) (1970 – 2000) = mean annual precipitation (MAP) / mean annual potential evapotranspiration (MAPET, Zomer et al. 2022). Carbon dynamics in Drylands are a large source of uncertainty in global carbon budgets that have estimated US dryland carbon sinks at 0.13 Pg C yr^{-1} (Houghton et al. 1999). Drylands within the conterminous US support 234 federally recognized Tribal Nations, including 25 Tribes that are partially within and 209 that are fully within drylands. Herein, we address two propositions of carbon dynamics in Tribally controlled drylands of the United States:

- Proposition 1 (P1): a key finding of the US Global Change Research Program in the US Second State of Carbon Cycle Report stated that "... scientific data and peer-reviewed publications that pertain to carbon stocks and fluxes on Indigenous (native) lands in North America are virtually nonexistent, which makes establishing accurate baselines for carbon cycle processes problematic." (McCarthy et al. 2018).
- Proposition 2 (P2): A study by Robinson et al. (2019) addressed P1's concerns by comparing the NPP of Tribal, Private, and Public land ownerships within US drylands and concluded that privately owned land was more than twice as productive as Tribal and Public lands and thus the most sustainable type of land ownership A re-analysis of this study's ecoregion X land ownership stratification found that the productivity of Tribal lands was comparable to privately owned lands and had greater NPP than public lands (Washington-Allen and Emanuel 2020).. However, land ownership is neither a valid experimental unit nor treatment as it lacks uniform and low variance at the landscape spatial scale, and it has no agency. Public lands in US drylands are managed by multiple federal agencies and contain multiple land uses, including cropping, mining, forestry, commercial grazing, and conservation reserves, e.g., national parks. Consequently, the experimental unit should be the intersection of land ownership with individual land-uses, e.g., rangeland and cropland by ecoregions. These experimental units will have low variability and be highly homogenous.

Methods

Comparison of Land Use across Ownerships

We assembled a GIS database of publicly available datasets that included the Protected Areas Database of the U.S. that provides polygons with public, private, and tribal attributes of land ownership. The Global Aridity Index provides aridity index values as means throughout 1970 to 2000. The National Land Cover Database (NLCD) provides land use and land cover across the USA between 2001 and 2016. We addressed P1 by acquiring and intersecting with the previously mentioned GIS datasets, the 250-m pixel resolution Moderate Resolution Imaging Spectroradiometer (MODIS)-derived NPP_{M250} dataset from 2001-2019 (Robinson et al. 2018). This dataset explicitly shows annual carbon uptake from photosynthesis in g C m^{-2} yr^{-1} on Tribal lands at local to global spatial scales.

We addressed P2 by following a recommendation by (McCarthy et al. 2018) to conduct estimates of carbon cycle impacts on tribal lands by comparing **with practices on similar non-tribal lands, i.e., we stratified land ownership by ecoregions and land use.** We followed the procedures by Robinson et al. (2019), but rather than comparing land ownerships, we compared the NPP of the rangeland and cropland land uses within the three land ownerships using the Nattional Land Cover Database's (NLCD) discrete time series. We show the result for the rangelands land use that composed 40 of 55 shared ecoregions (Fig. 1). The cropland's land use was composed of 33 of 56 shared ecoregions.

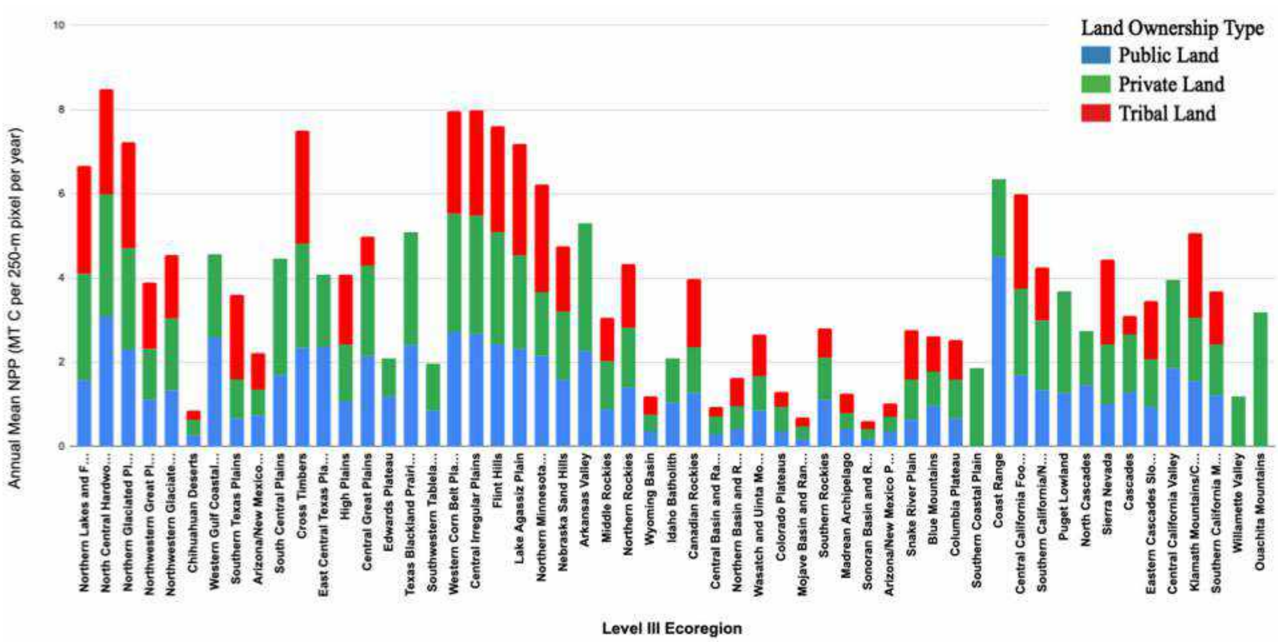

Figure 1. Comparison of NPP for three land ownerships that were stratified by EPA ecoregions and treated by the rangeland land use., i.e., grazing by commercial livestock.

Ecological Resilience

Ecological resilience is the pace, pattern, and recovery of an ecosystem in response to disturbance(s). It can be quantified in terms of amplitude, which is the threshold or magnitude of change in an ecosystem attribute, e.g., NPP over time in response to a disturbance, using a remotely sensed vegetation index change detection method. For example, in equation (1) below we calculate amplitude (the subscript A) using the 2001 MODIS $NPP_{\mathbf{M250}}$ versus the 2002 MODIS $NPP_{\mathbf{M250}}$ (the subscript D):

$$|\Delta NPP_{ijA}| = NPP_{ijR}\,(2001) - NPP_{ijD}\,(2002) + c \qquad \textbf{(1)}$$

The 2002 US drought was labeled a global change-type drought, because it led to major tree die-offs across the southwestern US (Breshears et al. 2005). The 2001 and subsequent scenes are the year before a disturbance or the reference year (the subscript R), and c is the error of uncertainty in the registration of scenes. The results of this change detection are that critical vegetation resources that “do not change” or are “increasing” in the face of drought or other disturbances are located and identified, i.e., the ecologically resilient resources are spatially identified (Washington-Allen et al. 2008).

Vulnerability to increasing Aridity

Berdugo et al. (2020) studied the response of 21 variables to increasing aridity and identified three aridity thresholds (1 – AI) that delineated four system states or phases of decline, including a state we designated “no abrupt changes” (1 – AI < 0.54), a “vegetation decline phase” (aridity threshold: 1 – AI > 0.54) that included two correlated declining variables: the NDVI and photosynthetic activity, the “soil disruption phase” (1 – AI > 0.69) that comprised 12 declining soil attributes such as soil fertility and structure, and a “systemic breakdown phase” (1 – AI > 0.83) that included declines in 7 associated variables including an increase in the variability of rainfall and a reduction in plant cover that leads to increased soil albedo and leaf stress. We assessed the mean AI’s contemporary spatial distribution for these 4 aridity states within U.S. Tribal drylands for 30 years (1970 – 2000) using the time series developed by Zomer et al. (2022),. We used the ‘landscapemetrics’ package in R to determine the patch area of the four aridity states within U.S. Tribal drylands (Hesselbarth et al. 2019, Fig. 2).

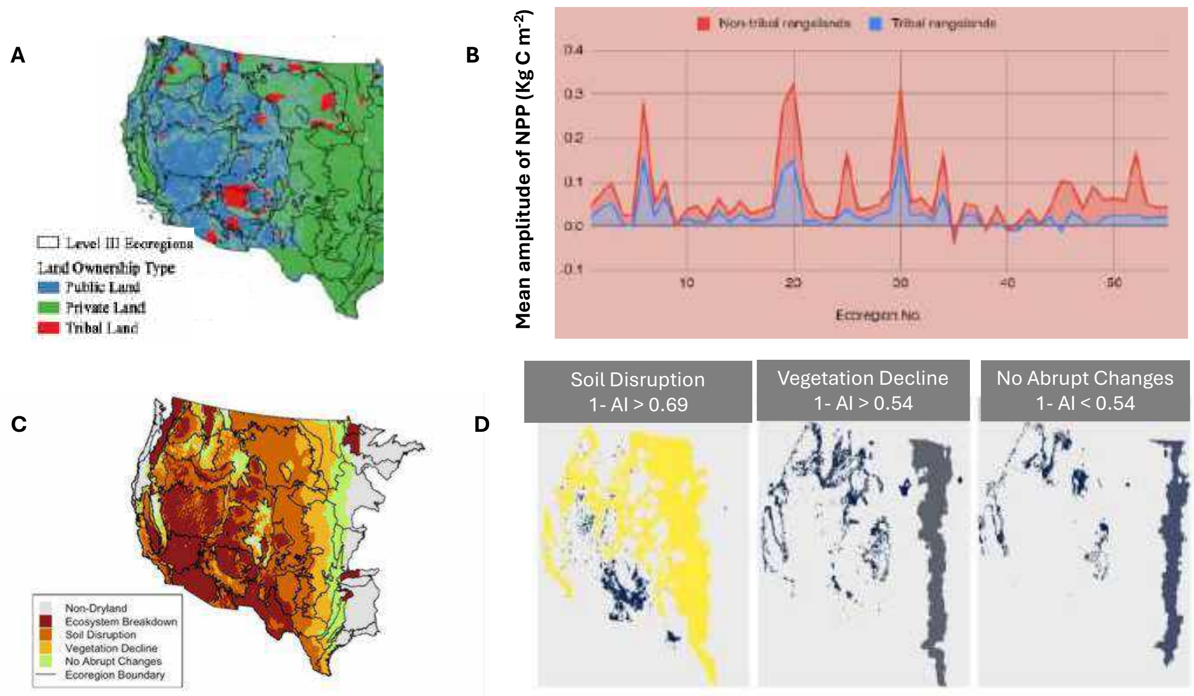

Figure 2. Comparison of the ecological resilience of tribal rangelands (in the red, A) to non-tribal rangelands (green and blue, A) where lower mean amplitude NPP values from 2001 to 2019 indicate greater resilience of tribal lands relative to the 2002 global change type drought (B). Application of the aridity thresholds to current conditions suggests the potential level of vulnerability of tribal land to increasing aridity (C). Green areas in C are stable, with the majority of tribal lands in drylands, spatially trending towards ”systemic breakdown” of 18% of the tribal lands (C).

Results

Comparison of Land Use across Ownerships

We found that the rangeland land use for the 234 Tribes in Drylands had greater productivity in 21 of the 40 shared ecoregions compared to public (4/40), and private (15/40) lands (Fig. 1). We found that the cropland land use had greater productivity in the shared ecoregions (15/33) than public (7/33) and private (11/33) lands.

Ecological Resilience

In the face of the 2002 climate-change drought, Tribal rangelands had greater ecological resilience, when quantified as amplitude, than non-tribal rangelands, i.e., public and private lands (Fig. 2B).

Vulnerability to increasing Aridity

We determined that 1,467,862 ha (14%) of Tribal lands were in the “no abrupt changes” phase (green in Fig. 2C and D) , 2,950,288 ha (29%) were in the vegetation decline state (Fig. 2D), 4,020,931 ha (39%) were in the ‘soil disruption’ state (Fig. 2D), and 1,796,894 ha of tribal lands (18%) were in the highest vulnerability category of “ecosystem breakdown” (Figure 2C).

Conclusions/Implications

We found that across the majority of the shared ecoregions, Tribal rangeland, and cropland land uses had higher productivity than Public and Private drylands and that this productivity made the rangelands more ecologically resilient in the face of a global change-type drought. However, in the face of increasing aridity, 86% of the Tribal land area potentially exhibits threats to livestock and human nutrition and food security, including sharp declines in species richness, canopy cover, productivity, soil fertility, and increases in woody encroachment, and albedo.

These potential vulnerabilities suggest the need for complementary field and remote sensing studies to determine the integrity of these predictions.

Key words: livestock; policy; trade-offs; pastoralists; rangelands

Abstract

The livestock revolution offers significant opportunities to enhance the livelihoods of smallholder farmers in Africa while improving nutrition and food security. In Sub-Saharan Africa, pastoralists play a crucial role in driving this transformation. However, current policies often fail to adequately support pastoralist livelihoods. This paper aims to analyze livestock policies in selected Anglophone and Francophone countries in Africa, examining the extent to which they integrate rangeland management and the interests of pastoralists. The study employs content analysis of livestock policies from 23 countries in Sub-Saharan Africa. Using a set of indicators from the Sustainable Assessment of Food and Agriculture (SAFA) framework of the FAO, the paper analyzes current policy objectives and strategies, and their social, environmental, and economic trade-offs, particularly with respect to pastoralists, rangelands and pastoral livelihoods. The data indicates that while pastoralists and rangeland management are recognized in livestock policies, policies may not always be conducive to pastoral livelihoods. Furthermore, policies that overlook environmental trade-offs could jeopardize pastoralist livelihoods, which heavily depend on natural resources such as water and pastures. Current policies need adjustments to accommodate the needs of pastoralists while fostering livestock growth and development.

Introduction

The livestock sector plays a crucial role in economic growth and development in sub-Saharan Africa. It serves as a source of livelihood for millions of people and fulfils multiple functions within the agricultural landscape (Banda & Tanganyika, 2021; Molina-Flores et al., 2020; Rayne & Aula, 2020). In an effort to harness the benefits of the livestock sector, many countries across the continent have introduced a range of policies. These policies aim to enhance productivity, improve food security, and support the livelihoods of communities dependent on livestock. While these policies hold promise, they often come with trade-offs or unintended consequences, particularly when key dimensions of sustainability are overlooked. Such policies risk being counterproductive if they marginalize certain groups, such as pastoralist communities, or if they exacerbate environmental degradation.

Recognizing these challenges, this study seeks to examine the coherence of livestock development policies with broader sustainability objectives. Specifically, it evaluates how these policies align with the unique needs of pastoralism and pastoralist communities, whose livelihoods depend on sustainable rangeland management and mobility. By identifying gaps and opportunities, this research aims to contribute to more inclusive and sustainable livestock development strategies that support pastoralism as a vital component of agricultural and rural systems.

Methods

The livestock policies were identified using various search engines, including Google, in November 2022. The following search strings were applied: (Country) AND livestock policy; national livestock policy AND (country name); agricultural policy AND (country) OR livestock policy. FAOLEX database, as well as the websites of the respective countries ministries, were explored for supplementary data. Only livestock and agricultural policies were considered for further analysis. Other documents, including bills, acts, and plans were excluded from the analysis. Overall, 23 policy documents were identified (Table 1). For the purpose of this study, only the most recent policies were included. Policies written in French were translated using the Deepl translator.

Table1: Summary of livestock policy documents in Africa

Livestock policy document	Country	Percentage (n=23)
Countries with stand-alone livestock policy documents	Burkina Faso, Mali, Senegal, Ghana, Mauritania, Liberia, Niger, Tanzania, Malawi, Somalia, Kenya, Zambia, South Sudan, Swaziland, Cameroon, Chad	16 (69%)
Countries with livestock policies integrated in overall agricultural policy documents	Benin, The Gambia, Namibia, Nigeria, Rwanda, Uganda, Zimbabwe,	7 (31%)
Total number of countries	23	23 (100%)

From the SAFA (Sustainability Assessment of Food and Agriculture), three main categories of indicators were selected for analysis: environmental indicators (including soil health, water pollution, and animal welfare), governance indicators (including land tenure security, conflict management, and human-livestock-wildlife interactions), and socio-economic indicators (including price stability). These indicators were chosen for their critical importance in assessing the sustainability of rangeland systems. They reflect key dimensions of ecological integrity, social equity, and economic viability, providing a comprehensive framework for evaluating the interplay between resource management, livestock production, and community well-being.

Results

The analysis of livestock policies from a governance perspective highlights key areas of focus and gaps. Land tenure emerges as a prominent priority, with 74% of the 23 policies reviewed addressing it as a critical issue. Conflict and insecurity management also receive considerable attention, featuring in 61% of the policies. However, a significant gap exists in addressing human-livestock-wildlife interactions—an essential element of sustainable rangeland management—appearing in only 9% of the documents.

From an environmental perspective, the findings reveal a stronger emphasis on soil health, with 78% of policies incorporating measures aimed at reducing soil degradation. Yet, other environmental concerns, such as water pollution management and animal welfare, are less frequently addressed. Only 26% and 35% of the policies, respectively, include these major aspects.

The economic dimension, particularly price stability, is also moderately reflected in the policies, with 56% addressing this issue. This suggests a moderate commitment to maintaining stable market conditions for livestock products, which is essential for supporting the sector's sustainability.

Despite the recognition of key sustainability issues, many policies lack clarity regarding their implementation. While 78% of the policies acknowledge soil degradation as a pressing concern, only 56% provide concrete measures to prevent or rehabilitate degraded soils. This inconsistency between policy objectives and actionable steps underscores a broader challenge in translating policy intentions into practical outcomes, especially in the environmental dimension.

Discussion

With 74% of policies prioritizing land tenure, there is a positive implication for pastoralists, as secure land rights are essential for sustaining grazing activities (Basupi et al., 2017). Land tenure security can enhance pastoralists' ability to manage resources, access credit, and invest in their livelihoods. However, without clear implementation strategies, policies may fail to translate into tangible benefits for pastoralists, particularly in areas with complex land ownership systems or competing land uses.

The fact that 61% of policies address conflict and insecurity management is crucial for pastoralist communities, who are often vulnerable to land disputes, resource conflicts, and insecurity in their grazing areas. Effective conflict resolution mechanisms can reduce disruptions to pastoral mobility, enhance community stability, and improve access to grazing lands (Chelang'a & Chesire, 2020). However, the success of these policies hinges on effective implementation and coordination at local levels, which may not always be guaranteed.

The underrepresentation of human-livestock-wildlife interactions (only 9% of policies) is a critical gap, particularly for pastoralists in areas where wildlife conservation and livestock grazing overlap. The absence of policies addressing these interactions can lead to conflicts, such as competition for water and grazing resources, and increased risks of zoonotic diseases (Vicente et al., 2021). As such, the lack of attention to this issue could undermine the sustainability of pastoral systems and negatively impact pastoralist livelihoods. These findings highlight a notable imbalance in policy priorities, suggesting that while governance frameworks largely emphasize land tenure and conflict resolution, they often overlook the complex dynamics between humans, livestock, and wildlife. This gap underscores the need for more integrative policy approaches that account for the ecological and social challenges associated with rangeland ecosystems.

The findings also reveal a disparity in the environmental priorities of livestock policies. While 78% of policies emphasize soil health and aim to reduce soil degradation, there is a mismatch between policy recognition of soil degradation as a major issue and the limited concrete measures provided (only 56% of policies include actionable steps). This discrepancy could lead to insufficient support for pastoralists who rely on healthy rangelands. Moreover, the lack of focus on water pollution management and animal welfare (addressed in only 26% and 35% of policies, respectively) poses additional risks to pastoralists, whose livelihoods depend on clean water sources and humane livestock practices. This uneven focus suggests a need for more comprehensive environmental strategies that balance soil conservation with broader sustainability goals, ensuring the long-term health of rangeland ecosystems and the welfare of livestock.

The moderate attention to price stability in 56% of policies suggests some recognition of the need for stable livestock markets, which are essential for pastoralists to secure fair prices for their products. However, the limited scope of these policies may leave pastoralists vulnerable to market fluctuations and unpredictable prices, affecting their income stability and long-term economic well-being.

Overall, the findings suggest that while livestock policies address several important issues, there is a need for greater coherence and specificity, particularly in the areas of human-livestock-wildlife interactions, environmental management, and practical implementation strategies.

Abstract

This study examines the impact of environmental shocks on livestock supply chains and consumption patterns in West Africa, focusing on three coastal capitals—Dakar (Senegal), Abidjan (Côte d'Ivoire), and Abuja (Nigeria). Using surveys of 4,000 households and 45 focus group discussions, we analyze how socio-demographic factors, such as income and household size, influence meat demand and the price and income elasticity of various types of meat. The findings show that beef and lamb have high price sensitivity, especially among low-income households, while fish is the most consumed protein across all income groups. Environmental shocks, including climate change and land degradation, disrupt supply chains, leading to higher meat prices and altered consumption patterns. The study highlights the importance of sustainable rangeland management practices, such as rotational grazing and agroforestry, to enhance the resilience of livestock systems and ensure food security in the face of these challenges.

Introduction

West Africa region spans arid, semi-arid, and sub-humid zones (Sahara, Sahel, Sudanian), with warm to hot temperatures year-round. It exhibits significant north-south heterogeneity, with rainfall ranging from 200mm to 1200mm annually, concentrated between July and September, influenced by the Inter-Tropical Convergence Zone. Coastal areas experience two rainy seasons: April to July and a shorter one in September-October. Frequent droughts and rising temperatures (1.7°C to 3.2°C) contribute to a 4% decline in annual rainfall, shortening crop and fodder growing periods by an average of 20%. Population growth around rural centres is increasing, but remote areas are declining. The region is home to significant livestock populations, including 25% of Africa's cattle, 33% of sheep, 40% of goats, and 20% of camels. To better understand the dynamics of livestock supply chains, it is crucial to analyze the interaction between rangeland ecosystems, livestock production, demand patterns, food security and value chain performances across the region.

Climate change and anthropogenic shocks can significantly impact livestock products' availability, quality, and safety, potentially leading to higher prices and increased price volatility (Godfray et al., 2018). Temperature fluctuations may also influence consumer preferences, though the specific effects on livestock consumption remain underexplored. Rising production costs and feed availability challenges are expected to increase prices, while supply chain inefficiencies will likely exacerbate price volatility (Muhammad et al., 2017; Mbow et al., 2019).

In addition, climate change is reshaping the socio-economic dynamics of the livestock sector, particularly for small-scale producers who are especially vulnerable (Hallegatte & Rozenberg, 2017). These changes are influencing both consumption patterns and the structure of the livestock industry, with significant implications for global and regional food security (Hasegawa et al., 2018; Amin et al., 2023) and growing awareness of climate change’s impact on livestock challenges the sector’s social license. However, the limited research on the evolution of meat demand and consumption in West Africa hinders a comprehensive understanding of how climate-related shocks could diffuse across the region’s highly concentrated and coordinated livestock supply and value chain. Therefore, complex ecological, economic, and socio-demographic factors shape the relationship between environmental shocks to rangelands and regional supply chains in West Africa. Understanding these interconnections is critical for ensuring the region's sustainable livestock systems and food security. To accomplish this, we must refine our understanding of the demand for and consumption of meat, which remains a prominent under-explored aspect in West Africa.

This paper bridges the knowledge gap by comprehensively understanding the dynamics of the demand for and consumption of meat in three West African coastal capitals: Dakar (Senegal), Abidjan (Côte d'Ivoire), and Abuja (Nigeria). It further explores how improved rangeland management, within a context of multi-dimensional shocks, could help secure the livestock supply chain and improve the livelihoods of millions across West Africa.

Method

This paper builds on the comprehensive literature review conducted by Godde et al. (2021) and the survey developed by Amin et al. (2023) on the impacts of climate change on livestock supply chains. Then, it addresses the missing link in the analysis of consumption nodes, especially for West Africa. Our approach combines quantitative and qualitative methods to analyze meat consumption and demand trends across Senegal, Nigeria, and Côte d'Ivoire. It explores perceptions of meat quality and attributes and the influence of sociodemographic factors (e.g., household size, age and gender of head, and location) on demand. The quantitative analysis uses the Almost Ideal Demand System (AIDS) model to examine family structure effects on meat consumption based on surveys of 4,000 households. Qualitative data were collected through 15 focus group discussions in each capital. Both surveys were conducted between July and September 2023.

Results

In Senegal, meat consumption varies significantly based on income, price sensitivity, and sociodemographic factors. Fish is the primary source of animal protein, followed by chicken and beef. Goat and pork consumption remains low, influenced by geographic and religious factors, particularly Islam's prohibition on pork. A baseline demand exists for beef, lamb, goat, chicken, and fish, largely unaffected by changes in income or price. Key sociodemographic factors include household size, which minimally impacts meat demand, except for eggs. Gender notably influences lamb consumption, especially during religious events like Aïd-el-Adha, when male heads of household typically purchase a ram for sacrifice. Geographic location also impacts regional consumption patterns, with certain areas displaying mimetic effects in demand for beef, lamb, goat, chicken, and fish.

The income elasticity of demand is positive for all meats. Among low-income households (average monthly income: 244,025 FCFA), demand for all meats is positively elastic, though beef and eggs exhibit inelastic demand when prices rise. Lamb, chicken, and fish show higher elasticity, responding more sensitively to price changes. For high-income households (average monthly income: 861,946 FCFA), income elasticity is generally more significant, particularly for beef (elasticity >1), indicating a higher responsiveness to income increases. Price elasticity is negative across all meats, with beef and lamb displaying significant reductions in demand with price increases. For instance, a 1% increase in beef prices leads to a 2.7% decrease in demand, and a 1% rise in lamb prices results in a 3.6% reduction in demand.

In Côte d'Ivoire, fish dominates meat consumption (98% of households), followed by beef (92%), eggs (73%), and lamb (43%). Pork (32%) and goat (7%) are less commonly consumed, with a marked decline in wild meat consumption due to diseases such as Ebola and COVID-19. Consumption patterns vary significantly with income. Beef, chicken, goat, and fish are consumed equally across income groups, while pork consumption is higher in low-income households (36%) compared to high-income households (23%). Lamb is primarily consumed by high-income households (60%), with lower consumption in intermediate (40%) and low-income (36%) groups. Egg consumption is notable across all income groups, ranging from 67% to 75%. Weekly meat consumption averages in Côte d'Ivoire are as follows: fish (1.5 kg in low-income, 2.1 kg in intermediate, 2.4 kg in high-income households), beef (1.1 kg in low-income, 1.8 kg in intermediate, 2.2 kg in high-income households), chicken (0.8 kg in low-income, 1.0 kg in intermediate, 1.5 kg in high-income households), goat (0.008 kg across all households), and lamb (0.8 kg in high-income households). Elasticity analyses show that all meats, except eggs, exhibit positive income elasticity, meaning demand increases with income. A 1% rise in income results in a 0.1% increase in beef demand and a 2.9% rise in lamb demand. Most meats show negative price elasticity, with lamb and pork being more price-sensitive than beef and fish. Cross-elasticities indicate that lamb and pork serve as substitutes for beef.

In Nigeria, fish, beef, and goat meat are the primary meats consumed. Fish is consumed by 87% of households, beef by 78%, goat meat by 67%, chicken by 64%, and eggs by 52%. Sheep and pork have relatively low consumption rates (29% and 8%, respectively), and bushmeat consumption has diminished due to bans associated with zoonotic diseases like Ebola and COVID-19. Beef is the most consumed meat, with an average weekly intake of 1.1 kg, followed by fish (0.8 kg) and chicken (0.7 kg). Pork is consumed the least, averaging just 0.2 kg. Among income groups, beef remains the dominant meat choice in low- and middle-income households, while fish and chicken are more commonly consumed in high-income households. Household size has a marginal impact on the demand for lamb, fish, and eggs but does not significantly influence the demand for beef, goat, pork, or chicken. Larger households tend to substitute lamb and eggs with more accessible fish, while beef, goat, pork, and chicken consumption remains stable. Gender influences pork demand but does not significantly affect other meats. Regarding price and income elasticity, all income elasticities are positive, except for beef. A 1% increase in income results in a 0.9% decrease in beef demand, while demand for lamb (2.3%), goat (0.4%), chicken (1.3%), pork (2.6%), fish (1.2%), and eggs (1.8%) increases. Price elasticities are negative for all meats, with pork, goat, chicken, and eggs showing higher price sensitivity than beef and fish.

Discussion

Rangelands in West Africa are vital for livestock production, forage and water, and livestock supply and value chain. However, environmental shocks degrade these ecosystems, including climate change, overgrazing, and land-use change. Climate change, marked by irregular rainfall and rising temperatures, accelerates land degradation and reduces grazing resources, directly affecting livestock productivity. Overgrazing leads to soil erosion, reduced biodiversity, and decreased land fertility, further limiting the capacity of rangelands to support livestock. Additionally, agricultural expansion and urbanization reduce available grazing areas, heightening competition for land and disrupting pastoral mobility.

Shocks to rangelands disrupt livestock supply chains by reducing herd sizes and meat production. This may lead to supply shortages and price increases across markets. Price elasticity studies indicate that a 1% rise in beef prices results in a 2.7% drop in demand, particularly impacting low-income households. Livestock trade flow across borders, especially between Sahelian and Coastal regions, is disrupted, increasing reliance on imports. If Sahelian supply sources are depleted due to multiple shocks, they may be substituted by imports from Latin America, Europe, or alternative protein sources.

Income levels, cultural preferences, and gender roles influence consumption patterns in West Africa. Price increases during supply shocks can lead wealthier consumers to reduce meat consumption or switch to cheaper proteins, while poorer households face more immediate nutritional deficits. Cultural preferences, such as the demand for specific meats during festivals, can also shift when certain types of beef become scarce.

Conclusion

The potential impacts of climate change on global livestock systems are a growing concern. Still, they are often underrepresented in major climate assessments like those by the Intergovernmental Panel on Climate Change (IPCC). This article explores how multifaceted shocks—climate change acting as both a direct and compounding factor—interact with rangelands along the land-based livestock supply chain, from production to consumption. Although quantifying the net impacts remains challenging, there is strong evidence that climate change will disrupt critical stages of the livestock supply chain, especially at consumption nodes. The study fills the knowledge gaps and underscores the importance of sustainable rangeland management practices, such as rotational grazing and agroecological practices, in enhancing livestock system resilience, supply and value chain performances, and ensuring regional food security.

Acknowledgments

CILSS, through the World Bank-funded Regional Sahel Pastoralism Support Project, offered financial backing for this study, ensuring sustained and comprehensive support.

Nurturing sustainability through pastoral livelihoods in Kashmir Valley

Mohapatra, SS

Member, Regional IYRP Support Group (RISG) South Asia, Jammu, UT of Jammu & Kashmir, India

ABSTRACT:
The Gujjars and Bakarwals form the third largest ethnicity in the Union Territory of Jammu and Kashmir in India. Gujjars rear large ruminants such as cows and buffaloes, whereas Bakarwals are goat and sheep herdsmen. The Chopans are semi-nomads involved in traditional sheep rearing for meat and wool in the Kashmir valley. The 2030 Agenda for Sustainable Development provides the 17 Sustainable Development Goals (SDGs), that recognize the need for action on climate change to preserve the environment while sustaining the livelihood of the vulnerable, migrating, and nomadic communities. Milk is a priceless commodity for those people involved in transhumance and pastoralism. Good market linkage for meat, milk, butter, and wool through application of modern innovations is necessary. It is high time that the contribution of pastoralism to the national economy by the custodians of livestock in the unpredictable mountain ecology of Jammu & Kashmir is recognized.

Introduction
The union territory of Jammu and Kashmir is an abode inthe Himalayan mountains with widespread and abundant natural resources. Production of fruits, spices, flowers, dry fruits, wool, and cold fish is high in the region. Jammu & Kashmir in India has the world's largest transhumant population with 612,000 in number. With the Kashmiris and Dogras forming most of the population in this region of the Himalayan valley, the Gujjars and Bakarwals form the third largest ethnicity in the region. Gujjars rear large ruminants such as cows and buffaloes, whereas Bakarwals are goat and sheep herdsmen. The Chopans are semi-nomads who are involved in the traditional rearing of sheep for meat and wool in Kashmir. The 2030 Agenda for Sustainable Development provides the 17 Sustainable Development Goals (SDGs), that recognize the need for action on climate change to preserve the environment while sustaining the livelihood of the vulnerable, migrating, and nomadic communities. The pastoralists of Jammu & Kashmir who largely migrate every year need to be inclusive, safe, resilient, and have sustainable livelihoods and communities.

Milk production in Jammu & Kashmir
In the agrarian economy of the union territory, the value of the milk economy in Jammu & Kashmir is Rs 90.8 billion AUD$163 million). The annual milk production of Jammu & Kashmir is 2.5 million tonnes. Though 95% of the milk distribution in this region is still in unorganized areas, the concerned authorities and stakeholders are trying their best to push Jammu & Kashmir to be part of the 'white revolution' (making India self-sufficient in milk production) in a sustainable manner. Pastoralists have a huge contribution to make in this regard. Though they have contributed least to climate change, they are suffering the most from its deleterious effects. Despite the impacts of climate change, the average annual milk productivity per cow is planned to rise from 2,380 to 4,300 litres by the year 2027.

Challenges facing pastoralism in Kashmir Valley

The Gujjar and Bakarwal pastoralists live in the scattered valleys and alpine meadows of Jammu & Kashmir. A paucity of water resources and green pastures/fodder during winters for livestock in the Upper Himalayas compels them to move towards the Jammu province while rearing small ruminants like sheep and goats. Most of them are engaged in rearing goats, sheep, cattle and buffalo. They sell milk in the local market to earn their livelihood. With continuous movement, the unacceptance of milk in the nearest milk cooperative at the village level has led to the exploitation of herdsmen by private dairies. Lack of access to a reliable market value chain and logistics, and varying demand and supply of such milk, milk products, manure, hair and wool and woollen products prevents them from selling their products at a good price. Insufficient resources for skill development and training of these tribal pastoralists in the valley have made them choose pastoralism as a source of livelihood for generations. Finally, due to such biannual transhumance, there is reluctance by the government authorities to provide them grants in the long term.

Gujjars – the cow and buffalo keepers

Gujjar is an ethnic pastoral community of India, Pakistan, and Afghanistan. The community has a strong presence in the Union Territory of Jammu & Kashmir. Gujjars are mostly settled at the lower slopes and valleys of the Pir-Panjal and the Shivalik hills, where ecological conditions are suitable for their nomadic pastoral economy, especially during winters. The important areas of Gujjars and Bakarwal settlement concentrations in Jammu District are Jandrah, Jahri, Grota, Golad, Charwal, Samoo, Rathi and Bindi and Upper Samba hills. The Gujjars are also highly concentrated in Rajouri and Poonch districts of Jammu province. Gujjars are of three categories - settled, half settled and homeless Gujjars. The settled Gujjars stay at one place and work in agriculture. Half-settled Gujjars are those who, although they live in villages and do agriculture, for six months of summer, they leave for Pir Panjal Gujjar region and move further to Drass and Kargil with their cattle where pastures are available for grazing.

The homeless Gujjars (i.e. no permanent settlement) can be further divided into two tribes- Dodhi/Banjara Gujjars and Bakarwal Gujjars. These people keep buffaloes and lead a nomadic life. In summer, these tribal pastoralists move to the lower areas - Reasi, Udhampur and Kathua in Jammu province and Pathankot and Gurdaspur in Punjab with the buffaloe herds. The Gujjars in Jammu city are spread around Akhnoor Road and Rajpura Mandi. When the summer sets in and the snow starts melting, these people start moving to the heights of the Himalayas where green grass is available sufficiently for their cattle. Gujjars are the milk producers in Jammu region due to the sub-tropical climate. Their staple diet includes dairy products such as milk, curd, cheese, kalari, karan and lassi. They dry cheese in sunlight and then use it in winter. Dahi plays a major customary role in the Gujjar marriage rituals. They sell milk and ghee for their livelihood.

Milk – a priceless commodity for Gujjars

A Gujjar household with milk buffaloes and a son is deemed to be 'illustrious'. Gujjars consider milk a very pious resource and do not let it get wasted. Gujjars honour milk more than respect the elders. Despite the community belief, Fareed Bhai, a Gujjar from Rajpura Mandi Morh, cites the plight and the loss incurred in milk production of 60-70 Gujjar milk producers in the Jammu region. Each family usually has 50-80 buffaloes. He states that 5000 litres of milk are produced every day from 15-20 milch buffaloes owned by each family. Due to the transhumant lifestyle, Gujjar milk producers do not have access to refrigerators and in summer it becomes hard to keep milk without refrigeration for long. It gets spoilt within a few hours. Sometimes the dairy farmers keep ice cubes around the fresh milk or leave milk containers near the canals, where they are living. This leads to theft. With the increasing cost of fodder and green grass for buffaloes, it is tough to manage and rear buffaloes in the present times. With the lack of dairy plants nearby and proper marketing channels, milk processing has become a huge challenge. They are unable to sell milk in the markets at a sufficient price.

The day of a Gujjar milk producer begins with waking up at 4 am, getting milk from buffaloes, collecting all the milk, and mostly keeping the milk near the canal for a few hours for preservation. If the milk fails to reach the markets in Jammu city on time, it is spoilt. This compels the Gujjar milk producers to make kaladi/cheese out of the milk, but at times they throw the milk away in the canals when it is of no use. These dairy farmers prefer to prepare ghee, butter, and kaladi in winter than in summer. Thus, with such continuous struggle, the lives of Gujjar milk producers of Jammu have not improved by much. With a low rate of milk production and delivery and increasing expenditures, making education affordable for their children becomes difficult for the guardians. While the cost of one buffalo purchased locally ranges between Rs 40,000 (AUD$ 720) and Rs 100, 000 (AUD$1,800), the buffalo purchased from Punjab, costs around Rs 200,000 (AUD$3,600) to 300,000 ($5,400) each. These Nili Ravi buffaloes produce 18-20 litres of milk per day, while the local breeds produce only 7-10 litres milk per day. All the family members in a Gujjar family are usually involved in animal rearing and taking buffaloes out for grazing. With none or poor literacy level, Gujjar pastoralists have chosen to work this way since childhood, as they do not do any other work. Sometimes Gujjar milk producers sell their cows and buffaloes to pay to meet the rising demands of fodder. Therefore, the Gujjars are demanding for the revision of milk prices so that can receive a fair price for their milk.

Bakerwals – the sheep and goat herdsmen

Bakarwal Gujjars and homeless Gujjars rear sheep and goats as their main source of livelihood. Bakarwals migrate to high summer pastures in April during summer and return to lower winter pastures in Jammu province with the onset of winter. It takes one and a half months to reach the high pastures in Kashmir province and another one and a half months to return to low-lying pastures in Jammu province. Their stay at one seasonal pasture is around four months. Along with sheep and goats, they take horses to carry loads and Bhakarwal dogs as the guardian of the livestock. Each Bakarwal possesses around 50-150 goats and sheep. The winter season is usually the time of ceremonies, functions, rituals, and marriages resulting in a sharp rise in the demand for chevon and mutton. The Bakarwals sell their goat and sheep to the local traders. Along with this, they also sell the wool of their sheep at the local wool centres. Horses and mules are rented out at construction sites and tourist spots by them to provide fundsfor the purchase of extra feed for their cattle.

Livestock breeds

The cattle and buffalo breeds reared by the pastoralists in Jammu & Kashmir include Hariana and Sahiwal, non-descript Kashmiri cattle, Holstein Friesian, and Nili Ravi buffaloes. Buffaloes migrate from Punjab and are seen more in the Jammu region. Jammu & Kashmir has a diversity of apparel and superior carpet-type wool breeds such as Gaddi, Rampur Bushair, Bakarwal, Poonchi, Karnah, Gurez and Kashmir Merino. The endangered Bakarwal sheep breeds are found in the higher ranges of Pir Panjal mountains, Kashmir valley and low-lying hills of Jammu and Kashmir. The Punchi Bakerwali sheep are now extinct. The goat breeds reared by Bakarwals are Bhakerwal goat, Kilan, Kaghani and Lubdi. These breeds are on the verge of extinction. Adult Bhakerwal goats grow well under low-input systems. Bakarwals value the extinct Yarkandi horses who survive extreme climates, thrive on coarse feed and fodder and travel with them during the seasonal migration to difficult topographies in the Upper Himalayas. Veterinary services are inaccessible to the migratory pastoralists due to tough topography at high reaches. Foot rot is a common ailment seen during seasonal migration. Herbs such as kuth, googal, raimand, ratanjot, kodpa trees, rattibuti, jogipadshah, jatlijadi, hand, hulla, Nera, chora are used to cure the animals. With the efforts of dairy cooperatives in Jammu & Kashmir, there are more than 500 milk cooperatives to provide market access to the dairy farmers of the valley. The sale of milk and wool from browsing goats and grazing sheep through off-farm and producer companies by the Bakarwal youth is very important.

What is needed?

Alternate routes of migration after weather prediction need to be provided by the government and concerned local authorities. Mobile animal husbandry and veterinary units should be established at the village level. Need-based vocational training/ skill development programme is necessary for the youth of this community. Protection of livestock from sudden natural calamities through training in disaster management for the youth is necessary. There is a need to form producer companies for milk, milk products and wool just like Farmer Producer Organisations (FPOs) for apples, and to promote alternative livelihoods through rent, tourism, and handicrafts for the Gujjar, Bakarwal and Chopan pastoral communities in the wake of hostile changing climatic conditions. Basic education to understand instructions on health and animals' treatment and schemes relating to animal husbandry, various policies that can be introduced by the respective state and central governments for their betterment and are also necessary. The youth of the pastoralist community must work along with the guidance of veterinary, agriculture, and livestock officers for herd improvement. Record keeping on the number of herds, cost and returns from investment on improved herding and grazing, and distance covered on seasonal movements needs documentation for covering insurance of the livestock after unruly disasters and man-wildlife conflicts. Good market linkages for meat, milk, butter, and wool by application of modern financial innovations is necessary.

Conclusion

It is high time that the contribution of pastoralism to the national economy by the custodians of the livestock in the unpredictable climatic zones is recognized. Ethnographic studies of pastoralism must be carried out to get valuable insights into the national forest policies and local adaptation strategies. Concepts of transhumance and pastoralism must be incorporated into the curriculum of veterinary science and animal husbandry in India. Therefore, it is important to conserve indigenous livestock breeds, traditional knowledge, and ethno-veterinary practices (EVP) of the rarest and dwindling ethnic pastoralist tribal community of Jammu & Kashmir in India.

Arresting grazing land condition decline in Queensland's northern gulf should be framed around improving business performance

Gobius NR*; English, BH*; Baker, KM*

* Department of Primary Industries, Queensland. Mareeba Qld 4880

Key words: land condition; extension; profitability; nutrition; business principles

Abstract

Monitoring Australia's Northern Gulf region over the past two decades has shown a continuous decline in land condition, reflecting declining capacity to respond to rainfall and produce useful livestock forage. In 2004, 69% of monitored sites had their carrying capacity estimate reduced based on one or more land condition indicators, increasing to 92% in 2023. If grazing pressure and management on the ever-diminishing natural resource base continues as is, the rate of decline in land condition may further escalate.

On-property experience and research results demonstrate the importance of improved land condition, and consequently improved long-term land and animal productivity, profitability, and resilience to climatic variability. Northern beef industry financial performance data confirm business performance is maximised when per animal performance is maximised. But barriers to adoption persist and these must be overcome. Therefore, landholder engagement and extension efforts to improve land condition should focus on improving business performance through maximising per head animal performance while addressing constraints to adoption.

Introduction

The Northern Gulf area of Queensland, Australia covers 19.7 million hectares of native pasture. Rainfall is seasonal and highly variable (500-1200 mm between December to March; CV = 34 to 45%), and extreme weather events (heat waves, floods, seasonal droughts) and fire common (Rolfe et al. 2016). Rainfall variability and strong seasonality (long dry season) are the main drivers of pasture production.

Forage quality is highest during the wet season but declines during the dry season. Low protein concentrations and high stem fractions at the end of summer are normal, so low nutritional quality predominates for most of the year. Pasture growth accounts for 77% of carrying capacity variation across Queensland's soil types, land systems, pasture communities, grazing enterprises and climatic zones (Hall et al. 1998). Such poor pasture quality leads to low average annual cattle liveweight gains (~ of 100 kg $head^{-1}$ $year^{-1}$), weaning rates (~56%), and high female mortalities of between 3 to 9% (Rolfe et al. 2016), and delivers low-income returns to grazing businesses. Many graziers have been caught in a downward spiral of carrying more animals (at ever declining productivity) to maintain the same output (Holmes, 2015; Rolfe et al. 2016). Chasing greater beef production per hectare, rather than per animal unit results in significant financial and environmental cost (O'Reagain, 2011; Walsh and Cowley, 2016).

Land condition decline is relevant across the rangelands in northern Australia, as well as around the world. Shaw et al. (2007) described a significant land condition loss in the Northern Gulf region, and subsequent monitoring in 2012 and 2016 recorded further declines (Shaw pers. comm.). Further monitoring in 2023 determined land condition had worsened.

Cost of Production ($ kg^{-1} LWt^{-1}) has the largest impact on northern Australian beef business profitability (McLean et al. 2023). Operating scale and labour efficiency are important in diluting these costs. However, kg beef AE^{-1}, a function of good reproductive efficiency, low mortality rates and higher turnoff weights, is best for measuring northern Australian beef enterprise productivity. These drive income but are impossible without good animal nutrition. Good nutrition can be either purchased or provided more cheaply by productive pastures under good land management providing better quality feed for much of the year. Less than ideal land condition can be considered potentially profitable but is inherently risky (MacLeod et al. 2004), with the link between good land condition and profitability not always obvious.

Our hypothesis is that Northern Gulf graziers should focus on kg beef produced Animal $Equivalent^{-1}$ (AE = 450 kg steer) output, associated with efforts to improve land condition. However, graziers firstly need to become aware that land condition is declining, and of the profitability-driving key performance indicators (KPI's) to facilitate change. This paper seeks to encourage extension efforts to be framed around the principles of good land condition providing nutrition and seasonal resilience, greater kg beef produced AE^{-1}, as a basis for sustainable profitability.

Methodology

The study comprised two research activities:

Land condition assessment in the Northern Gulf of Queensland

The ABCD framework describes grazing land condition (Chilcott et al. 2003). Pasture composition, soil condition, weed infestation and woodland density are assessed to assign a condition ranking to a land type. 'A' condition describes a land type at 100% of original carrying capacity; 'B' condition 75%; 'C' condition 45% and 'D' condition only 20% of original carrying capacity. Approximately 260 sites around the Northern Gulf region were assessed in 2004, 2012 and 2016 using Shaw's modified rapid land condition assessment methodology (Shaw et al. 2007). Their method relied on the observer having experience in the region to understand the original condition of a particular land type. 112 of the sites were revisited in each of the three years. In 2023, 289 sites were assessed for land condition around the same region using a land condition assessment tool (LCAT) App (Hassett et al. 2021). This tool enables rapid and consistent collection of standardised land condition data, and generates a land condition score immediately, based on the input data. However, LCAT scores are calculated differently to Shaw et al. (2007). Therefore, the 2023 LCAT data for above-mentioned 112 sites were reassessed in a desktop process using the rapid land condition assessment method. Three experienced land condition assessors, who had each been involved in all, or some, of the previous three surveys undertook the reassessment as a group with vigorous discussion. Site photos (usually 4 or 5) and species composition data collected through the LCAT App were used for the reassessment. Consequently, a standardised land condition dataset for the Northern Gulf region that includes site data from 2004, 2012, 2016 and 2023 was created (Gobius and Buchanan, 2024).

Remote sensing (VegMachine (https://vegmachine.net/)) was used to estimate canopy cover change as measured by Persistent Green, that portion of vegetation estimated to not completely senesce within a year, primarily consisting of woody vegetation (trees and shrubs), although occur exceptions occur when herbaceous cover remains green (Beutel et al. 2019).

Collating published evidence of a positive relationship between good land condition, good nutrition, greater kg beef/AE and profitability

Ten studies specifically linking land condition, livestock productivity and profitability were examined (Purvis, 1986; Landsberg et al. 1998; Paton et al. 1999; Smith, 2000; MacLeod et al. 2004; MacLeod et al. 2010; Broad et al., 2011; Walsh and Cowley, 2016; Bowen et al., 2019; and Hall et al. 2020).

Results

Land condition decline in the Northern Gulf

Carrying capacity in the Northern Gulf is estimated to have declined from 74% to 60% of the original since 2004, a 0.75% loss per annum, with pasture composition and timber thickening most responsible for land condition discounts (61% and 54% of sites, respectively). In 2004, 69% of rapid assessments were discounted due to one or more land condition indicators. This increased to 76% of sites discounted in 2012, 91% in 2016, and 92% in 2023. Persistent green woody vegetation levels increased from 13% in 2003 to 22% in 2022.

Collating published evidence of a positive relationship between good land condition, good nutrition, greater kg beef produced/AE and profitability

The key management decisions identified through the literature review leading to improved land condition were:
Good record keeping to objectively measure change in management and productivity over time; reduced stock pressure, safe stocking rates, constrained variable strategies or better matching of stocking rate to carrying capacity; enabling rest and wet season spelling; using fire to manage trees, pasture quality and grazing pattern; timber thickening management; rehabilitation of degraded land and pasture improvement; cross breeding for better productivity; pregnancy testing and culling non-performers; a supplementation program.

The key benefits of improved land condition identified through the literature review were:
Improved land condition and resilience in a variable climate; improved live weight gain and turnoff weights; improved body condition scores and weaning rates; reduced mortalities; reduced steer turnoff age, earlier mating, higher turnoff percentages; no need to reduce stocking rates; less feed shortages, stable animal/herd production and sizes, lower frequency and scale of feeding costs; lower input costs and improved profitability and business resilience in variable years; more sleep and fewer worries; reductions in livestock greenhouse gas emission intensity.

Discussion

The literature evidence, in conjunction with the Australian Beef Report evidence (McLean et al. 2023) that income from profitable enterprises is derived from kg beef produced/AE, suggest that improving land condition in the northern Australian rangelands will increase profitability. The Australian Beef Report identifies that Cost of Production (COP), kg beef produced/AE and operating scale are the main KPI's for northern beef enterprises. When kg beef produced/AE is optimised, COP/AE is diluted, particularly when scale and labour efficiency are maximised. This discredits the common practise of targeting kg beef/ha by increasing stocking rates to combat declining land condition and productivity.

Species composition interacts with seasonal conditions to define animal production potential. Although relationships between liveweight gain per hectare and per animal are well understood (Jones and Sandiland,1974), they are often ignored or misunderstood by graziers. Perennial species contribute most to rangeland animal production on a long-term basis, and when seasonal conditions are near or below the mean. But in certain above average rainfall years (particularly when both rainfall amount and wet season duration are above average), short annual and biennial plant species can significantly augment animal production (Hacker and Tunbridge, 1991) and so create significant inter-annual liveweight variation. This inconsistency in the impact of perennial species can act as a barrier for graziers in clearly understanding the land condition/stocking rate/liveweight gain relationships, as graziers tend to 'anchor' on these 'good' years, making extension messages difficult. While recognizing this potential variation between years, extension effort must focus on making graziers more aware of the overarching and positive relationship between good land condition, appropriate stocking rate, good nutrition, greater kg beef produced/AE and profitability.

Group extension work with graziers serious about achieving financial and environmental sustainability should firstly be about awareness of the degree of land condition loss regionally and on their own properties; understanding the business profit drivers and having a sustained focus on them; and acquiring financial literacy. Consequently, one-on-one extension should: enable managing landscapes using evidence-based knowledge and skills; use Breedcow Herd Budgeting software to model the impact of declining land condition and identify herd management practises that can improve productivity while reducing stocking rates (Bowen et al., 2019); enable management decisions based on both financial and environmental outcomes (Walsh and Holmes, 2023). If grazing pressure and management on the ever-diminishing natural resource base continues as is, the rate of decline in land condition may further escalate. Once land condition declines to ~ 20% of original condition, it is almost impossible to reverse without costly mechanical intervention (MLA, 2024). We are under no illusions of how long land condition recovery might take; it is likely to be slower than the recorded 0.75% per annum loss of retained original carrying capacity. If land condition could be improved at 0.5% of carrying capacity per year, improving from 60% back to 75% retained original carrying capacity (B condition) will be the responsibility of the next generation of land managers. This next generation should be targeted by beef extension officers.

Conclusion

Land condition decline is relevant both across Australia's rangelands and internationally. In the absence of legislative oversight of rangeland condition, solutions are required to arrest this decline. Barriers exist to the adoption of extension messages. Extension must focus on grazier understanding of the decline in land condition, and the link between greater land condition and potential long-term profitability, highlighting management practices that will maintain or improve profitability through improved reproductive efficiency and turnoff weights, and reduced mortality and costs of production, while reducing stocking rates. Decades of warning producers of excessive stocking rates have been ignored. Stocking rates are more important than management systems in determining vegetation change (Hacker and Tunbridge, 1991) and should be closely matched to sustainable use the available pasture supply, providing homegrown feed base quality and quantity. In collaboration with industry, we need to facilitate necessary land management change before further damage to landscapes and livelihoods becomes irreversible.

Sustainable management to reduce grasslands grazing pressure and improve household income in northern China

Rong, Y

College of Grassland Science and Technology, China Agricultural University, Beijing China 100193

Key words: Farm optimized model; household production; lambing time; pen feeding; seasonal grazing.

Abstract

Analyses of the status of current livestock production and alternative management practices for livestock production can help farmers improve their farming systems based on their particular local resources and markets. The farm surveys and parameterization of the models were developed by scientists and farmers working together to evaluate the effects of finances, grassland management, animal management and changes in farm infrastructure. Our study aimed to utilize bioeconomic models to optimize farm and livestock production systems in the agro-pastoral area in northern China. These analyses will hopefully lead to improved incomes, provide workable options for farmers and policy makers to restore grasslands and result in sustainable utilization of China's grassland resources.

To examine possible ways to sustainably manage grassland in the agro-pastoral areas, a formal survey of sheep farmers was conducted, and data from experimental trials were obtained in Hebei Province of northern China. The model of farm management analyzed annual feed supply and demand and showed that the gap of the annual feed supply and demand could be reduced by using improved sheep breeds for meat production instead of current breeds. The model of economy analysis showed that maximal profits could be achieved by using a combination of seasonal grazing at a grazing intensity of 5.4–6 sheep ha^{-1} and pen feeding. In addition, changing lambing time to November would reduce grazing pressure during the summer, which will be beneficial for grassland restoration and enhanced ecosystem services.

By obtaining accurate on-farm information from pastoralists and using these data to parameterize two models, realistic changes in management strategies were identified to increase farm income and reduce grassland grazing pressure. This activity increased public awareness of optimized farm management tools and provided a sound basis for identifying management alternatives for the sustainable management of grassland resources.

Introduction

Traditional livestock management practices in northern China are often based on survival through the year rather than producing goods for a market and running the farm as a business. What happens on these grasslands has important implications for millions of people in this region of China, and also safeguards the northern and the southeast cropland region of China. Analyses of the status of current livestock production and alternative management practices for livestock production can help farmers improve their farming systems based on their particular local resources and markets (Takahashi et al. 2011; Komarek et al. 2012; Zheng et al. 2013). Model analysis of farm production provides a valuable tool for both government officials and farmers to optimize natural resource use for livestock production. Model solutions have been used to try and guide farmers to increase market access and develop quality standards, thereby making livestock production more profitable Parsons et al. 2011; Komarek et al. 2012; Zheng et al. 2013). The objective of our study was to utilize bioeconomic models to optimize farm and livestock production systems in the agro-pastoral area of Fengning County, Hebei Province in northern China. The farming analysis model was developed by scientists and farmers working together in the northern grassland area of China to evaluate the effects of finance, grassland and animal management and farm infrastructural changes (Kemp et al. 2011). The objective of our study was to utilize bioeconomic models to optimize farm and livestock production systems in the agro-pastoral area of Fengning County, Hebei Province in northern China. These analyses will hopefully lead to improved incomes, provide workable options for farmers and policy makers to restore grasslands and result in sustainable utilization of China's grassland resources.

Methods

Data to parameterize the models were obtained from various sources, including farm surveys, published information, expert opinions and field trials (Ma et al. 2014). Several functional relationships between various biological parameters and either grassland condition or livestock condition were derived using experimental trials in the local area (Figure 1).

Data collected from the farm surveys and field trials were used to parameterize two models: StageONE Feed-Balance Analyser Model and StageTWO Optimising Model (Takahashi et al. 2011). The model uses metabolisable energy to link feed supply, demand and utilization. Both models derive net farm livestock financial returns for the starting conditions using biophysical and financial data.

Figure 1 Study location of Fengning County, Hebei Province in northern China.

Results

Current sheep production system in Fengning County

In the southeast portion of the Mongolian Plateau, Hebei fine-wool sheep and small-tail sheep crossed with Mongolian sheep are the dominant livestock. The typical farm averages 5 to 8 ha of land for fodder (typically maize silage, oats, wheat and potatoes), and about 700 ha of grassland is communally used by the village. Lambs are born from January to March and sold at about 8 to 12 months of age, according to the herder's need and market price. Grassland is continuously grazed at a stocking rate of 4.0 sheep ha−1 throughout the year, resulting in very high grazing pressures. Though a few small household farmers feed sheep during winter, energy and nutrient deficiency are typical from late-September to May because of poor forage nutrition and animal management (Figure 2a).

Options for farm improvement using different sheep breeds

In recent years, most farmers switched their focus to meat production due to the favorable mutton market. Farmers prefer small-tail sheep to other varieties because of the high birth rate, though this variety is not good for meat production. Given the poor nutrition of animals during winter and the high cost of purchased fodder, one alternative strategy is to use sheep varieties with good meat production. Some local farmers have crossed local ewes such as small-tail sheep with German Merino rams or Dubo rams for improved meat production. These crosses can increase live-weight gain with grazing during the summer and pen feeding in winter. Data from these new sheep breeds and the pen feeding trial were used to re-run the StageONE Model. The model results showed that the energy gap between maintenance and actual feed intake was narrowed (Figure 2b).

Options for farm improvement by changing lambing time

Results from the StageONE Model showed that lambing in January through March resulted in a sub-maintenance level of energy intake for ewes during most of the year (Figure 3a). Lambing in Jan. would be predicted to result in a major feed deficit from January through April (60% of maintenance). April lambing was closer to the maintenance level during November to February, but resulted in a large feed deficit during March to June (50% of maintenance). Lambing in June enabled an improved feed equivalent during winter and spring; however, intake did not meet maintenance levels during summer grazing in June and July. Lambing in November allowed intake to reach maintenance levels for nearly the entire year. This strategy might be further improved by possibly selling lambs and cull animals earlier (3 to 4 months of age) and by providing good nutrition in feeding pens. By lambing in November, pregnant ewes would have a greater probability of accessing higher quality forage during the summer, resulting in a higher lamb birth weight.

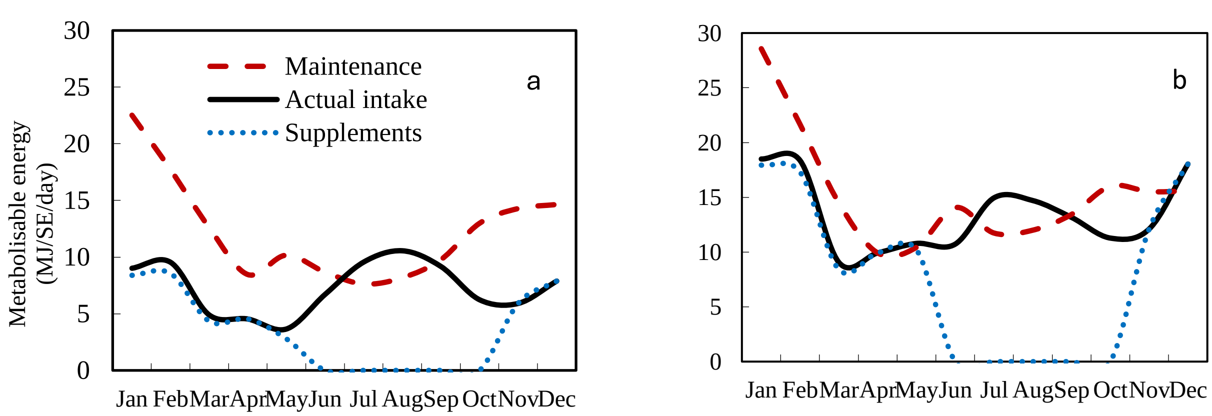

Figure 2 Metabolisable energy (ME) requirement, total ME intake and ME from supplements at the same live-weight per sheep equivalent for a typical farm in Fengning County, Hebei Province: a) current farm production and b) farm production using an improved sheep breed. (Note: Total ME intake is the intake of forage plus supplements. Ewes lambing in January).

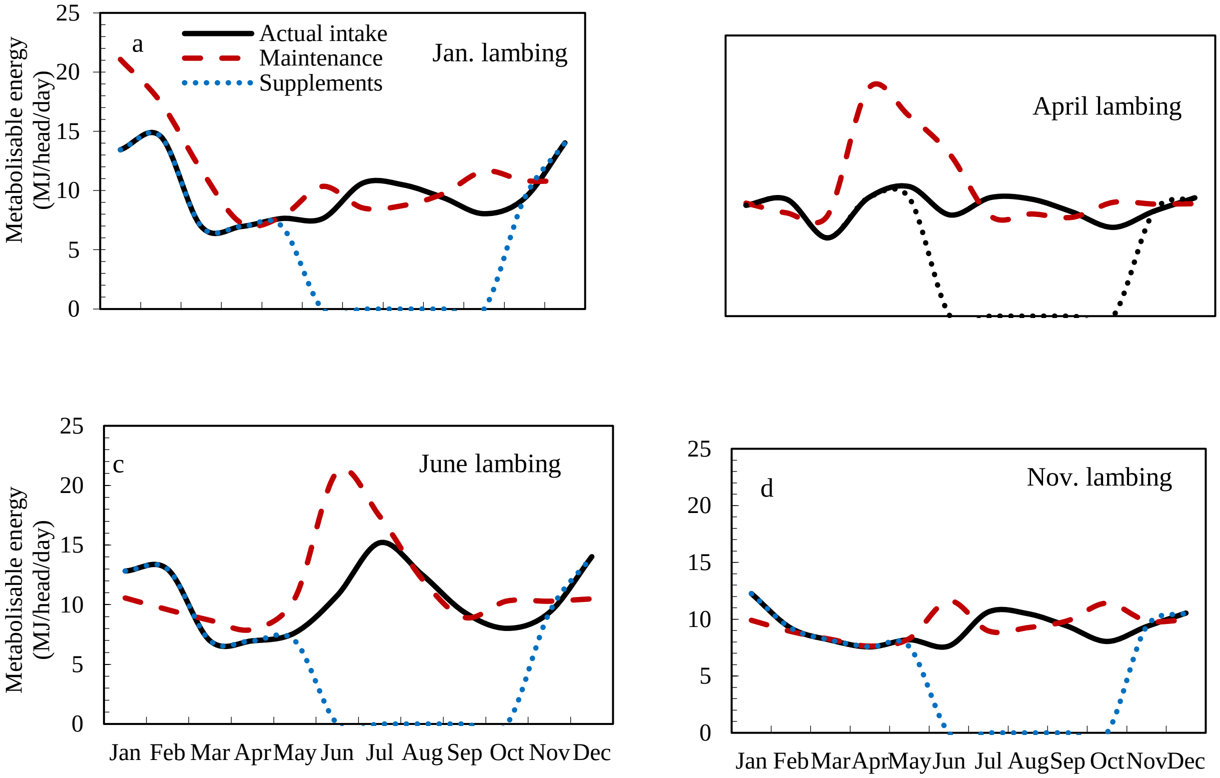

Figure 3 The effect of lambing time on feed energy balance for ewes in Fengning County, Hebei Province for: a) lambing in January (typical practice), b) lambing in April, c) lambing in June and d) lambing in November. With pen feeding from 15 Oct. to 15 June, feeding oat hay at 0.2 kg/day/head, alfalfa hay at 0.5 kg/day/head, maize grain at 0.1 kg/day/head, and other protein sources at 0.1 kg/day/head (ME = metabolisable energy).

Discussion

A key issue for managing livestock is maintaining a balance between livestock feed requirement and livestock feed availability (Darnhofer et al. 2010; Ma et al. 2014). Efforts to achieve this balance typically focus on increasing the forage and feed available to livestock and improved livestock performance through breeding (Herrero et al. 2009). Based on our local farm survey and the application of *StageONE* and *StageTWO* Models, we identified several strategies that may be beneficial for improving sheep management in northern China.

Analyses of the current livestock production status and alternative production management strategies through on-farm surveys and the application of model analysis showed the following changes should be made to the current farming system: 1) grasslands should only be grazed during the growing season, 2) pen feeding should be done during the non-growing season and 3) lambing time should be changed. These changes would better match local resources and lamb markets. The farm surveys and parameterization of the models were developed by scientists and farmers working together to evaluate the effects of finances, grassland management, animal management and changes in farm infrastructure. By obtaining accurate on-farm information from pastoralists and using these data to parameterize two models, realistic changes in management strategies were identified to increase farm income and reduce grassland grazing pressure. This activity increased public awareness of optimized farm management tools and provided a sound basis for identifying management alternatives for the sustainable management of grassland resources. Hopefully this process can be applied in other regions of China to more sustainably manage China's vital grassland ecosystems and improve the livelihood of pastoralists.

Abstract

Ranching has historically been one of the most economically and socially rewarding activities for many families in the Western United States. However, climatic and socioeconomic changes have brought public scrutiny to the environmental impact of ranching. Our Imperial Stock Ranch, with a 153-year legacy, has proactively addressed these challenges by adopting advanced sustainable practices to "make the land win" while producing commodities from dryland cropland and livestock grazing for local markets. In 2016, we achieved certification to the Responsible Wool Standard (RWS), becoming the first ranch globally to meet this leading standard for sheep and wool production. This milestone enabled us to partner with renowned fashion brands, providing sustainable wool that was even used in Team USA Olympic uniforms (2014, 2018, 2022 and 2024). In 2018, we founded Shaniko Wool Company (SWC) as a Farm Group to expand the supply of wool in the US that meets RWS global standards. SWC now includes ten ranches, collectively grazing over 1 million hectares across the country. To quantify the impact of our sustainable wool production, we collaborated with Oregon State University in 2019. By 2020, a program was developed to measure organic soil carbon and model greenhouse gas emissions for the entire farm group using the COMET Farm Model. This model indicates that the farm group can offset all emissions from our operations. For instance, the Imperial Stock Ranch alone has the potential to offset 2,809 tons of CO_2 annually, while the entire farm group can offset an estimated 91,444 tons annually. The future direction for our farm group involves certifying the entire group to sell carbon credits, creating a new income source alongside our existing production of food and fiber, sustaining humankind. Our commitment to sustainability not only benefits the environment but also strengthens the economic resilience of our ranching communities.

Ranch history

The family owned ranch; Imperial Stock Ranch is located in the high desert of Oregon's interior in the western United States. It was started by a young man who was born in a covered wagon as his family traveled west on the

Oregon Trail in 1852. He grew up in western Oregon where his family had settled, but in 1871, when he was 19 years old, he went east over the mountains into Oregon's dry interior to make his own start, filing on a homestead claim of 64 hectares (160 acres). He brought in cattle and sheep to graze the range lands and plowed enough land to establish grain and hay crops. He grew his operation from this modest beginning, and by 1900, he was Oregon's largest owner of land and livestock with a ranch of 13,000 hectares (32,000 acres). For 154 years, the Imperial Stock Ranch has been producing sheep, cattle, grains and hay on the same landscape. We recognize that we are temporary stewards of the land; that the land was here before us and will be here long after we're gone. We're aware of both our insignificance and our importance; and that the land provides sustenance for all life.

Stewardship

My husband's (late Mr. Carver) goal was always to "see the land win." He knew that the health of natural resources has a direct effect on your harvests, your bottom line, and your hope for the future. Working with local natural resource agency partners, by 1989, we had a written Conservation Management Plan for our whole operation that put the health of natural resources as the top focus; and we began implementing a host of changes. In our region of the high desert, we receive less than 200 mm of precipitation per year. Our plan considered both grazing management and crop management, with water conservation at the core.

Our plan included creating many off-stream water developments capturing, storing and safely releasing the water from rain and snow events, as well as natural springs. We changed the grazing strategy and were very strategic with the placement of supplements for the livestock. We created fencing to control grazing pressure and rest for plant communities. We converted thousands of acres of dry farm ground to no till, parking the plow forever, and keeping plants in all the fields every year.

Two creeks are born on our ranch, and in 1990, about when we were beginning this comprehensive mind shift on management, only two salmon returned to spawn in the local Buckhollow Creek. The first 15 miles of that stream start in our ranch, and this statistic was a huge wake-up call. Working with our agencies and other landowners in the basin, the Buckhollow Watershed Project (NRCS, 1994) was born as a collaborative, comprehensive, basin-wide approach to restoration. We hoped we would see a difference in our lifetime, but we did not know if it could happen that fast. We began to see changes after the first year. By 2010, just 20 years later, we saw thousands of salmon return to Buckhollow Creek showing a significant change.

Adaptation to changing market conditions

For 100 years, we always sold our wool harvest to the same company. However, in spring of 1999, changes in the market made the company stop buying the wool as they changed their operations to other countries. That would profoundly change our life. It was a time when tens of thousands of U.S. sheep producers were going out of the sheep business largely driven by this textile manufacturing shift. My husband said, "Find a new way to sell the wool, or sheep will be gone."

From that day forward, I took us from ranch to retail in our own branded products: wool yarns, and eventually, apparel, home fashions, and production yarn to brand partners. I built supply chain relationships to transform the raw (greasy) wool, and wholesale / retail relationships with brands and stores, eventually working with some of the most influential brands in North America and known around the world. But this did not happen overnight. This effort was made by pairing the wool with our heritage and the leading agricultural practices we had now been implementing for decades. I was busy telling our "sunlight story" of the land, grazing animals, and the gifts of creation. About how sheep transforms plant protein into the food, fiber and shelter that give us life. And how we are called to honor that. It resonated with authenticity. The provenance of the wool was critical to our effort and story, in yarn, home fashions, and apparel. We used every part of the harvest and then added value to the waste created at each step of the process. We shifted to this new model of marketing just as we had shifted our ways on the land.

After 13 years of hard work, we got a call from Ralph Lauren during the 2012 London Olympics, when there was a controversy over the Chinese-made Team USA uniforms. They were looking for an American yarn and to see if they could make the uniforms in the U.S. again. That all eventually led to an order that became the yarns for the 2014 Team USA uniforms for the Winter Olympics in Sochi, Russia. And then, Ralph Lauren told our story. This influenced others, and more brands came calling. That call too, changed our life.

I began my journey in textiles in 1999 in an effort to preserve sheep on our land. I had no idea that it would take me back to our collective history and simultaneously propel me into a future I could never have imagined. That it would become the vehicle that would connect me to the timeless traditions and skills of making textiles, take me to their roots, teach me, and deepen not only my agricultural experience, but my whole life perspective. This journey of taking our harvest direct to the market, shepherding it through every step, opened windows through which I gained clarity on things I had never even thought about before, bringing important and unforgettable people into my life. It built meaningful connections that erased the urban/rural divide for us, and bonded me to folks far across the country, and now the world, in a way I'd never been nor would have been otherwise. I began to know how important their work is. It helped me see our own work in agriculture with an even deeper purpose. I learned how much we needed each other; how we could learn from each other; and our lives became richer because of it. We began to rebuild the connections that were destroyed through globalization and the separation and isolation of individual steps in the textile supply system. With separation and isolation, the importance of place has been diminished, and with it, the motivation for stewardship. We're left with anonymity, which contributes to devaluing products, and breeds distrust in the marketplace. Perhaps the greatest consequence has been the degradation of natural resources and negative climate impacts.

Certification
Following our 2014 Olympic notoriety, we saw tremendous growth in our textile journey. Many brands were calling. One of those was Patagonia, who asked us to be third-party audited for our land and animal practices. Patagonia was part of an international working group that was developing a new global standard for sheep and wool production called the Responsible Wool Standard (RWS) (reference). When the RWS standard was launched in 2016, Imperial Stock Ranch became the first ranch in the world certified.

Expansion
In 2018, we established Shaniko Wool Company to scale the supply of American wool that met RWS certification, choosing a name that honored a story greater than our ranch alone. Shaniko Wool is a Farm Group supplying RWS certified wool. Together, we shear about 226,796 kg of wool each year and are grazing over 1 million hectares (2.6 million acres) in the western U.S. Shaniko Wool is continuing the strong relationships we had built within the U. S. textile industry in our own ranch's efforts since 1999; and my husband's legacy in resource stewardship. When Ralph Lauren called on us for wool for the 2022 Team USA Winter Olympics uniforms, they were made with Shaniko Wool.

Beyond the Standard
In 2019, we were criticized about the impacts of agriculture and in particular, livestock production. It was the motivation I needed to take the next logical step. What was our net footprint as ranchers? In early 2020, we responded to this increasing concern over the ecosystem and climate impacts of ranching, specifically sheep production. Working with a team of range and soil scientists from Oregon State University, we launched a measurement and research effort I called the Shaniko Wool Carbon Initiative. Up until now, we had our observations, and some monitoring, yield data, species counts, resource agency testimony, and certification to third-party standards in support of our work. But we had never formally "measured" or quantified our ecosystem deliverables. I did not even know if we could!

Our purpose was to determine the ecosystem and climate impacts of each ranching operation with carbon as a key performance indicator, plus collateral benefits. Science says that if soil carbon levels increase over time, additional positive benefits may include:

- Increases in soil organic matter
- Increased nutrient availability
- Improved water infiltration and water holding capacity
- Greater system biodiversity
- Improved habitats
- Resilience to extreme weather events
- Improved disease resistance
- Improved livelihoods

By 2023, we had baselined all 2.6 million acres.

Our research team is presenting our data and findings at this conference (Prado-Tarango *et al*. 2025), and I want to emphasize why this work is significant. When we began measuring, I was not sure what the sampling would reveal. However, I knew it would provide us with valuable information and a new tool to better understand our system. The primary purpose of this research is to offer actionable feedback to farmers and ranchers, enabling them to refine their management practices. What we have discovered has been overwhelmingly positive. Our operations are functioning as carbon sinks, with negative net greenhouse gas emissions. The methane produced by livestock is being fully offset by the carbon sequestration capacity of our rangeland ecosystems. These findings not only validate our observations but also provide robust evidence of our environmental impact. This data has proven instrumental in supporting the sale of our wool, instilling confidence in the companies that purchase it, and enhancing the marketability of our products. Additionally, our research has undergone auditing by ecosystem services organizations, resulting in the Shaniko Wool Farm Group being approved as a “project” capable of generating high-quality carbon credits. These credits can serve as offsets or insets, opening up a promising new revenue stream for family agriculture. The term "regenerative" is widely used today, but this research has provided concrete evidence that we are achieving regenerative outcomes. It transcends mere practices or approaches, offering quantifiable proof of success. For me, this has been the most meaningful work I have ever been involved in. It validates the vision my husband and I shared decades ago and the transformative changes we made to see the land thrive. Today, we are measuring that success and witnessing the results firsthand.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

It's time to revisit the dichotomy between researchers and producers regarding rotational grazing

Norton, BE

Utah State University (Emeritus). 1004 Canterbury Lane, Logan, Utah, USA 84321, brien_norton@comcast.net

Key words: livestock, forage, defoliation, meta-analysis

Abstract
In 1998 Norton offered an explanation for why researchers and commercial producers have opposing views on rotational grazing. Most researchers agreed to a lack of evidence of an improvement to forage yield or animal production due to rotational grazing, while producers were generally happy with higher production and income. He attributed this difference to a question of scale: research studies in small paddocks carry the implicit and reasonable assumption that both forage availability and its utilization are spatially homogeneous, whereas those parameters are highly variable across a continuously grazed rangeland landscape. Rotational grazing can ameliorate the patch grazing patterns encountered on extensive rangelands. An unheralded outcome from many grazing trials is that the stocking rate on experimental pastures could be maintained at much higher rates than on commercial properties near the research station, without adverse ecological impacts for either treatment. This appears to be a small-paddock phenomenon. Since 1998, many studies have looked at rotational grazing at a landscape/property scale with mixed results: some positive, some neutral, some negative. However, the adoption of rotational grazing on 130,000 ha of communal rangeland in Central Asia is a testament to its potential benefits to land, livestock and households. Adding to the confusion, recent meta-analyses of grazing studies have generated contrasting conclusions. The key issue appears to be the degree to which the design of a rotation is reflected in the plant/herbivore interface. A disconnect between the intended treatment and its expression in grazing behaviour is evident when defoliation frequency has been measured in grazing trials. We can hypothesize, therefore, that failure of the rotation treatment to be implemented as intended could explain a lack of differentiation between continuous versus rotation treatments. This paper surveys rotational grazing studies to examine this hypothesis.

Introduction
One of the most intriguing aspects of rangeland grazing research is the persistence of opposing views about rotational grazing, one claiming benefits to both forage and livestock production while the other states that the rotation is no better than continuous grazing. Reviews of published research going back to Sampson (1951) and many others since then demonstrate a general disadvantage to rotational grazing management, while reports indicate that commercial producers enjoy higher plant and animal production; their adherence to rotation practices is confirmed by a consensus of higher income. Norton (1998) attempted to resolve this dichotomy by showing that a flaw permeated most grazing trials in the form of research designs that utilized relatively small research paddocks. In those research situations, behavioral limitations on access to the entire pasture on a daily basis did

not apply. He argued that on extensive rangelands, rotational grazing could mitigate the patch-grazing patterns that concentrate grazing impacts on focal points from which degradation spreads. There have since been a number of studies of grazing rotations at a commercial station, landscape or ranch scale, but the dichotomy remains.

Meta-analyses of rotational grazing

Among reviews of grazing research studies, the oft-cited analysis by Briske et al. (2008) concluded that continuous grazing was superior or equal to rotational grazing in terms of both plant and livestock production in the vast majority of the 47 papers they reviewed. They employed a simple ‘vote count’ method of assessment. Wolf (Wolf & Horney 2015, based on Chapter 2 in Wolf’s 2016 thesis, University of California, Davis) addressed the same 47 papers but went deeper in a meta-analysis that teased out discreet variables that may not have exhibited significant differences in Briske et al.’s coarse analysis. She used a response ratio to measure the effect size, Rotation/Continuous, and looked at plant production (kg/ha), animal production per head (kg) and animal production per ha (kg/ha). She confirmed the broad conclusions of Briske et al. but also found that rotational grazing performs better in larger rangeland areas, in more seasonally variable environments, in more arid environments, and as grazing periods become longer.

McDonald et al. (2021) conducted a systematic review of global literature (280 studies) that compared ecological and production outcomes of rotational grazing to continuous grazing. Most studies reported no difference or no consistent difference in biodiversity, land condition or production variables, similar to conclusions in reviews by O’Reagain & Turner (1992, >50 studies), Briske et al. (2008) and di Virgilio et al. (2019, 278 publications). However, where differences were observed by McDonald et al., more studies reported positive rather than negative responses under rotational grazing. The exception was livestock weight gain, where 34% reported a negative response.

In a companion report, McDonald et al. (2019, 176 studies) addressed the specific question of how the length of the rest period in rotational grazing systems affects biological outcomes. They found a significant effect: at rest:graze ratios greater than 6:1, plant biomass was greater under the rotation; as rest:graze ratios increased, there was greater weight gain and more livestock production per ha. Meanwhile, plant diversity and species richness declined as rest:graze ratios increased.

In contrast to previously cited meta-analyses, Hawkins (2017), through a meta-analysis of data sets from 1972 to 2016 comparing continuous grazing to the Holistic Planned Grazing™ method of rotational grazing, found no difference in plant basal cover, plant biomass or livestock weight gain.

Rotational grazing on commercial-scale properties

The preference among commercial producers for adopting rotational grazing in place of traditional continuous grazing is evident in the small proportion who have rejected rotations after a trial period (e.g. Bork et al. 2021). There is a relatively small number of commercial enterprise-scale studies of rotational grazing. However, let us look closely at a few cases of grazing at a landscape scale.

On semi-arid, degraded rangeland in Southwest Tajikistan, an IFAD (International Fund for Agricultural Development) project (2014–2019) recommended rotational grazing for households herding livestock on communal village land, with each grazing unit area being grazed only once per year or per season to reverse the pervasive degradation. Impact analyses in 2018 and 2022 of the 400 participating villages managing 130,000 ha of rangeland revealed that cow weights were higher, herds were bigger, milk yield had doubled, and household income substantially increased (Norton 2022). Forage was more abundant. A rest:graze ratio of at least 15 was suggested. A follow-up survey indicated that households continued to practice rotations long after the project concluded, and voluntarily reduced herd numbers.

In Patagonia, Oliva et al. (2021) found that the application of rotational grazing for 3 years (mid-2012–mid-2015) under Holistic Resource Management (HGM) on 13,600 ha divided into five paddocks versus a matching area continuously grazed, caused negative effects on ewe liveweights and lambing rates. The only significant change in vegetation saw cover of the low-palatable tussock grass increase under continuous grazing. Rainfall was below an average 239 mm and declined throughout the study period. Grazing periods ranged from 23–68 days (mean 34), with rest periods of 160–319 days (mean 246).

In the Flooding Pampa region of eastern Argentina at higher rainfall (935 mm), Jacobo et al. (2006) studied rotational grazing for 4 years (1993–1996) at four sites; at each site one cattle farm managed with rotational grazing while the adjacent farm was kept under continuous grazing. The rotations involved 10–12 paddocks occupied by 400–500 breeding cows at a mean stocking rate of 1 AU/ha, 60% above the average for the region, for the continuously grazed farms as well. Grazing periods ranged from 3–15 days, and rest periods 25–90 days, the timing adjusted according to the growth rate of dominant grasses. Rotational grazing promoted high-value forage species such as legumes while low-value species, like prostrate summer grasses, decreased. This benefit was more pronounced in drier years. More litter cover and less bare ground signaled an improving ecological condition.

Augustine et al. (2020) cooperated with a consortium of livestock producers on the short-grass prairie of north-central Colorado – the Collaborative Adaptive Rangeland Management group (CARM) – to implement a grazing experiment on 2600 ha (340 mm average rainfall), evaluating responses of vegetation and cattle performance to multipaddock adaptive rotational grazing and season-long continuous grazing. The 11-member CARM group made decisions on annual stocking rate and the sequence and timing of movements among the rotation paddocks. Ten paired 130-ha paddocks were grazed by a single herd of steers. This design matched a continuous paddock to its rotation counterpart; the continuous grazing herd was spread among the ten paddocks for the grazing season. The herd size started at 214 yearling steers in 2014, but rose steadily to 280 steers by 2018, upon the recommendations of the stakeholder group. This trajectory is consistent with Norton's (1998) perspective on the amplifying effect of moderately small paddocks on carrying capacity. The authors could not find any grazing management effects on grass production, but they observed a 12–16% decline in cattle weight gain each year under the rotation compared to continuous grazing. A following paper (Porensky et al. 2021) documented tiller defoliation frequency and intensity on the dominant western wheatgrass (*Pascopyrum smithii*) within the grazing-system experiment described by Augustine et al. (2020). Roughly two-thirds of grass tillers remained ungrazed under both grazing systems.

Another way of referring to this result is to say that the experimental design was not reflected in the plant-animal interface. This phenomenon, of failure to infer the rotational grazing plan from evidence of livestock defoliation activity when the rotation study is accompanied by data on defoliation patterns, has been reported a number of times: for example, Gammon (1978), Hart et al. (1993), and Heitschmidt et al. (1990). In these examples, the effect of the rotation *per se* on defoliation pattern is weak or absent. As Gammon (1984) observed, if the rotation design cannot be deduced from defoliation patterns alone, the rotation was not implemented as intended.

Conclusion

The lack of congruence in performance between rangelands rotationally grazed and those continuously grazed may be due simply to a failure of the rotation design being expressed in the defoliation behaviour of grazing livestock. In other words, the rotation was not really implemented at all. However, as the rest:graze ratio increases, with longer rest periods and increasingly shorter graze periods, rotations are more likely to exhibit improvements in ecological condition and increases in both forage and livestock production. The range management profession still lacks a clear understanding of how rotational grazing works, and so contradictions in the research record and conflicting recommendations persist.

Virtual fencing aids rest-based grazing and mustering in an extensive cattle grazing system

Willis, MB[1]; Tschirner, AK[2]; Fennell, JM[3]; Fennell, FE[3]

[1] South Australian Research and Development Institute, Struan Research Centre, Naracoorte, South Australia; [2] South Australian Arid Lands Landscape Board, Port Augusta, South Australia; [3] Wintinna Station, Via Coober Pedy, South Australia

Key words: Virtual Fencing; Cattle; Grazing; Regenerative; Rangelands

Abstract

Virtual fencing (VF) remotely manages livestock grazing using GPS-enabled collars that communicate the location of boundaries to animals. This technology has been demonstrated in cattle, with commercial use occurring in Tasmania and Queensland. VF is of particular interest for livestock management in rangeland environments where property size and topography can reduce the economic viability of installing new fencing infrastructure.

This research aimed to assess VF as a tool to facilitate rest-based grazing and aid mustering in an extensive beef grazing system. A trial involving 100 mixed breed heifers was undertaken at Wintinna Station (via Coober Pedy) in South Australia from April – October 2023. During the trial, the cattle were trained to a commercial VF system. A range of inclusion zones were established in different areas of a 4,500ha paddock with a central dam. Cattle were successfully contained by the VF system and grazed within each new inclusion zone once activated. The VF system was also used to aid in mustering the trial paddock. A virtual laneway 1km in width was activated 24 hours prior to scheduled mustering and all 100 cattle were contained within it. The following day the laneway was deactivated, and the paddock was mustered by two motorbikes in approximately three hours with no requirement for aircraft. The GPS tracking function of the technology enabled all animals to be accounted for.

The results of this trial indicate that VF can facilitate rest-based grazing practices within extensive beef grazing systems. VF's use as a tool to aid in mustering cattle was also demonstrated. With further development and reduced regulatory constraints, VF could have a significant impact on the way that rangelands are managed into the future.

Introduction

The potential for virtual fencing as a management tool in extensive cattle grazing systems has become an area of interest for Australian pastoralists. Rotational grazing is a valuable tool for protecting soil health (Byrnes et al. 2018). and plant biodiversity in grazing enterprises (McDonald et al. 2019). However, implementing rotational grazing using physical fencing presents significant challenges for extensive grazing systems. The large area of these systems makes temporary fencing and the cost of installing permanent fences impractical (Anderson et al. 2014). Consequently, virtual fencing has emerged as a potential solution to enable rotational grazing and improve management in extensive grazing systems.

Virtual fencing is a GPS-enabled technology that delivers cues to livestock via a collar, encouraging containment or exclusion from a prescribed area. An audio cue paired with an electric pulse informs the animals of the GPS boundary, defining their grazing area.

This study investigated the suitability of virtual fencing to facilitate rest-based grazing in the South Australian rangelands. The role of virtual fencing in aiding mustering was also investigated to assess virtual fencing as a holistic tool for improved operations on cattle stations.

Methods

This experiment was undertaken in Dead Finish paddock at Wintinna Station (via Coober Pedy SA), a 45km^2 (4,500ha) area comprising of uplands and open gently sloping plains with shrubby drainage lines. The predominant pasture species in Dead Finish paddock were Mitchell Grass (*Astrebla spp*.), Bladder Saltbush (*Atriplex vesicaria*), and Flinders Grass (*Iseilema spp.*). The water source in Dead Finish was a dam located in the West/Northwest of the paddock.

In April 2024, one-hundred mixed breed *Bos indicus/Bos taurus* heifers (average liveweight 300 ± 50kg) were selected from the herd at Wintinna Station. The heifers were weighed and confirmed not pregnant via rectal palpation prior to allocation to the trial.

The Vence virtual fencing system and CattleRider virtual fencing collars were used in this experiment (Vence, MSD, San Diego, California, USA). CattleRider collars were fitted to each heifer as per Vence protocols (Purcell, pers. comment). Virtual fences were created using the Vence online computer software and communicated to collars via long range wide area network (LoRaWAN) connectivity and global positioning system (GPS). The virtual fencing was implemented via the collars through administration of audio and pulse signals underpinned by associative learning theory (Lee et al. 2009).

The heifers were trained to the virtual fencing system in a 1.5km^2 (150ha) holding paddock. A virtual fence was activated along the physical boundary fence of the holding paddock for three days. The virtual fence was then changed to exclude the cattle from approximately one third of the paddock for a further four days.

On day 0 of the experiment, the heifers were walked approximately 8km from the holding paddock to Dead Finish. A virtual fence was activated in Dead Finish to exclude the heifers from an approximately 11km^2 (1,100ha) strip along the northern boundary of the paddock. On day 28, the virtual fence was changed to create an approximately 16km^2 (1,600ha) rectangular grazing area in the southwest of Dead Finish. On day 92, a capture lane (1km wide, 5km long) was activated to concentrate the cattle prior to mustering. Twenty-four hours later the capture lane was deactivated, and the cattle were mustered on two-wheeled motorbikes and walked approximately 8km to the closest cattle yards.

GPS heat maps were generated using the Vence virtual fencing online computer program and contain information from activation to deactivation of each virtual fencing configuration.

Results

The training period was successful with effective exclusion from one third of the training paddock achieved for four days (Fig. 1). Minor breaches of the virtual fence occurred during this time, indicated by blue shading within the red exclusion zone in Fig. 1.

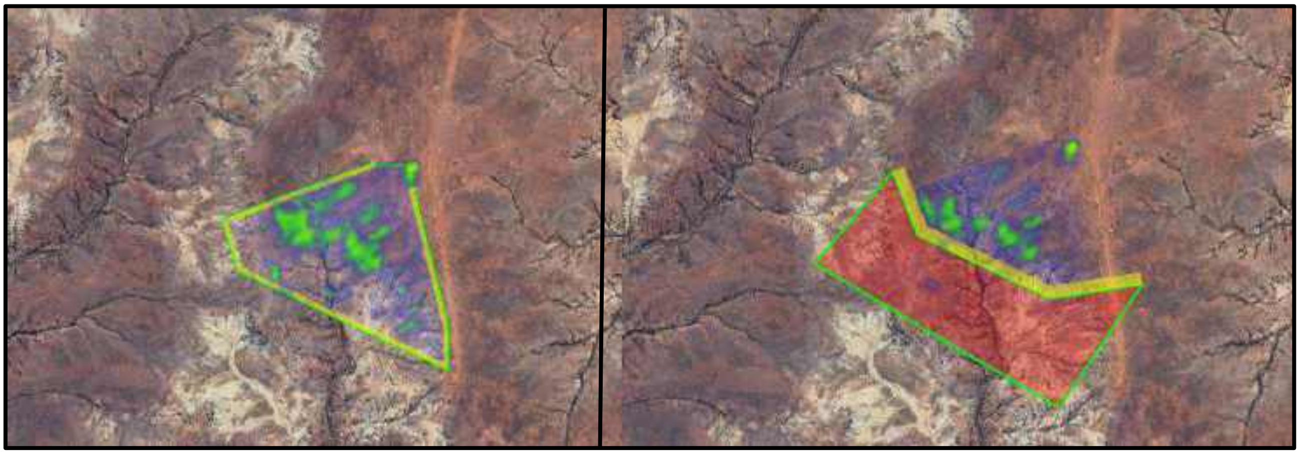

Fig. 1. Virtual fencing configurations and GPS location heat maps in the holding paddock during the training phase

A virtual fence successfully excluded the heifers from the northern boundary of Dead Finish for 27 days. Grazing distribution across the allocated area was relatively uniform with some concentration of grazing around shrubby drainage lines (Fig. 2). There were minor breaches of the virtual fence along a main drainage line through the virtual fence, indicated by blue shading along the prominent creek line in Fig. 2.

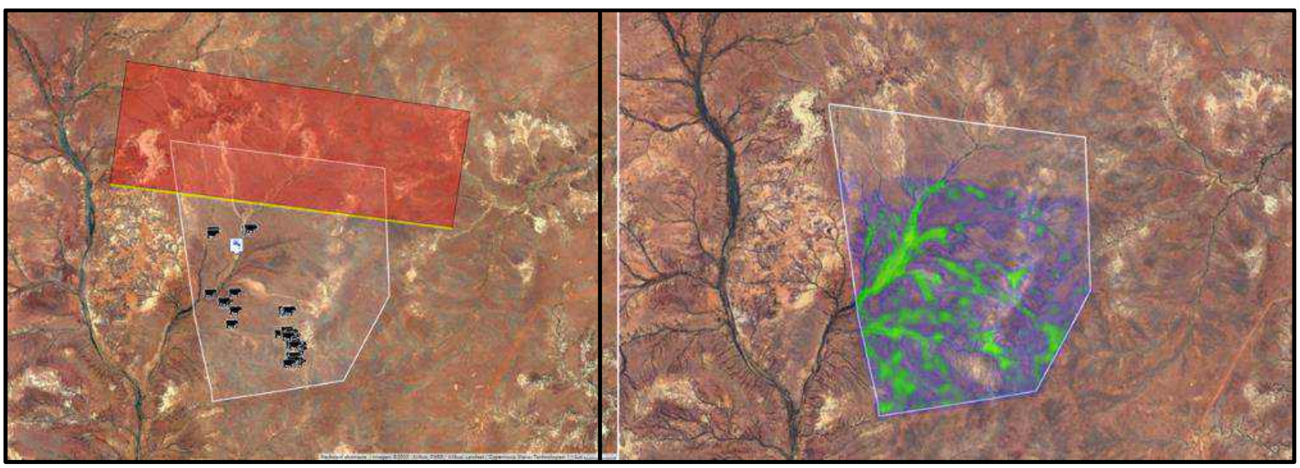

Fig. 2. The virtual fence configuration and GPS location heat map in Dead Finish from day 0 to end of day 27

The heifers were effectively contained within the Southwestern corner of Dead Finish by the virtual fencing system (Fig.3). Grazing locations were uniform across the allocated area. However, locations surrounding shrubby drainage lines were accessed more heavily, indicated by green shading in Fig. 3. There were breaches of the virtual fence along drainage lines to the west, north and east of the allocated area.

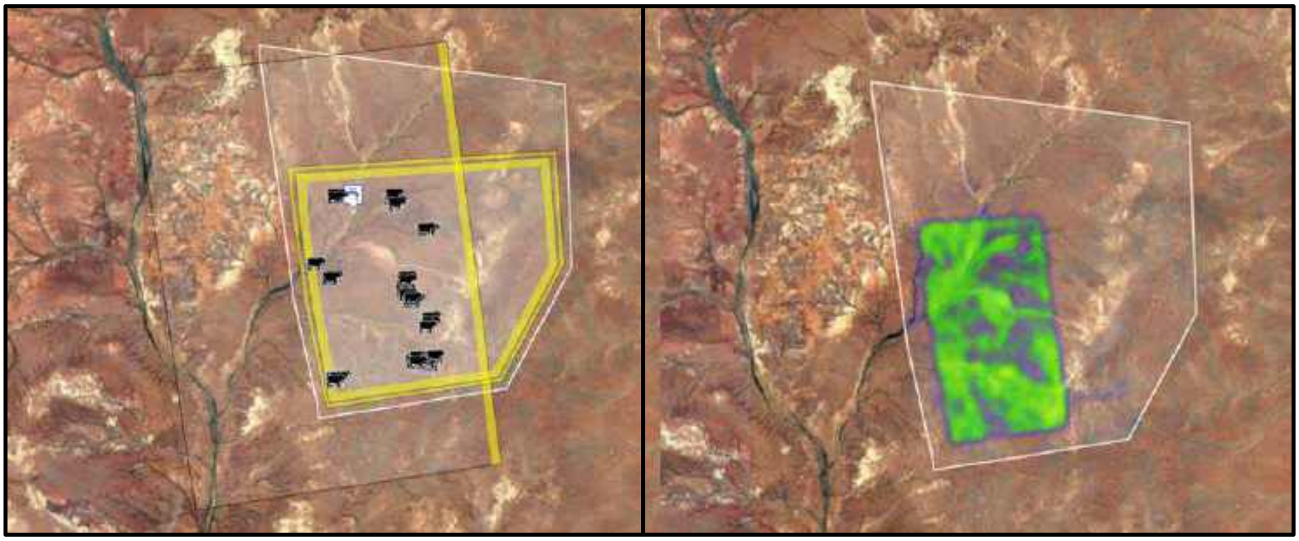

Fig. 3. The virtual fence configuration and GPS location heat map in Dead Finish from day 28 to end of day 91

The capture lane on day 92 effectively contained the heifers during the 24 hours prior to mustering. When the capture lane was deactivated immediately prior to mustering, all collars successfully received the instruction. All 100 heifers were mustered from Dead Finish within three hours by two people on two-wheeled motorbikes.

Discussion

Virtual fencing effectively contained heifers to specified areas within Dead Finish. Minor breaches of the virtual fence occurred throughout the experiment. However, overall containment of the heifers was acceptable. Breaches occurred mostly along drainage lines through the virtual fences. This was most likely due to the presence of moisture and abundant palatable pasture species in these areas. On day 61 of the experiment, a storm occurred at Wintinna Station and 35mm of rainfall was recorded. Twelve heifers breached the virtual fence during this storm, contributing to the GPS location recordings outside of the allocated grazing area. It is common for cattle to travel large distances through physical fences during a storm (Fennell, pers. Comment). The virtual fencing allowed identification of those who had breached the boundary and assurance that they had returned following the storm.

Virtual fencing improved the efficiency of mustering the heifers from Dead Finish. The use of a capture lane to condense the heifers prior to mustering saved the labour of two people for two hours each and the cost of an aircraft. Utilising virtual fencing enabled mustering of 100% of the heifers in Dead Finish, a very rare occurrence on cattle stations of this size.

Virtual fencing shows promise as a tool for improved grazing management and mustering efficacy in extensive cattle grazing systems. The use of virtual fencing at Wintinna Station increased monitoring of animals, reduced labour inputs, improved pasture management through rotational grazing and improved farm safety through reduced requirement for large musters and aircraft. The availability of virtual fencing to Australian pastoralists has the potential to contribute to sustainable rangeland management into the future.

Acknowledgements

The authors acknowledge the technical support provided by Vence, notably that provided by Jason Purcell and Todd Parker. We also thank Taine Te Kawau, station hand at Wintinna Station, for his operational support throughout the experiment. Thank you to Landscapes SA Arid Lands for facilitating and supporting this experiment.

This experiment was approved by the South Australian Department of Primary Industries and Regions Animal Ethics Committee (PIRSA AEC, project #05/23).

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Improving tactical decision making in the western NSW pastoral zone

Plummer, CRE[1]

[1] Western Local Land Services, Buronga, NSW, Australia

Key words: grazing management; livestock production; decision making

Abstract
The Profitable Grazing Systems program: Improving Tactical Decision Making (ITDM) is a group-based training program designed specifically for the New South Wales rangelands. The objective of the program is to assist pastoralists with the adoption of strategic grazing management practices to improve farm business profitability. The program launched in 2021 and has since graduated three groups of pastoralists from Packsaddle, in the state's northwest corner, to Booligal, in the south-eastern rangelands.

Over a 12 to 18 month period, a small group of pastoralists participate in five training sessions. Each session covers a different aspect of rangeland grazing management, culminating in the development of a tactical grazing plan during the final session. At the program's onset, pastoralists are assigned the task of establishing a monitoring paddock, a pivotal tool enabling them to gauge progress towards their management objective. This strategic approach facilitates the self-assessment of the applied grazing strategies' efficacy within their unique landscape, providing guidance for informed decision-making at the program's completion.

Combining their own property knowledge with targeted grazing strategies, pastoralists learn to assess pastures, identify the productive species in their landscape and manipulate grazing management to increase the prevalence of valuable, perennial plants in the feedbase, thereby, improving their ability to condition paddocks to respond to rainfall and withstand dry periods. Complementary skills in livestock production are also covered to build capacity in condition scoring and optimal feed allocation to achieve production goals.

Upon program completion, pastoralists depart equipped with an enhanced ability to monitor, measure, and record pasture and livestock condition, thereby fostering improvements in whole property performance. By merging their existing property knowledge with fresh skills in grazing management, participants are better equipped to navigate the challenges of rangeland management, ultimately paving the way for sustained profitability and resilience within their operations.

Introduction
In the diverse arid and semi-arid rangelands of New South Wales (NSW), effective pasture management is critical for maintaining sustainable and productive grazing businesses. Pastoralists need to manage distinct challenges, including unreliable rainfall, total grazing pressure, variable feedbase composition and growth (Hacker et al. 2019; Hacker and McDonald 2021), leading to the need to make informed, real-time decisions about livestock management and resource allocation.

The Improving Tactical Decision Making (ITDM) program, developed by Western Local Land Services and part of Meat & Livestock Australia's Profitable Grazing Systems (PGS) initiative, is designed to support pastoralists in navigating these challenges by equipping them with practical tools and approaches for strategic grazing management. The group-based coaching model is tailored specifically to the needs of rangeland pastoralists in NSW. By focusing on increasing the capacity of pastoralist's decision making related to grazing periods, key species management, and livestock production, the program aims to enhance whole-property performance and drive greater productivity, sustainability, and profitability for grazing enterprises.

Program Structure

The ITDM program follows tactical management principles (Campbell and Hacker 2000) where participants develop their ability to set an objective, determine strategies to achieve the objective, implement their strategy and monitor accordingly. Five coaching sessions are held on property with a small group of pastoralists for up to 18 months. In preparation for each session, a pasture sample is conducted on four key pasture species at the host property monitoring site. The pasture sample informs feed budgeting activities and discussions relating to plant availability compared to animal selectivity assumptions (Graetz and Wilson 1980; Pahl 2019).

Each session covers different aspects of rangeland grazing management building on from the last, with the final session focused on creating a tactical management plan (Figure 1). The program emphasises practical skills in pasture evaluation, livestock condition scoring, and feed budgeting, all aligned with production objectives. Participants learn to identify key pasture species, recognise quality and quantity trends, and understand crucial rest and recovery phases for landscape health. Grazing management techniques are demonstrated to promote palatable, perennial plants, and participants develop the ability to assess the impact of grazing on plants at different growth stages. Seasonal trigger points (Hacker et al. 2006) are identified for each property and decision plans are created aligned with the livestock production system. Additionally, the program incorporates livestock condition scoring training and remote sensing technology, alongside on-ground measurements, to support decision-making. By the end of the program, pastoralists are equipped to monitor pasture and livestock conditions more effectively, aiming to improve overall property performance and supporting sustained profitability and resilience.

All participating pastoralists complete a baseline survey prior to entering the program and again at completion to assess the knowledge and skills gained from participating. Commencing with the 2023-2024 intakes, pastoralists were also surveyed on their intention to change their business practices as a result of participating. Smaller surveys are conducted at the end of each session to gain feedback on the delivery and inform improvements throughout an intake.

Following each intake, a review of the sessions is undertaken by staff to improve program delivery. Resulting modifications are based on staff experience and direct feedback from pastoralists, aiming to increase pastoralist engagement and knowledge comprehension throughout the program.

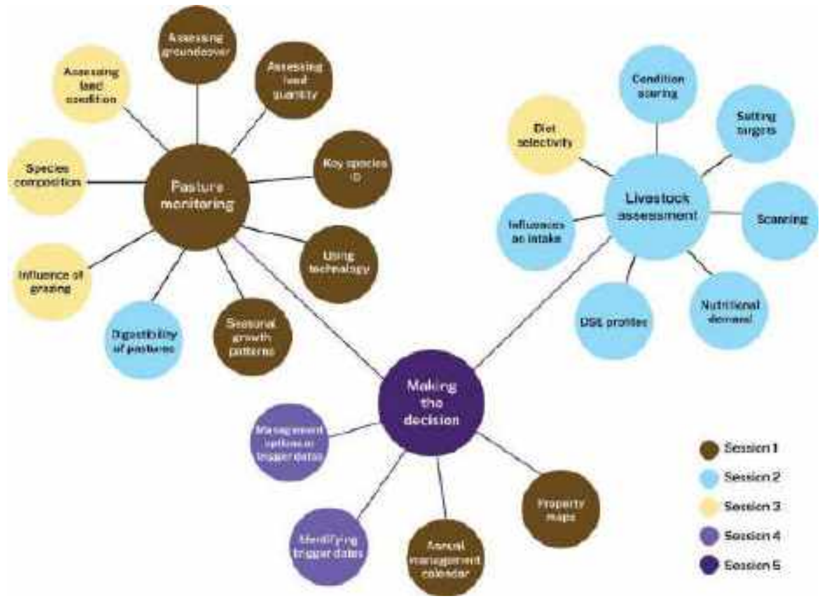

Figure 1. Session breakdown of the ITDM program.

Outcomes

At the time of writing, the ITDM program has been successfully implemented through three groups based in the Oxley (2021), Packsaddle (2023-2024), Ivanhoe and Booligal (2023-2024) areas where the total area managed by participating pastoralists equates to 482,654 ha. In each locality, pastoralists have self-assessed an increased capacity in grazing management and livestock production techniques (Tables 1 and 2).

Table 1. Averaged pre- and post-program self-assessment survey results from three groups of ITDM participants.

On a scale of 1 (low) to 10 (high), how confident are participants in their ability to:	Pre-Program	Post-Program	Change (+/-)
Assess feed digestibility	4.07	7.69	+ 3.62
Estimate feed quantity in kg DM/ha	2.57	7	+ 4.43
Use condition scoring to assess livestock condition	6.36	8.69	+ 2.33
Adjust stocking rate based on feed supply and demand	5.93	8.38	+ 2.45
Manage livestock nutrition to meet production targets	5.57	7.69	+ 2.12
Manage ewes according to their pregnancy status to reduce lamb and ewe mortality	5.64	7.77	+ 2.13
Adjust stock numbers guided by your grazing strategy and monitoring	6.14	8.62	+ 2.48

Table 2. Averaged pre- and post-program self-assessment survey results from the Oxley (pilot program) and the Packsaddle (P), Ivanhoe (I) and Booligal (B) (2023-2024 groups) participants of ITDM.

On a scale of 1 (low) to 10 (high), how confident are participants in their ability to:	Pre-Program - Oxley	Post-Program - Oxley	Change (+/-) - Oxley	Pre-Program – P, I, B	Post-Program– P, I, B	Change (+/-)– P, I, B
Assess feed digestibility	4.75	6.75	+ 2.00	3.80	8.11	+ 4.31
Estimate feed quantity in kg DM/ha	3.00	5.25	+ 2.25	2.40	7.78	+ 5.38
Use condition scoring to assess livestock condition	7.50	8.25	+ 0.75	5.90	8.89	+ 2.99
Adjust stocking rate based on feed supply and demand	7.25	8.00	+ 0.75	5.40	8.56	+ 3.16
Manage livestock nutrition to meet production targets	5.50	7.50	+ 2.00	5.60	7.78	+ 2.18
Manage ewes according to their pregnancy status to reduce lamb and ewe mortality	7.50	7.50	0.00	4.90	7.89	+ 2.99
Adjust stock numbers guided by your grazing strategy and monitoring	7.50	8.50	+ 1.00	5.60	8.67	+ 3.07

All participants (10) from the 2023-2024 intakes indicated they plan to make changes to how they manage their business as a result of participating in the program, and fifty percent (5) had already made changes before program completion. Pastoralists in the first (pilot) intake of the program were not surveyed on practice change.

Learnings

Improving Tactical Decision Making was first delivered as a pilot program in 2021. This initial intake of pastoralists had a reasonably high self-assessed confidence in livestock production related skills (7.25 - 7.50) prior to their participation in the program. When reassessed at the conclusion of ITDM, a small increase (0.00 - +1.00) in confidence was seen across these skills compared to feedbase related skills (+2.00 - +2.25). In contrast with the two 2023-2024 groups, whose livestock-based skills were rated lower overall (4.90 - 5.90) and saw a larger increase in confidence (+2.18 - +3.16), finishing the program at a similar level of confidence to the pilot participants. Interestingly, all intakes shared a low confidence in their ability to assess feed digestibility and estimate feed quantity in kg DM/ha prior to the program, with the largest increase in confidence post-program seen in the more recent intakes (+4.31 - +5.38).

Following the delivery of the pilot program, modifications were made based on experience and feedback from the initial delivery. Predominant changes included refining session plans and presentations, redesigning feed budgeting templates and the creation of supporting material. Additional interactive field activities were also developed for the final session to encourage pastoralists to utilise skills obtained earlier in the program and present findings to the group. Following the delivery of the 2023-2024 Packsaddle, Ivanhoe and Booligal groups, each session will be reviewed, and updates made before delivery to future intakes of the program. Adjustments are informed by the level of expertise in the incoming groups but also the lessons learned from the past groups.

It is difficult to discern whether the preliminary modifications of the program led to the larger increase in confidence level between the pilot and recent program intakes or pastoralists with lower initial confidence gained more from the program. The pilot program was conducted directly after an extended drought when pastoralist focus was likely directed towards more intensive livestock management due to ration feeding programs.

Additionally, service provider support is known to increase in dry periods, likely contributing to an increase in capacity before participation. In contrast, the most recent intakes were initiated during a high rainfall period. Moreover, the geographic spread of participants could lead to discrepancies in opening confidence levels due to differences in production systems, climate and landscape challenges. Furthermore, additional differences in the implementation of the content have occurred at each intake due to changes in personnel delivering the program.

The commitment to practice change demonstrated by the survey results of the ITDM program suggests that when pastoralists are coached through the tools and knowledge to tactically manage their pastures, significant capacity building improvements can be observed. Therefore, the integration of monitoring tools, such as condition scoring, feed budgeting, and remote sensing technology, with increased understanding of grazing management principles enables pastoralists to be more confident in making informed, tactical decisions that align with environmental conditions. Although the program successfully built participants' capacity to make data-driven decisions, long-term monitoring and ongoing support are essential to ensure that these new practices are maintained and refined over time. Furthermore, while the integration of remote sensing technology has been beneficial, it requires pastoralists to have adequate technological ability and appropriate training to operate independently, which may present challenges for some participants beyond the program.

Conclusion

The Improving Tactical Decision Making program has proven to be an effective tool for enhancing grazing management and resource allocation confidence in three groups of pastoralists in the NSW rangelands. As climate variability continues to impact the productivity of rangelands, adaptive management strategies like those taught in the ITDM program will be increasingly important for the long-term viability of arid and semi-arid grazing systems. The success of this program to date highlights the value of providing pastoralists with the knowledge, skills, and tools necessary to make informed decisions and adapt to changing conditions. Through continued support and innovation, the program has the potential to make a significant contribution to sustainable grazing management in the western NSW pastoral zone.

Fenceless grazing

Kentish, N[1]

[1] Low Stress Stock Handling; Resource Consulting Services; nic@kentish.biz

Key words: Livestock; Grazing; Regenerating Agriculture

Abstract

Whilst it should be a given that livestock handling and instinctive behavior is a primary skill taught to every apprentice stock-handler, the fact remains that many animals never achieve their full production potential due to poor juvenile imprinting and mishandling by humans. This human/animal interaction and primary contact that carries throughout the lives of both can strongly influence animal impact on rangelands.

Roaming livestock that are contained by random fences, or limited by their walking distance to water, can have a significant impact on soil structure, surface water quality, perennial plant root survival and leaf regeneration. These and other degradations do little to endear livestock to ecologists and with little to no management of grazing practices in vast areas of the planet's grasslands, may see the forced disappearance of introduced livestock from our ecosystems.

Yet, what if we could accurately manage productive, carbon-sequestering grasslands through training humans to teach livestock to graze better? This remains my quest as a teacher of farmers.

Introduction

I have come to understand how easily we can 'park' or place animals in specifically suitable areas of the range through Low Stress Stock Handling training and the study of human/livestock communication. The specific movements that the handler should perform to train livestock to herd in this manner through body language are complex, and the associated skills are advanced yet, once understood, easily replicated.

Methods

Within the training of livestock to 'park', we aim to encourage the herd to move and stop responsively, then take all of the movement out of them for a given time. As the herd becomes superbly trusting and disciplined, the shepherd will need to pay intense attention to the available feed and move the animals accordingly. Individual animals that are troubled by humans will need extra work or possibly be culled from the herd.

The movements and body language conveyed to the herd or mob by the shepherd, work with the training of Low Stress Stockhandling instinctive behaviors, namely that –

1) Animals generally move in the direction they are facing
2) Herding animals mostly want to follow other animals

3) Animals strongly want to keep an eye on that which is pressuring them
4) Animals will do what they can to have pressure released

Combining these instincts with a principle of animal movement that parallel movement with the animal whilst in the forward section of one or both of its eyes will tend to slow it down or stop it, enabling communication to neutralize forward movement. This will ultimately stop the leaders of a herd or mob from grazing and wandering beyond the pasture or range upon which they are being 'parked.' To start the movement up again, the shepherd must re-form the herd or mob from its leadership to its tail animals and gently drive them away from the pressure.

Results

10 Meaningful Outcomes of Training Livestock to 'Park'

1. Significant reduction in overgrazing of edible plants
2. Elevated graziers ability to select areas for grazing and nutrient defecation
3. Increased on-Range decision making to avoid grazing-sensitive regions and areas
4. More specific control of animal traffic and camps on riparian zones
5. Improved and impactful grazing pressure on higher and steeper Range areas
6. Significantly reduced waste deposition in waterways
7. Improved animal production gains due to less herd movement
8. Targeted nutrient movement and dispersal uphill from water sources
9. Enacting time-controlled grazing plans for livestock
10. Herds that require less pressure to move or control

Implications

Evolution has determined that herding animals are a protein and energy source for their carnivorous predators. In the absence of these predators, most herds, great and small, rapidly become sedentary. This is extraordinarily detrimental to water points and riparian zones that were historically the domain of the predator and at which prey animals drank quickly and left, not lying around like a hotel poolside.

Historically, a balance of vegetative cover was maintained by not overgrazing due to the herds being moved on by the predators. There are thousands of hectares of degraded landscapes across the rangelands due to soil salinity escalation from the baring out of vegetation by herding animals.

Yet, if herding animals can learn to trust their handlers or shepherds' decision-making that there will always be continual adequate feed and water provided, their demeanor will change positively by reverting to a psychology that is controlled by instinct but without predatory pressure. Thus, they can be trained to spend their non-drinking time well away from vulnerable waterways and riparian zones. These grasslands on the range have added benefits of providing a wider diversity of edible and non-edible plant species, open visibility to provide safer loafing pastures, more relaxed and complete rumination time and thus feed conversion and less competition from other herds or mobs.

Conclusions

Ultimately, heavy-handed laws may be enacted to control and restrict grazing pressure on rangelands. These would unlikely be as effective as the motivation of the shepherd, herdsman or farmer to maintain their livestock in a positive plane of nutrition whilst simultaneously regenerating their rangelands.

If it is possible to regain the skills, knowledge and experiences of the shepherds of 1925 and earlier, grazing livestock with the capacity to remain where 'parked' would certainly become best practice for the modern grazier.

Groundcover, biodiversity, soil health and functional water cycle are all indicators of rangeland health. Whilst many of these regions are designated National Parks or Conservation areas, those that are managed by grazing livestock can also be maintained with these indicators functional.

By understanding and practicing these methods of 'parking' animals, as well as effective shepherding, it is possible to decommission infrastructure such as fences on the rangelands and at the same time, regeneratively manage vast areas of the planets grass and shrublands.

Abstract

In the semi-arid rangelands of southern Australia livestock producers must balance livestock production with landscape function to achieve business resilience. Under highly variable climatic conditions, their approach to grazing management is a key element in achieving production and landscape targets. At the same time, the socio-economic environment is difficult as they typically live on very large, isolated properties subject to a highly variable climate and financial volatility. We conducted semi-structured interviews with six producers, three operating in a ‘well-functioning’ landscape and three in a ‘recovering’ landscape, to provide a detailed description of their approach to grazing management and explore the perceived production, biophysical and personal benefits derived from their grazing practices. Producers in a well-functioning landscape focussed on animal and plant performance, prioritising the management of productive/palatable forage species, implementing extended rest periods for regeneration while managing stock numbers conservatively. In a recovering landscape, producers primarily focussed on improving landscape function with enterprise type and animal production adjusted to support regeneration. These producers place emphasis on the seedling growth of valued species, encourage the growth and expansion of perennial species and adjusting livestock number to match carrying capacity as the country improves. A key personal benefit is a sense of accomplishment from ‘care’ of country demonstrated by producer ‘attentiveness, responsiveness, and adaptation’ in their grazing management practices. In addition, producers often expressed an emotional connection with country: *“my mental health is very attuned to the health of the land”* and *“I really want to heal the land”*. Our work reveals a positive feedback loop between environmental stewardship and personal well-being.

Introduction

Livestock producers in the semi-arid rangelands of southern Australia need to be particularly attuned to the natural environment to balance livestock production while maintaining or improving landscape function to support profitable and sustainable enterprises. Operating under highly variable climatic conditions including frequent periods of drought, producer approaches to grazing management are critical to achieving landscape and production targets. Key elements of management in these grazing enterprises include, for example, managing the carrying capacity (i.e. matching livestock numbers to available feed), implementing strategic rest from grazing to preserve/increase desirable, productive forage species and to maintain/enhance ground cover (Hacker and McDonald 2021).

The socio-economic environment in which producers operate is also complex and dynamic. They typically live on very large (>10,000 ha), isolated family run properties subject to high inter-annual financial volatility reflecting fluctuating seasonal conditions and commodity prices (Sinclair et al. 2019). Nevertheless, these properties are more than places of economic dependence, they enable a distinctive way of life in which the natural environment is often valued for its 'vastness and openness imbued with significant meanings' (Holmes and Day 1995, Masterson et al 2017). These meanings frequently lead individuals to acquire an affective attachment to the land they manage (Mullendore et al. 2011).

In this paper we describe the different approaches to grazing management used in the semi-arid rangelands of southern Australia. We provide insights into these producers' perceptions of the production, biophysical, and social co-benefits derived from their grazing practices. The paper will contribute to an improved understanding from a producer's perspective of how the different grazing systems affect productivity, resource condition and profitability in semi-arid rangeland livestock production systems.

Methods

Semi-structured interviews were conducted with six producers purposively selected based on the status of their country and were drawn from a list provided by an informant with extensive experience working across the Western Division of New South Wales (NSW), Australia. Three producers (known as Producers 1, 3 and 5) operated more in a 'well-functioning' landscape whereas the other three producers (known as Producers 2, 4 and 6) operated in a 'recovering' landscape progressing to a better state. A 'well-functioning' landscape is viewed as one in which the biophysical system is functionally sound (with soil, water and nutrients retained on-site). A 'recovering' landscape is viewed as one that has been mismanaged in the past but now the function of the biophysical system is improving over time with management (with soil, water and nutrients increasingly retained on-site) (Tongway and Hindley 2005).

An interview schedule was designed around broad questions but with prompts to ensure the relevant data was collected. Firstly, background information was collected including a description of the enterprise (e.g. livestock type, herd/flock size, markets targeted) and the property (e.g. size, soil type, vegetation). This was followed by a broad discussion around the grazing management system (e.g. stocking rate, grazing practice, stock movement, mob numbers); management objectives (e.g. production and resource targets); and factors influencing the approach taken (e.g. physical, market). Finally, a discussion centred on the benefits from the grazing management system including both biophysical (e.g. landscape changes) and personal (e.g. wealth creation, lifestyle, well-being).

The interviews were conducted by telephone between July 2022 and February 2023 and with the permission of the interviewees the interviews were recorded digitally. The interviews were transcribed 'intelligent' verbatim by a private transcription service and are the principal source of data used in this paper. The median time taken for an interview was approximately 90 minutes with a typical word count around 12,000 words. The transcription data were examined and categorised around responding to the interview topics.

Key findings

All producer interviewees practiced rotational grazing in paddocks that had been previously subdivided apart from Producer 5 who set stocked large paddocks with extended rest periods. Livestock were run as single or multiple mobs according to producer preference. Merino or Dorper ewes were the core enterprise with most properties harvesting managed or unmanaged goats. The overarching management objective for producers: *"We just want to keep our grazing numbers at an appropriate level that can balance production and the natural environment"*

(Producer 3). There were, however, differences in management focus reflecting the status of the country they manage as explained below.

Well-functioning landscape producers

The primary focus of well-functioning landscape producers was to maintain and opportunistically improve healthy and diverse country allowing them to concentrate on achieving the highest quality feed practicable and to set high animal production targets. Producer 5 summed up the approach to their business:

"… trying to regenerate some land and maintain the better country as it is which, in turn, means we can have all year-round production and be able to turn off a large number of finished lambs from a small number of breeders."

The approach is underpinned by three core grazing management principles: maintain a consistent, conservative livestock number, foster productive, palatable plant species and implement flexible rest periods as this group of producers explained:

"The nature of the seasons out here is that when it's good, it's so good. … it's important to have the breeding stock at the right numbers so you can capitalise on that from an economic perspective, but also having the number set so if the season does dry off, you're still not rushing to sell a heap of stock off."

"We watch certain species like … bladder saltbush. Once the animals start to graze them the alarm bells start to ring. … It's a fairly unforgiving species … because if you graze too hard you've got to start from scratch again."

"So, any country that needs a spell to regenerate bush we can give the country … six months or one or two years off or whatever we think it needs."

The grazing strategy employed ensures ground cover is at least maintained, if not improved, enabling the country to withstand frequent and severe droughts minimising any soil loss from erosion.

Recovering landscape producers

The focus of recovering landscape producers was primarily on progressively improving landscape function and the role of livestock was to support achieving landscape goals. Initially when these producers acquired the property, they made substantial production trade-offs but overtime as their management gradually improved the landscape, they made less production trade-offs and had more enterprise options available, for example, moving from agisting cattle to a self-replacing Merino flock. The typical business approach for these producers:

"What drives our business here is … call it a goal what we want our landscape to look like … which determines most of our actions. As in our stock [numbers] … have got to be in balance with the land" (Producer 2).

The approach is underpinned by three core management principles: foster the seedling growth of valued species, encourage the growth and expansion of perennial species and adjust stock numbers to match carrying capacity. As these producers explained:

"Where we have potential [for] a lot of new seedlings of desired species coming on … our grazing [duration] would certainly be much shorter … particularly the seedlings that are coming away [i.e. recently emerged]."

"We've got to monitor and know how much distance there is between our perennial plants. So, we do monitor … at least annually. After a year's grazing [we know] we are actually improving the volume of perennial plants."

"The recovery of the most severely grazed perennial plant is the key to when you move them [livestock] and how long before you can come back."

The grazing strategy enables renewal of country with a change to more desirable species, a re-establishing of existing plants, an improvement in soil health and a *"better"* ground cover. But as Producer 2 cautioned: "*These rangelands out here are very fragile. One good year of work can be undone and can set you back 10 years of progress by getting one year wrong"*.

Personal benefits

Producers identified a mix of economic, environmental and social benefits attached to their grazing management and property. Producers expressed a sense of accomplishment from their 'care' of country as demonstrated by their 'attentiveness, responsiveness and adaptation' (Dreyfus and Dreyfus 1986 cited in Krzywoszynska 2015) in their grazing management practice: *"how we run our business ... it's in our best interest to take care of our landscape. That's very important to us."* and from building a viable, resilient business in a "*very reliably unreliable location"*. It provides a satisfying way of life: *"a beautiful place to live. And you get to see a huge variety of seasons. And you watch the weather every day. It is a great and exciting place to live and work."*

Producers described the connection between the status of country and personal well-being. "I didn't realise it, but my mental health is very attuned to the health of the land. … So, when the country's doing well, I'm doing well." Another important factor … is actually having land, which is in the condition it's in, because that makes life a lot easier. We're so fortunate to have a … pretty healthy environment". Country is viewed as something producers can nurture and restore back to health: "I really want to heal the land … I do admire the way we're doing it".

Discussion and conclusion

A key limitation of this study is that only six rangeland producers from across the Western Division of NSW were interviewed and there is no suggestion that these findings are reflective of the industry. Rather it provides some insights into how producers manage their livestock operation under differing landscape conditions and the co-benefits they believe they receive.

The producers interviewed considered land condition, the quality of the forage base and animal requirements in developing their grazing management strategy. Irrespective of whether producers operated in a well-functioning or recovering landscape, they practised a system of rotational grazing and prioritised the management of native pasture species reflective of the 'tactical' approach recommended by Campbell and Hacker (2000) as 'best practice'. However, there were differences between producers in their management objectives, and this depended on the productive capacity of the land in setting production and landscape targets.

Despite the property size, these producers possessed an intimate knowledge and understanding of the natural environment, its complexities and frailties. This study provides insights into how they use their grazing to maintain or build ecological resilience, in so doing demonstrating their environmental stewardship (Rajala et al.).

Producers revealed a strong connection to their land as evidenced by the positive emotions they expressed about it. To an extent this connectiveness bestows these producers with a personal resilience compensating for the difficulties they may face working and living in a challenging environment on which they depend for their livelihood.

This study provides policymakers with an understanding of how some rangeland producers are balancing production and landscape function for long-term viability. Irrespective of whether they operate in a well-functioning or a recovering landscape, producers interviewed were not prepared to compromise resource condition over production.

Acknowledgements
We would like to thank the red meat producers interviewed for their time and valuable insights. This research study was a component of the Meat and Livestock Australia Limited funded project, "Sustainable Pathways to CN30" (project number B.CCH.2121). The study was approved by the NSW Department of Primary Industries and Regional Development Human Ethics Committee, approval number 'HRE-NLR—2021-6 Pathways to a carbon neutral red meat sector by 2030'.

Cattle walk further than 3 km from water in central Australia, but only if they have to!

Materne, C[1]; Taber, L[1]; Cowley, R[2]; Wirf, B[2]

Abstract
In arid central Australia pastoral leases are very large (2000–5000 km^2), with large paddock sizes (200–500 km^2), are often poorly developed with few waters, and some stations remain largely unfenced. Although cattle spend most of their time within 4 km of water, it is not uncommon for more than 50% of station area to be beyond 4 km from water. This has consequences for carrying capacity and utilisation of central Australian stations. If paddocks are stocked to total area rather than watered area, this can lead to high pasture utilisation within 4 km of water and low animal performance. Cattle landscape use was investigated in the Paddock Challenge project (Materne *et al.* 2025) to help inform producers about future development options and to test current carrying capacity methodology assumptions. The study used GPS collars to track the location of 280 cattle in nine paddocks on four stations. In this paper we examined the locational data to see how water location influenced cattle landscape use. The data can be used to identify future infrastructure investment and adjustment of stocking rates to optimise landscape use, and cattle performance and production. Cattle spent about 70% of their time within 3 km of water and 90% of their time within 4 km, but this depended on pasture utilisation. The higher the pasture utilisation, the further cattle walked from water. This is consistent with the current Northern Territory (NT) long-term carrying capacity (LTCC) methodology, which assumes cattle use all the area within 3 km and half the area between 3 and 5 km. Information about cattle landscape use was used by producers to inform management and development decisions. The results highlight new opportunities for improving cattle management and addressing environmental, production, and economic goals on Central Australia's commercial cattle stations. The locational data will be further analysed to look at the effect of land type, fire, rainfall and seasons on landscape use and link landscape use to animal performance.

Introduction

Arid rangelands in central Australia, with large pastoral leases and paddocks, often face significant infrastructure limitations. Water points are a large factor influencing cattle distribution and forage utilisation in northern Australian rangelands (Hodder and Low 1978; Tomkins *et al.* 2009). As a result, an estimate of watered area needs to be factored into the assessment of safe utilisation rates on extensive properties (Walsh and Cowley 2011). In central Australia, a 5-km grazing radius was recommended to capture most grazing pressure (Squires 1981), but Hodder and Low (1978) found cattle typically grazed within 3 to 4 km of water in good seasons and up to 8 km in drier years. In the Barkly region, while cattle can range up to 11 km from water during the late dry season, 80–90% of their activity occurs within 5 km, and 65% of that is within 3 km (Fisher 2001; Cowley *et al.* 2020).

Current NT LTCC methodology assumes the majority of grazing occurs within 5 km of a watering point, most of which occurs within 3 km (Cowley and Walsh 2023). This has been reduced from 8 km (Bastin and Shaw 1988) and 5 km (Chilcott 2005) previously used in the region. The assumed watered area has a large impact on a station's estimated carrying capacity. The Paddock Challenge was a federally funded project aimed at evaluating the profitability of applying recommended carrying capacity on two pastoral properties in Central Australia. As part of the Paddock Challenge project, landscape use was monitored by GPS collars to provide local data to test the watered area assumptions of the carrying capacity methodology used in central Australia (Materne *et al*. 2025).

Methods

Cattle landscape use was tracked with Global Navigation Satellite System (GNSS) collars. Three hundred GNSS collars were deployed across four stations and nine paddocks, between July 2023 and May 2024. Each paddock contained 20 collared animals per class, providing tracking data every 10 minutes (Table 1). Each collar was swapped approximately every 4 months depending on stations' planned activities. Data within 100–150 m of a waterpoint was excluded from the analysed data to remove the records of cattle camping at waters. GNSS data was processed using QGIS and Python scripting for spatial analysis and pattern identification, with data points filtered based on distance from water. Pasture utilisation (the percent of annual pasture growth eaten by livestock) was modelled in paddocks following Cowley and Walsh (2023) assuming cattle grazed within the watered area, defined as all the area within 3 km and half the area within 3 to 5 km. Where modelled data was not available, pasture utilisation was estimated based on previous years modelled data on the Old Man Plains Research station (OMP) and knowledge of current stocking rates and percentile pasture growth.

Results

All stations experienced well above average rainfall (80th percentile class) and pasture growth prior to the deployment of the GNSS collars (2022/23). Mt Denison (MDS) and OMP recorded a further above average season in 2023/24 in the 75th percentile class while Mulga Park (MGP) and Lyndavale (LDV) only recorded average conditions in the 50th percentile class. Data duration varied between collars due to battery life and retention. Not all deployed collars were retrieved on all dates, hence the range in number of collars given in Table 2. Cattle predominantly spent time within 4 km of water, despite significant areas of the paddocks being further than 5 km from a water source.

Utilisation rate influenced time spent with distance from water. With low pasture utilisation rates (5–15%) cattle generally spent greater than or equal to 70% of their time within 3 km from water, and 90% within 4 km, while paddocks with medium to high utilisation (>15%) only spent 45–50% of their time within 3 km of water and up to 28% of their time further than 5 km from water (Table 2). The exception to this was Mary's Paddock on Mulga Park where cattle spent time in the far northern side of the paddock greater than 5 km from water, even with low utilisation rates, perhaps due to localised storm activity. Landscape use with distance from water did not vary with cattle class or coat colour.

Discussion

Producers in the Paddock Challenge used information on how cattle were using the paddocks to inform future water development. In the NT, LTCC is calculated by:

Median Pasture Growth × Utilisation Rate / Demand × Watered Area (100% within 3 km + 50% within 3–5 km).

Cattle landscape use with distance from water in these central Australian paddocks is consistent with the watered area assumptions of this methodology and is consistent with findings on the Barkly in an extensive Mitchell grass paddock, where the number of cattle per waterpoint was the most reliable indicator of grazing distance from water (Cowley *et al*. 2020). Higher utilisation rates are associated with poorer animal performance due to decreased diet quality and quantity (Ash and Stafford Smith 1996). Stocking to the LTCC by watered area will help to ensure adequate feed is available within their preferred 0–4 km grazing range and potentially improve animal performance and productivity. Here we found that cattle walked further with higher utilisation rates, which suggests cattle were walking further from water to meet their nutritional requirements. Walking further distances will incur an additional energy cost which could further reduce animal performance.

Table 2. Summary of time spent in relation to distance from water. * Estimate

	Stuart South	Steer	n =18-3	5-15*	87.3	12.0	0.5	0.2
	Stuart North	Steer	n =16-3	15-30*	44.6	32.5	13.8	9.1

Paddock size will influence how cattle use the landscape. In the small 26-km^2 South Stuart paddock only 1% was beyond 5 km from water, which obviously limited use beyond 5 km. However, the pattern of paddock use was very similar to that observed in the massive 2960-km^2 Night paddock with 40% of the total area beyond 5 km from water. Both paddocks had low estimated pasture utilisation, and in both paddocks, time spent within 3 km from water was more than 80% and beyond 5 km less than 1%.

Although pregnant cows’ increased water needs during late gestation leads them to visit water points more frequently (Creamer and Horback 2024), steers did not travel further from water than breeders, regardless of pasture utilisation levels, or whether over the cooler (MDS) or hotter (OMP) months. Similarly light-coated cattle are more heat adapted than dark-coated cattle (Barendse 2017), which could potentially influence time spent with distance from water. However, breeder time spent with distance from water on Lyndavale did not vary between coat shades. It is possible that heat stress was not an issue when data was collected, although it did include data during spring and summer.

In this study we estimated pasture utilisation for some locations, but we intend to model pasture utilisation for these sites in the future. Additionally, factors such as land type, fire, rainfall, and seasons and using the speed animals were travelling to distinguish between cattle grazing, walking, and resting will be examined, as well as linking landscape use to animal performance. Although this study was based on relatively small numbers of cattle, they represent real commercial enterprises. It provided an invaluable demonstration to producers of how their cattle are actually using the landscape, opening up discussion on current management practices and planning future developments.

Conclusion

Data from the Paddock Challenge project provided insights into cattle movement patterns, highlighting that despite large paddock sizes, cattle class or coat colour, if stocked to the LTCC, cattle often used only a fraction of the available grazing land beyond 4 km. The influence of water and land type on grazing patterns warrants further exploration, particularly in relation to stocking rates and carrying capacity over different seasons. Investing in water infrastructure to better distribute grazing could reduce pasture utilisation and enhance animal performance and production in poorly watered areas.

Cushioning pastoralist against the effects of drought: The case of beef feedlotting and rangeland restoration

Nenkari, Halima[1]; Menjo, D[2]; Muiruri, P[3]; Tura, I[4]

[1] State Department for Livestock Development, Kenya; [2] Executive Office of the President, Kenya, [3] Food Systems Resilience Project, Kenya; [4] Kenya Agricultural and Livestock Research Organization, Kenya

Key words: Feedlotting; Rangelands; Pastoralism; beef; Bottom-Up Economic Transformation Agenda.

Abstract

The beef industry in Kenya is the largest contributor to livestock value added products as well as a major contributor to income and employment. Its contribution to societal welfare is particularly relevant in the rangelands, where beef production is the main economic activity. The four major beef production systems in Kenya are pastoralism, ranching, agro-pastoralism systems, and feedlots (FAO, 2017). Feedlotting is one of the initiatives, being promoted through the Bottom-Up Economic Transformation Agenda (BETA) to cushion the pastoralists from perennial livestock losses, avail sufficient feeds and water, and access high-end and export markets for both live animals and meat. Currently the feedlot system is under-developed and faces challenges that affect returns; lack of stratification of production, high capital investment and low technical skills in feedlot management, limited availability of suitable feed due to competition for grains and long finishing times of up to 12 months in feedlots with poor productivity. The success of the BETA agenda will contribute to increased productivity, reduced livestock losses, increased incomes, and restored rangelands. At least 450 feedlots are to be established, one in each identified ward, to support at least 10 cooperatives, create employment for livestock extensionists/advisors/service providers and entrepreneurs in the value chain using the best technologies and innovations. Pastoralists will have guaranteed market for their livestock and the reduced stocking pressure will facilitate recovery of rangelands.

Introduction

Globally, rangelands are considered to be the world's largest ecosystem biome with high biodiversity and socio-economic and cultural value (Bengtsson et al. 2019). Rangelands cover over 54% of the world's terrestrial surface (Rangelands Atlas 2024) and support over 30% of world's human population (Sala et al. 2017). Locally, the Arid and Semi-Arid Lands (ASALs) cover 80% 89% of Kenya's landmass (Birch 2018), accounting for 30-out of a total of 47 counties, with these areas mainly defined by their levels of aridity, consistently high ambient temperatures, and low rainfall that has high spatial and temporal variation of 200 to 750 mm annually (Pratt and Gwynne 1977; Heady 2019). Vegetation of the ASAL areas is made up grasslands, wooded grasslands and shrub/woodlands (Nyongesa et al 2023).

Estimates show that the ASAL areas hold approximately 16 million people, which is about 30% of national population (Njoka et al 2016). The climate and vegetation type has for centuries supported pastoralism as the main livelihood (Nyariki and Amwata 2019). While traditionally pastoralism was classified as a livelihood type where majority of the people derive more than 50% of the livelihoods from livestock (Dong 2016), we adopt a much broader definition that embraces a landscape and systems approach (Plieninger et al 2023). This is because of the many goods and services that are provided by pastoralism and its landscape that have often been overlooked, namely fish, tourism, inputs in agriculture, recreation, environmental, support and regulatory services.

Recent estimates quantified the value of the pastoral sector to have an economic worth of US$1.13 billion (Nyariki & Amwata 2019) with the livestock sector and non-livestock sector accounting for 92% (US$1.04 billion) and 8% (US$0.0903 billion) respectively. The livestock sub-sector, which is the mainstay of the ASALs contributes 10% of the GDP (KNBS 2023), and employs more than 50% of the ASAL based workforce (AECF 2020).

Despite their demonstrated and strategic importance to Kenya's economy and overall development, the ASALs face several challenges limiting their potential and contribution to national development. The ASAL areas are prone to droughts, which have become more frequent and intense in the last 15 years (Haile 2019). They are also very susceptible to the vagaries of climate change (SEI 2023); aside from droughts and low rainfall, these include floods, livestock disease outbreaks, attacks by invasive species, and even locusts.

Before the advent of the devolved government (Odhiambo 2013) ASAL areas received minimal national development investments. The ASALs have also attracted increasing human population given their vast spatial coverage on the one hand and increasing population pressure in the more mesic parts of the country. The majority of these people (One future trust 2024 settle down to practice crop production in these marginal lands but often with inappropriate technologies and mindset of the higher potential areas. Vast areas of the ASALs are also degraded (Wavinya 2023) with patches of bare soils, gulleys, hard pans and species (NRT 2023), rendering pasture production and access by livestock impossible. These challenges have negatively impacted the environment and livelihoods in these areas, including massive loss of livestock during droughts (NDMA 2023), floods and disease outbreaks (SEI 2023) e.g. Peste des Petits Ruminants (PPR), East Coast Fever (ECF), Foot and Mouth Disease (FMD), Rift Valley Fever (RVF); degradation of the range and environment, and visible low Human Development Index (HDI). Consequently, literacy levels, sanitation, social amenities are low, while poverty and malnutrition are very high (GoK 2016).

The estimated livestock population of Kenya's ASALs is 16 million beef cattle, 33 million goats, 22 million sheep and 4.4 million camels. With respect to production of beef, Kenya currently produces 244,217 MT as at 2022 (Statista 2024; NIPFN.KNBS 2024) annually, a huge drop from about 589,000 MT in 2017 (Statista 2024). Consumption is estimated at 553,200 MT (FAO 2016; Kenya Market Trust 2020, PETs- BETA 2023) with per capita consumption estimated at 16 kg (Kenya Market Trust 2019). Kenya has an estimated beef production deficit of some 308,983 MT (Kenya Market Trust 2019), a gap that needs to be closed. Currently, the gap is filled informally by livestock from neighbouring Tanzania, Uganda, Ethiopia and Somalia (ibid).

It is against this background that the government through its Bottom-up Economic Transformation Agenda (BETA) developed a Pastoralist feedlot system program to address the challenges.

Methods

Based on the above, we propose a food systems approach that targets the traditional livelihoods of the pastoralists as possible and pragmatic options that can address the challenges in the long run. The proposal is anchored on establishment of pastoralist feedlot systems integrated with measures of improvement in the primary resource base – rangelands, improvements of livestock production and provision of opportunities for diversifying sources of incomes.

The project will be implemented in 450 wards of 31 counties with Arid, Semi-Arid and marginal environments. Each feedlot will be made up of approximately 5,000 acres of land, a water reservoir (dam) of 750,000 to 800,000m^3 capacity, water sources for the surrounding communities (e.g. boreholes).

One feedlot is expected to directly benefit ten villages around each feedlot, with an average of 25 households in a community for about 112,000 Households in total. It is expected that indirect beneficiaries from the program would be five times the number of beneficiaries per feedlot, giving an estimated 562,500 indirect Households as beneficiaries. This brings the total number of all beneficiaries to 674,500 Households that can be extrapolated to an average of 3 million persons. In addition to the direct beneficiaries, the program is projected to create at least 2,700 jobs directly in the feedlots, and a factor of at least 10 (27,000) jobs indirectly linked to the feedlots.

The feedlot systems program has been designed to open up opportunities for MSMEs and further jobs. The projected employment and business opportunities will also encourage children to go to school as the families will now settle and not move from place to place (nomadic lifestyle). The design is heavily reliant on the feedlots accessing livestock from the neighbouring pastoralist communities. The expectation is that each household will be able to sell at least two heads of cattle per month (24 annually) to the feedlot. The feedlots are expected to intensively fatten and finish the livestock with natural grass over a target three-month period (more realistically six months initially). The feedlots can sell finished livestock as live animals or slaughter and sell as carcasses. Whichever option, it is expected that the feedlot will share a portion of the profits as bonus payments to the supplier communities.

Secondly, the feedlot system will strive to enhance rangeland improvement outside the feedlots, directly targeting the neighbouring pastoralist grazing areas. This will be a collaboration with the local communities in a participatory manner in order to secure the targeted area for rehabilitation. For a start, the program will target about 20,000 acres of pastoral land through the in-situ soil and water conservation method, using the Vallerani system that has already been tried and tested. The Vallerani System (VS) is a mechanized system that combines traditional water harvesting techniques and the mechanization of micro-basins, for the restoration of large-scale degraded soils, which can be applied for reforestation, pasture improvement, crops, windbreaks, etc (Vallerani System EN | Vallerani System). Other rangeland rehabilitation techniques including bush clearing, scratching and in extreme cases, reseeding will be applied to enhance rangeland pasture and forage production and productivity.

To increase feedlot production and productivity, the program will target the improvement of pastoralists livestock genetics, through a participatory breeding program and a comprehensive livestock disease surveillance and management program. Because of the prevalent droughts where water and pasture become inadequate, each feedlot will have a portion of the land dedicated to pastoralist resilience. The feedlots will produce forages and sell these to the pastoralists during periods of scarcity. A key feature underpinning the program design is ensuring investments have quantifiable and positive returns on investments. It is proposed that the feedlots be run as a profitable venture, even while involving participation of the local communities. The program will provide options and guidance for effective management of the feedlots.

Results/Progress

Three Counties already have the feedlot infrastructure in place and are at different levels of implementation with more counties committing resources to fence off the initial 5,000 acres identified with the community. It is expected that once the first three take off the rest will be motivated to fast track their implementation

Abstract

These projects were conducted in the subhumid rangelands (Klemme Research Range [KLEMME]) and on introduced forages Oklahoma (Eastern Research Station [ERS]) USA. Targeted supplementation to increase performance of growing cattle, maximise production per hectare, and replace synthetic fertiliser on pasture. Treatments at Klemme included: 1) Positive Control (PC)– 1 kg daily supplementation with distiller's grains (DDGS) cubes in late summer, or 2) High Supplement (HS) - DDGS cubes offered at 0.75% of liveweight all summer with 33% increase stocking rate. Treatments at ERS included: 1) Fertilized Control (FC) - no supplementation on N fertilized pastures; 2) Fertilized Supplement (FS) – steers fed 1.2 kg/day supplemental DDG cubes on N fertilized pastures throughout the summer; or 3) High Supplement (HS) – steers supplemented DDG cubes at 0.75% of BW/d on unfertilized pastures.. The HS treatment increased LW gain/ha by 89% compared with PC at KLEMME and increased steer performance while replacing synthetic N inputs in FC and FS treatments at ERS. At KLEMME, calculated N use efficiency, N2O emissions, methane emissions, total CO2 equivalent emissions and CO2 equivalent emission intensity (kg/kg LWG) were decreased in HS. At ERS calculated N use efficiency, N2O emissions, total methane emissions total CO2 equivalent emissions and CO2 emission intensity were intermediate for HS, but CO2 equivalent emission intensity was improved. Performance of steers followed through finishing on high-concentrate diets were not affected by previous supplementation treatment during grazing and increased gains prefinishing resulted in similar carcass weights with decreased days on feed and 15% less total feed required for finishing without impacting carcass quality. Targeted supplementation has the potential to increase performance in intensified grazing systems, increase beef production per hectare, and reduce grazed forage and harvested feeds with the potential to reduce the overall environmental impact of beef production.

Introduction

Producers are under significant economic pressures to maximize production per acre, which can prove harmful to the range condition, when desired forage species are overgrazed and decline in the stand. Feeding high levels of supplemental feed based on corn co-products of the ethanol production industry can offset forage consumption by 0.5 to 0.55 kg per kg supplemented in grazing calves (Adams et al., 2022a) and lead to higher stocking rates, without reductions in forage mass and animal performance (Wallis et al., 2023).

Research examining subsequent feedlot performance and carcass quality as affected by stocker supplementation programs continues to be limited and generally inconsistent (Reuter and Beck, 2013). A novel extruded dried distillers grains (DDG) cube (MasterHand Milling, LLC; Lexington, NE) has recently reached the market in the Great Plains states, expanding the potential utility in feeding these byproducts without feedbunks and losses to wind. Therefore this project is proposed to investigate the impacts of DDG cube supplementation and increased stocking rates on performance, sustainability, and subsequent finishing performance of growing steers grazing native range in western Oklahoma (Klemme Research Range, Besse Ok; KLEMME) with comparison to similar projects conducted at the Eastern Research Station near Haskell OK, which is composed primarily of bermudagrass based pastures (ERS).

Methods

Klemme Range Research Station

Grazing trial was conducted Marvin Klemme Range Research Station (Klemme), near Bessie, Oklahoma (35°25’00.4” N, 99°03’42.6” W). This site is characterized by rolling Red Shale uplands (2 – 15% slopes) dissected by deep drainages with shallow Cordell silty clay loam soils, which are shallow (25 to 36 cm) and contain numerous rocky outcrops of hard red siltstone. These Red Shale sites support mixed-grass prairie as the potential climax natural vegetation (Gillen et al., 2000). The steers grazed for 130 days from mid May to early October each year and were follwed through finishing in a commercial feedlot.

In each year, 140 steers (BW = 240 ± 21 kg in yr 1 and 255 ± 19 kg in yr 2) were randomly allocated to the 6 pastures. Pastures were allocated to 2 supplementation treatments (n = 3 pastures/treatment), 1) Positive Control (PC) - steers were stocked at 2.4 ha/steer and provided with 2.26 kg of supplemental DDGS cubes on alternate days (daily supplementation rate of 1.13 kg/steer) only during the late summer; and 2) High Supplement (HS) – stocking rate of steers were increased by 33% (1.6 ha/steer) with supplemental DDGS cubes provided at a rate of 0.75% BW/d for the entire grazing season.

Eastern Research Station

Grazing trial was conducted at the ERS station in eastern Oklahoma, the methods and results of the grazing experiment are reported in Adams et al. (2022b). Briefly, each year, crossbred steers (n = 140) were assigned to pastures, and pastures were assigned to one of three treatments (n = 3 pastures/treatment); 1) Fertilized Control (FC) - steers grazed N fertilised pastures (112 kg N/ha) with no supplementation; 2) Positive Control (PC) – steers were supplemented DDG cubes at 1.2 kg/d prorated for 3-d/wk feeding on N fertilized pastures; or 3) High Supplement (HS) – steers were supplemented DDG cubes at 0.75% of BW/d prorated for 5-d/wk feeding on unfertilized pastures.

Subsequent Finishing

Following summer grazing at KLEMME and ERS, steers were transported to a commercial finishing operation (Buffalo Feeders LLC in Buffalo Oklahoma) to evaluate the carryover effects of summer supplementation on finishing performance and efficiency. Because of the size and scale of the pens in the commercial feedlot used for finishing the steers, the steers were comingled across treatments and pastures within the commercial scale pens to remove and confounding effect of pen allocation. Steers were transitioned to high concentrate finishing diets by providing a starter and 2 step-up diets with progressively lower concentrations of roughage for 5 days each with 2 day rations blending between each step. Steers were fed until a targeted 1.5-cm backfat was reached at the 10th rib.

Calculations

Equations from Garrett et al. (2004), Guiroy et al. (2001), and Tedeschi et al. (2004) were used to estimate composition of BW and gain and to allocate individual DM intake (DMI) to steers within pens. This allowed for determination of feed efficiency (G:F), and days on feed required to reach 28% EBF during the finishing period for individual animals. Nutrient retention and greenhouse gas emissions were calculated as well, based on NASEM (2016) and IPCC (2007) equations. Net protein retained in LWG (NPg) and Net Nitrogen (NN, g/day) were used along with estimated N inputs to calculate N use recovery. Enteric methane and emissions were calculated using equations from the Intergovernmental Panel on Climate Change (IPCC, 2006). Methane emission conversion to CO2 equivalents were made using a conversion factor of CH4 $\times 25$ and Nitrous Oxide conversion to CO2 equivalents were made using a conversion factor of N2O $\times EF \times 298$.

Statistical Methods

Performance and calculated greenhouse gas emissions were analyzed for each location separately using the mixed procedure of SAS (SAS Inst. Inc. Cary, NC). The original pasture group was used as the experimental unit in this analysis, due to the comingling of cattle in pens for finishing. The fixed effects in the model included the supplementation treatment on pasture, the year and the year by treatment interaction. The random effect included pasture within each treatment by year. Least-squares means were separated using the predicted differences statement in SAS.

Results

Grazing Performance and Calculated Greenhouse Gas Emissions

At the KLEMME site, steers grazing native range with the HS treatment gained 0.12 kg per day more than PC (0.98 vs 0.87 kg/d, respectively), even though stocking rates of the HS was increased by 33%. This led to a 75% increase in LW gain/ha for HS (84kg/ha) compared with PC (48 kg/ha), which indicates that the increased feeding rate more than offset the reduction in forage availability and reduced grazing selectivity from the increased stocking rate. The increased performance lead to an increase in protein accretion by the steers improving N use efficiency, which reduced calculated N_2O emissions. There was no difference in calculated enteric methane production per steer, but total emissions (kg CO_2 equivalents/steer) and emission intensity (CO_2 Equivalent/kg LW gain) were less for HS than PC, which is related to the increased intensity of production in the HS treatment.

At ERS, supplementing at the high rate increased overall LW gain/d (0.87, 1.10, and 1.16 kg/d for FC, FS, and HS, respectively) and LW gain/ha (360, 458, and 487 kg/ha, respectively), indicating that supplementation rates offset the use of synthetic fertilizer for beef production. Nitrogen use efficiency was greater for FC than FS and HS, which did not differ. N_2O emissions were greater for FS than FC, while HS was intermediate. Calculated ruminal enteric methane production per steer was not different, but similar to N_2O emissions, Total emissions in CO2 equivalent per steer were greater for FS than FC with HS being intermediate. Due to the higher production in HS the emission intensity was lowest for HS compared with FS and FC which did not differ.

Finishing Performance and Calculated Greenhouse Gas Emissions

Steers from HS at the KLEMME range site were 25 kg heavier than PC at entry into the feedlot (393 kg vs 368 kg, respectively). The HS steers maintained this weight advantage by the time steers were reimplanted. Liveweight gain per day (1.5 kg/d) was not different during the finishing period, but Gain:Feed was greater for HS than PC. The lack of performance difference and reduced feed efficiency in PC are indications that there was no compensatory gain from the gain reduction on pasture for the PC steers. There was no difference between treatments in liveweight at harvest, hot carcass weight, backfat thickness or carcass quality, but PC steers took 27 more days to finish than HS (192 days vs 165 days, respectively). There was no difference in N use efficiency during finishing buy N2O emissions, enteric methane and total emissions (CO2 equivalents, kg/steer) were reduced for HS compared with PC. Emission intensity (CO_2 Equivalent/kg LW gain) tended to be less for HS than PC.

Similar to KLEMME, for steers from ERS there was no difference in liveweight at harvest or hot carcass weight, but the FC took more days on finish than FS and HS. Nitrogen use efficiency was highest for FC, but total N2O and methane emissions (and thus Total Emissions, CO_2 equivalent/steer) were greater for FC than FS and HS.

Discussion

Producers in the USA are under pressures to maximize production by increasing stocking rates which can harm range condition and animal performance. A compact and durable DDG cube produced via a novel extrusion process improves utility in pasture supplementation by reducing wind loss and soil mixing, which is common when supplementing loose DDG in pasture settings. Feeding supplemental dried distiller's grains (DDGS) has been shown to offset forage consumption (Adams et al., 2022a) by 0.55 kg for each kg of DDGS cubes fed, which may allow for increasing stocking rates without impacting range condition. This research indicates that stocking rates can effectively be increased on native range pastures in the Southern Great Plains of the USA without reducing individual animal performance, thereby increasing total production per hectare. Replacement of synthetic N fertiliser without impacting pasture carrying capacity while increasing grazing performance is also a boon to sustainable grazing systems in introduced pastures.

Many producers are wary of adding weight gain while grazing steers fearing that additional gain prior to entering the feedlot will adversely affect finishing performance. In the current experiments, there were very little if any indications of compensatory growth in the control calves. The calves fed supplemented at the high rates in both experiments retained the advantages in weight during finishing and required less days on feed to reach the targeted finishing end point.

The increased performance while grazing to offset increased stocking rates (KLEMME) or reduced synthetic fertiliser use (ERS) reduced the environmental impacts of the grazing enterprise and these benefits carried over into the finishing phase of production by reducing feed use, days on feed, and greenhouse gas emissions.

Intensification of extensive livestock systems using irrigated forages or hay – a bioeconomic modelling approach

Watson, I[1]; Prestwidge, D[2]; Liedloff, A[3]

[1] CSIRO Agriculture and Food, Ian.Watson@csiro.au

[2] CSIRO Agriculture and Food, Di.Prestwidge@csiro.au

[3] CSIRO Environment, Adam.Liedloff@csiro.au

Key words: Northern Australia; regional development; water resources; Victoria River catchment

Abstract
Despite its intuitive appeal, there is very little irrigated hay or forage production in the extensive rangelands of northern Australia used for beef cattle production. There are many reasons for this, including: constraints related to lease tenure conditions; difficulty and expense of obtaining regulatory approval for irrigation development; differing skills and capacity amongst the pastoral workforce; and the economic viability of growing irrigated hay or forage.

Theoretically, the use of irrigated hay or forage production would allow pastoralists (ranchers) more options for marketing cattle: meeting market liveweight specifications for cattle at a younger age; meeting the specifications required for different markets than those typically targeted by cattle enterprises; and providing cattle which meet market specification at a different time of the year. Forages and hay may also allow graziers to implement management strategies, such as early weaning or weaner feeding, which should lead to flow-on benefits throughout the herd, including increased reproductive rates.

We used a bio-economic model (CLEM, Crop Livestock Enterprise Model) to investigate the financial and production implications of growing forages for both hay production and for ‘stand and graze’ systems in the Victoria River catchment of the Northern Territory (NT). Predicated on the average annual utilisation rate of native pasture being kept constant, the use of irrigated hay or forages allowed a higher number of breeder cattle to be maintained. Total income, liveweight gain per animal, and total beef production increased with the use of irrigation. However gross margins were typically higher for the base enterprise, i.e. without irrigation. An analysis of NPV (Net Present Value) which considers the capital cost of development as well as the annual costs, suggested that irrigated forages and hay were only viable when the capital cost of development was low and the price of beef was high.

Introduction
The majority of catchments in northern Australia contain little intensive agricultural development, such as for cropping. Extensive beef cattle grazing (pastoralism) is the dominant agricultural land use and there is very little

development of surface water or groundwater resources, except for domestic use or to supply drinking water for livestock. However, there is recent interest, and research and development, aimed at investigating options to use these water resources more intensively (Moore et al., 2021).

The Victoria River catchment of the NT covers approximately 82,400 km^2 and about 62% is used for pastoralism (Petheram et al., 2024). The majority of property sizes are between 2,000 and 4,000 km^2 (Cowley 2014). Carrying capacity estimates range (depending on range condition) from a maximum of 12.5 to 23.0 AE/km2 (AE = Adult Equivalent, a 450 kg dry cow) on basalt-derived cracking clay soils to a low of 0.5 AE/km^2 on sandy and gravelly soils in poorer condition (Pettit, undated).

The predominant beef production system is a cow-calf operation with sale animals turned off at weights to suit the live export market. About 78% of all cattle across the broader region were Brahman, with about another 17% being Brahman derived (Cowley 2014). The majority of properties surveyed ran between 15,000 and 20,000 head of cattle. The majority of cattle (68%) were bred for live export with 22% bred to be transferred and grown-out elsewhere, often on properties which are part of the same aggregated agricultural business.

Feed quality of native pasture declines in the dry season, and cattle struggle to maintain weight during this period. To counter this, a commonly held view within the northern cattle industry is that the development of water resources would allow irrigated forages and hay to be integrated into existing beef cattle enterprises, thereby improving their production and potentially, their profitability. Ideally, production would increase by allowing cattle to reach minimum selling weight at a younger age and allowing for greater weight gain during the dry season when animals on native pasture alone either lose weight, or gain very little weight. There are also potential benefits to the reproductive capacity of the herd by providing better nutrition to young females. Finally, the addition of forages and hay should allow more cattle to be carried, while still maintaining a constant average utilisation rate of native pastures. However, despite this, there are very few examples across northern Australia of beef enterprises integrating irrigation into the business.

Methods

A bio-economic modelling approach was taken using CLEM (Liedloff et al., 2024). The model is a more sophisticated improvement of an earlier model but retains the core principles of a whole-property dynamic simulation which links feed availability, animal performance, management operations and business performance (Ash et al., 2015).

Simulations included: a base enterprise with no supplemented feed; a base enterprise in which weaners were supplemented with hay bought on the open market (common practice within the industry); stand and graze options for both forage sorghum and lablab and; hay produced on-farm from both forage sorghum and Rhodes grass. Forages or hay were fed to all cattle which were weaned and less than 24 months old during the period from June to October (or June to September for the shorter growing season lablab). Excess hay was sold into the open market. Selling months were May and September/October. All male cattle (not including bulls) were sold once they had reached a minimum liveweight of 280 kg. The bottom 30% of females (as a proportion of normalised weight) were sold at a minimum liveweight of 280 kg while the model dynamically balanced breeder numbers at each sale date with further sales where required. The maximum breeder numbers were set for the period of the model run so as to maintain an average annual utilisation rate of 20% (cattle offtake of native pasture equal to 20% of native pasture growth, averaged across years), as recommended by Walsh and Cowley (2014) and in the Land Condition Guide of Pettit (undated) for clay soils. A limited sensitivity analysis was performed by considering LOW, MED (Medium) and HIGH beef prices. Gross margins, profit (as EBITDA earnings before interest, taxes, depreciation and amortisation) and NPV (net present value, which captures the capital costs required for irrigation development) were considered. The number of breeders on properties in the Victoria catchment is typically higher than the number modelled here, due to large output file sizes from CLEM's individual animal modelling. The herd size (and subsequent results) could be scaled by a factor of around 10 to reflect this (notwithstanding economies of scale in such scaling) but the raw modelled results are presented here. Further detail of the enterprise set-up and modelling assumptions are provided in Webster et al., (2024).

Results

Irrigated forages and hay increased the total liveweight of cattle sold and weaning percentages (Table 1). Gross margins were higher under the two baseline enterprises, reflecting the high variable costs associated with growing irrigated forage and hay, although the decision to irrigate becomes more attractive at HIGH beef prices. At MED beef prices, EBITDA was highest for the Rhodes grass option – profitability is highly sensitive to the cost of the irrigation options and the area of irrigation required to provide sufficient feed for each cohort. The NPV analyses showed that none of the irrigated options had a positive NPV. A significant proportion of the animal production increases at the property scale were due to increased number of breeders which could be carried when irrigated forages or hay were included in the feedbase. The estimated capital cost of development was between AUD $1.3 million and $8 million, depending on scenario and cost per ha of development.

Cattle fed irrigated forages or hay increased their rates of growth compared to the two baseline options. This meant that sale weight was reached at a younger age (Table 1). At the extreme, nearly 79% of the cohort of male cattle between 8 and 12 months old were sold in October under both hay options while none of the same cohort were sold then under the two baseline options. The majority of these cattle were sold in the following May, contributing to the stocking rate over the wet season.

Discussion

Despite the intuitive attractiveness of introducing irrigation to extensive beef cattle enterprises, very little is practiced in northern Australia. While animal production benefits can be obtained, both the initial capital outlay and ongoing costs of intensified development preclude it being a viable option – unless graziers are able to operate under a lower cost structure than modelled here, or have patient capital. In addition the enterprise would need to develop, or buy in, the additional expertise and knowledge required to run a successful irrigation enterprise of that scale. This is a constraint recognised by graziers elsewhere in northern Australia (McKellar et al 2015) and almost certainly contributes to the lack of uptake of irrigation in northern Australia. Specialist hay production is another option, but largely occurs now outside of the extensively grazed rangelands.

Key words: legume/grass mixtures; semi-arid; Cenchrus; Megathrsus

ABSTRACT:
Sixty per cent of the IGAD landmass is arid and semi-arid. In Kenya the semi-arid and arid (ASAL) make-up 80% of the land mass. Over 60% of the livestock in the region are found in the ASAL areas and contribute between 10-50% of the GDP of individual countries in the region. The ASAL areas are faced with a myriad of challenges including climate change, livestock forage availability and environmental degradation. During the last drought Kenya lost 2.1 million animals valued at USD 406,153 (KES 52.8 Million). The frequent droughts and reduced productivity of rangelands threaten the sustainability of the livestock sector in the region. The lack of year-round adequate quantity and quality feed supply results in low weight gain and milk production and high greenhouse gas emission per unit of livestock product. To address the challenge of feed quality and quantity, the performance of improved range grass varieties (*Megathrysus maximus* variety Siambasa and *Cenchrus ciliaris*) were evaluated as sole crops or intercropped with *Clitoria ternatea* or *Macroptilium atropurpureum*) at the KALRO centre in Kiboko Eastern Kenya. The experiment was an RCBD with treatments in a 2x3 factorial arrangement. Dry matter yield, proportion of grass/ legume, chemical composition, digestibility and in-vitro fermentation were determined. The DM yield ranged from 3.3 to 5.8 tonnes/ha with the highest in *M. maximus* mixtures and the lowest in *C. ciliaris* plots. The proportion of legume in the mixtures ranged from 84-20% with the highest levels in the *C. ciliaris* mixtures. The improved range grass varieties have the potential to increase forage availability.

Introduction

Approximately 62.9 million people in the IGAD region of East Africa are currently experiencing acute food insecurity (IGAD 2024). This is approximately 25% of the entire population of the region. About 60% of the region is classified as arid and semi-arid rangelands and livestock play a key role in food security. In the semi-arid areas of IGAD, livestock provides food, income and employment for millions of livestock farmers and pastoralist's communities in the region. Export of livestock and livestock products are a significant export from the region earning foreign exchange that is seriously required in the region. The livestock sub-sector contributes between 10-50% of the GDP of individual countries in the region. In Kenya, the semi-arid lands (SAL) make-up 80% of the land mass and are home to approximately 25% of the human population. These areas face persistent for insecurity a situation that is made worse by climate change. The semi-arid areas of Kenya are home to over 60% of the livestock (cattle, sheep, goats and camels) and over 70% of the wildlife (Odero-Waitituh 2017). Livestock production is the major economic activity in these areas and is key to food security, income and employment.

However, livestock production is constrained by a number of factors including; inadequate feed quantity and quality, low yielding breeds, poor animal health services, poor market infrastructure and environmental degradation among others. This has been made worse by climate change where we have more frequent severe climatic events including droughts and floods. During the last drought Kenya lost 2.1 million animals valued at USD 406,153 (KES 52.8 Million). The frequent droughts and reduced productivity of rangelands threaten the sustainability of the livestock sector in the region. Beef cattle grazing is a key enterprise in the Semi-arid areas, however poor quality and inadequate feeds especially during the dry season. Incorporating legumes into pastures improve the cattle diet and this study aims to evaluate the productivity of mixed range grasses and tropical legumes in the semi-arid areas of Kenya.

Methods

The study was carried out at the Kenya Agricultural and Livestock Research Centre in Kiboko, Eastern Kenya. Land was prepared and divided into 5 blocks with 8 plots of 5 x5 m. The treatments included two range grasses; *Megathrysus maximus* variety Siambasa and *Cenchrus ciliaris* and two tropical legumes *Clitoria ternatea* and *Macroptilium atropurpureum.* The experiment was established during the OND 2022 rain season. The grass and legumes were grown as sole crops or as mixed crops. The experiment was an RCBD with treatments in a 2x2 factorial arrangement. Four harvests were taking starting in April to November 2023. Proximate analysis was performed using standard AOAC methods (2006)> Fibre fractions were determined using the detergent fraction method (Van Soest, 1967). Dry matter yield, proportion of grass/ legume, chemical composition, digestibility and in-vitro fermentation were determined.

Results

Forage Yield

The DM yield ranged from 3.3 to 5.8 tonnes/ha with the highest in *M. maximus* mixtures and the lowest in *C. ciliaris* plots. The proportion of legume in the mixtures ranged from 84-20% with the highest levels in the *C. ciliaris* mixtures. The improved range grass varieties have the potential to increase forage availability.

M. maximus var Siambasa as a sole crop had a signifactly higher yield *($P<0.001$)* than *C. ciliaris* (Figure 1). *C. ternatea* had a significantly higher *($P<0.03$)* dry matter yield than M. atropurpureum (Figure 1). The M. maximus intercropped with *C. ternatea* and *M. atropurpureum* had lower dry matter yield than *M. maximus* sole crop.

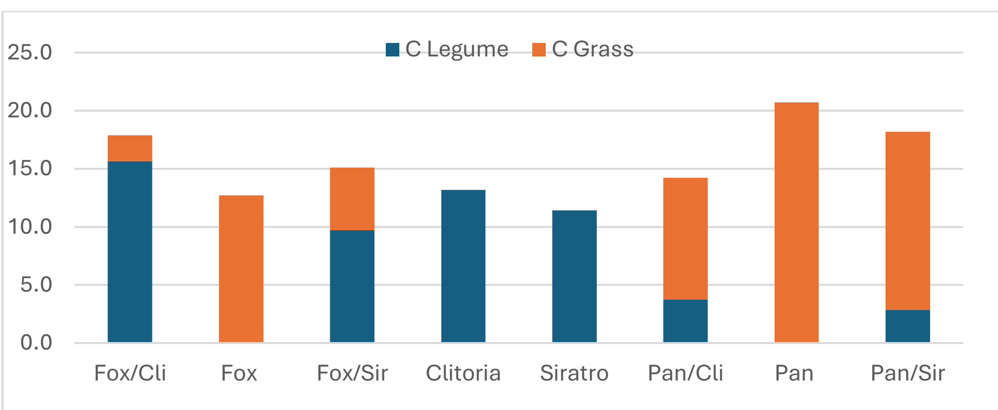

Figure 1: Forage Dry Matter Yield of Range Grasses and Tropical Legumes (t/ha)

The crude protein yield for the grass/ legume mixture ranged from 1.2 to 2.6 tons/ha/year (Table 1). The inclusion of legume increased the total crude protein yield especially when grown with *C. ciliaris*. However, the total crude protein yield was lower in both the *M. maximus* legume mixtures (Table 1).

Table 1: Crude Protein Yield for Range Grass and Legume Mixtures in Kiboko, Kenya (kg/h)

	C. ciliaris/Clitoria	*C. ciliaris*	*C. ciliaris/ siratro*	*Clitoria*	*Siratro*	*M. maximus/Clitoria*	*M. maximus*	*M. maximus/Siratro*
Grass	2176.0	1232.9	523.8	0	0	1143.6	2259.3	1671.9
Legume	30.8	0	1553.6	2597.4	1825.6	737.7	0	45.6
Total	2206.8	1232.9	2077.4	2597.4	1825.6	1881.5	2259.3	1717.5

Digestibility

Dry matter digestibility was lowest in the C. ciliaris and *M. atropurpureum*. The other mixture ha similar dry matter digestibility which ranged from 52.5 – 54% (Table 2). Organic matter digestibility was higher in the mixtures with *M. maximus* and much lower in the mixtures with *C. ciliaris* (Table 2).

Table 2: Digestibility Coefficients of Mixed Grass and Legume diets

Feed Mixer Type	DMD%	*OMD%*	*DoMD (g/Kg DM)*
C. ciliaris/Clitoria	54.0	57.1	503.0
C. ciliaris/Siratro	43.0	48.1	541.4
M. Maximus/Clitoria	52.5	54.5	466.9
M. maximus/Siratro	53.7	64.1	456.4

Discussion

Legume and grass mixtures have the potential to improve soil health and livestock production. In the ASAL areas of Kenya feed quality and especially the low digestibility and crude protein content of the local grasses limits livestock production. Legumes have a higher crude protein, energy and mineral content than tropical grasses and can be used to address the N deficit in tropical grasses. However, the selection of grasses and legumes to grow in a mixture will determine the success integrating legumes into grass pastures. Recently a number of grass varieties have been introduced in the semi-arid areas of Kenya and this experiment evaluated the compatibility of the tropical legumes and two of the grass varieties. The two legumes used reduced the *C. ciliaris* yield from 12 to only about 5 tons/ha per year. This reduction was highest in the early stages of establishment and although the proportion improved in later harvests the total yield was still very low. However, the two legumes seem to compensate for the low grass yield and there was no difference in the yield per year between the legume/grass mixtures and the grass sole crop. However, the crude protein yield was higher than that of the sole *C. ciliaris* crop. Sole *M. maximus* produced much higher yield than the grass legume mixture which could have been an indication of competition for water and minerals between the legumes and this tall tufted grass. The sole M. maximus crop had a higher crude protein content than the legume grass mixtures implying no major advantage of growing the grass in a legume mixture. As the legume proportion seems to increase with time, the trail will be keep for a number of seasons to determine if this finding will change.

Implications of the results

Although intercropping C. ciliaris reduces grass yield significantly the mixtures produce more forage of higher nutritive quality and therefore can be recommended to farmers growing *C. ciliaris*. However, different planting arrangements should be tried to determine whether the competition between the legume and grass can be reduced. More work is required before a decision on which legumes can be intercropped with *M. maximus.*

Beef cattle grazing rangeland pastures augmented with naturalised Stylo had higher liveweight gains in the Victoria River District of the Northern Territory

Williams, M[1]; Pettit, C[2]; Hearnden, M[2]

[1] Department of Agriculture and Fisheries, Katherine, Northern Territory; [2] Department of Agriculture and Fisheries, Berrimah, Northern Territory

Key words: Legumes; cattle production; improved pastures, Northern Australia

Abstract

The Victoria River District (VRD) in the Northern Territory supports extensive cattle grazing on native pastures. The pasture quality and quantity of this tropical savanna is subject to significant seasonal variability with most of the rain falling between December and March. During the dry months, pasture quality rapidly declines, and protein becomes the most limiting nutrient, which is commonly replaced with urea to supplement nitrogen (Silva et al. 2022).

To address the seasonal protein deficits, the benefits of augmenting exotic legumes into the native pastures is being demonstrated at Victoria River Research Station (VRRS) situated 400km south-west of Darwin. The high protein content in legumes make them an ideal cattle feed to fill the protein gap that occurs naturally in rangelands when pasture dries off in the late dry season (August-December).

The project includes a live weight gain trial for young heifers between 6 to 12 months old grazing an existing legume augmented pasture compared to a control paddock with <5% legume yield. Near Infra-Red Spectroscopy (NIRS) data was collected in October 2023, December 2023 and May 2024 to compare crude protein content and metabolisable energy in the legume paddock versus the control. Early results from the first year suggest the weight gain of weaner heifers was significantly higher with naturalised Stylosanthes legumes.

Introduction

In the Northern Territory (NT), almost all beef cattle production occurs in extensive rangelands where cattle graze native pastures. Native rangelands are a low input and low-cost method of growing cattle on large areas of land where it is not feasible to have intensive cattle production practises such as feedlots.

In the tropical savannas of the Northern NT, annual cattle weight gain coincides with wet season rainfall, falling between December and March (Burns et al. 2010). During the wet season, consistent rainfall enables the pastures to remain green and nutrient rich, providing adequate energy and protein to cattle. After the wet season, a prolonged dry season (April–October) leads to pastures drying out and maturing, causing a decline in nutritional quality. This is characterised by a reduction in protein and energy content and an increase in indigestible components such as lignin and cellulose, making the forage less suitable for supporting consistent weight gain in cattle (Norman 1963). Often at this time cattle will be offered a urea supplement as a replacement protein source.

The ’protein gap’ that occurs from the middle of the dry season until after rain when pasture growth occurs, presents an opportunity to investigate augmenting native pastures with high protein legumes in the Victoria River District (VRD) region of the Northern Territory.

If young cattle can continue to put weight on during this time of year, it would bring heifers to joining weight sooner and provide earlier turn-off of steers. Generally, in Northern Australia, cows calve around October-December (Bortolussi, 2005). A cows energy requirements is higher in their last months of gestation and when they start lactating (McCosker et al. 2023). Legumes may provide higher energy and protein during this time, which could be extremely valuable management tool for cattle producers.

Methods

Improved paddock (1.9km^2) at Victoria River Research Station (VRRS) is predominately loamy red earths with a tall, open woodland and has a substantial amount of Stylo spp. present (*S. hamata*, *S. scarbra* and *S. viscosa*). The Stylo spp. were planted as part of a previous research trial in the 1970’s and has since become naturalised. Native grasses present in Improved paddock include *Heteropogon contortus* (Black spear grass), *Setaria surgens* (Pigeon grass), *Aristida holathera* (Kerosene grass), *Enneapogon purpurascens* (Limestone grass) and *Mnesithea formosa* (Silkytop grass). There are small areas of improved pastures including *Cenchrus setiger* (Birdwood grass) and *Urochloa mosambicensis* (Sabi grass). This paddock was referred to as (+ legume) or legume paddock.

Little Rosewood paddock (7km^2) at VRRS is a mix of alluvial cracking clays and shallow limestone country and has little to no introduced legumes (<5% total legume composition). Pastures are dominated by *Chrysopogon fallax* (ribbon grass), *Aristida latifolia* (feathertop wiregrass), *Ophiuros exaltatus* (cane grass) and *Panicum decompositum* (native millet). Native legumes include *Sesbania sp.* (pea bush), *Neptunia sp.* (Neptunia) and *Phyllanthus maderaspatensis* (spurge). This paddock was referred to as (- legume) or the control paddock.

Heifers between the age of 6-12 months were inducted into the paddocks in July 2023. 33 heifers in Improved paddock and 45 heifers in Little Rosewood paddock were measured over the trial period. Little Rosewood was stocked with a further 59 heifers and steers to ensure stocking rates matched long-term carrying capacity and paddocks had similar utilisation rates.

The animals were weighed in July 2023 when inducted to their allocated treatments and then again in September 2023, December 2023, and May 2024. Faecal NIRS samples were collected from both paddocks in October 2023, December 2023, and May 2024.

Each paddock has a series of permanent pasture photo monitoring sites that were used to record any changes throughout the trial.

Results

From July 2023 to May 2024, heifers grazing the legume augmented pasture were on average 31.3kg heavier ($p<0.001$) and grew faster (0.45kg/day v 0.35 kg/day, $p<0.001$) (Table 1).

Table 1: Average liveweight gain in the control and legume augmented paddocks from July 2023 to May 2024

Treatment	Proportion of total yield of introduced and native legumes (%)	Number of animals	Average weight gain (kg) (± 95% Confidence Interval)	Average daily weight gain (kg/day) (± 95% Confidence Intervals)
– Legume	7	45	109.9 (105-115)	0.35 (0.337 – 0.370)
+ Legume	31	31	141.2 (135-148)	0.45 (0.432 – 0.476)

Faecal NIRS was used to analyse protein and energy levels of the feed consumed by cattle in both paddocks. The improved paddock heifers' diet had a lower dry matter digestibility (DMD) to crude protein (CP) ratio and higher metabolisable energy compared to Little Rosewood paddock heifers.

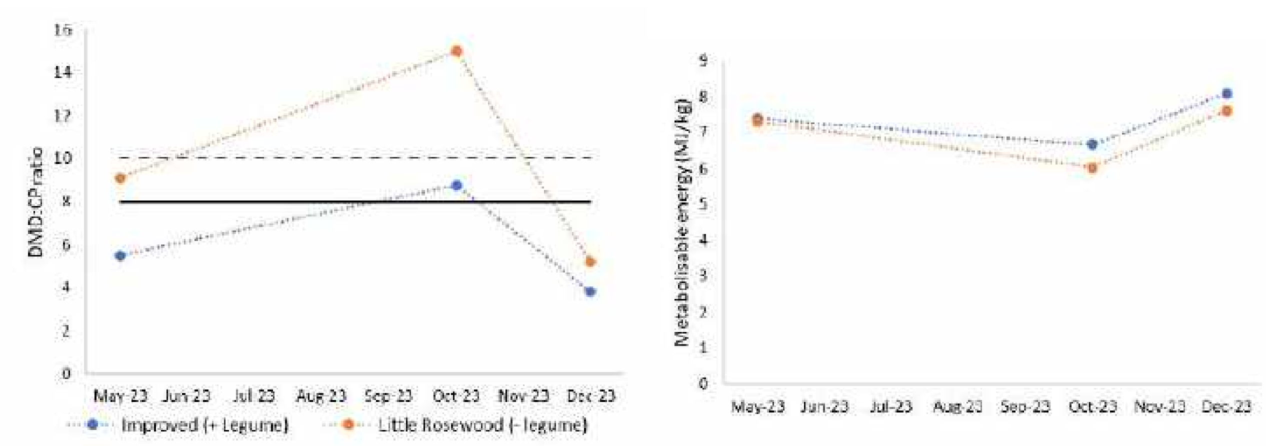

Figure 1: Faecal NIRS derived DMD%:CP% ratio and metabolizable energy in the legume and control paddocks, from October 2023 to May 2024. DMD:CP > 10 response to urea highly likely. DMD:CP>8 probable response to urea

Discussion

Heifers in the + legume paddock gained on average 100 grams more per day compared to heifers in the - legume paddock (Table 1). The increase in weight gain aligned with faecal NIRS data indicating a consistently higher crude protein (CP%) to dry matter digestibility (DMD%) ratio in the + legume paddock (Figure 1). In the late dry season, there was more metabolisable energy available in the pastures in the + legume paddock (Figure 2). This finding is consistent with previous research by Gardener (1980) which demonstrated that steers grazing a *Stylosanthes hamata*-native grass pasture exhibited improved diet selection and liveweight performance due to the higher quality forage provided by legumes. Notably, during the late dry season, metabolizable energy was also more available in the legume paddock (Figure 2), a critical period when protein and energy are often the primary constraints on cattle growth (Silva et al. 2022; Charmley et al. 2023).

The nutritional advantage of the legume paddock reduced after the wet season rains (December 2023–March 2024), as metabolizable energy levels equalized between the two paddocks. This suggests that the benefits of legumes are greatest during resource-limited periods, such as the late dry season. The late dry season nutritional benefits observed in the legume paddock are particularly significant for this environment, where limited protein and energy often constrain cattle growth. The continuation of this study through the 2024–25 wet season will provide valuable additional data to assess the long-term impact of legume augmented native pastures on cattle weight gain and overall performance.

However, the study faced challenges in selecting a true control paddock with comparable soil fertility and pasture composition. The variations in soil quality and pasture composition may have influenced the results, highlighting the complexity of isolating treatment effects in extensive grazing environments.

Abstract

Growing season droughts can have major impacts on grassland vegetation and are predicted to become increasingly frequent in temperate rangelands due to climate change. To sustain livestock production systems, we need to understand what grazing management strategies will best support long-term ecosystem and livelihood sustainability in the face of increasing drought. Little is known about how droughts interact with grazing management to affect forage quality and quantity. In two North American grasslands where grazing by domestic livestock is the primary land-use, we assessed the separate and combined effects of experimental rainfall reductions and grazing management strategies on forage quality and quantity over five years. During a 2-yr experimental rainfall reduction period, rainfall reductions decreased both forage quality and quantity at one site. At a second site, heavy grazing during the first year of experimental drought reduced forage biomass and digestibility during the second year. In the first year after experimental rainfall reduction treatments ended, plots that formerly received large rainfall reductions displayed strong legacy effects. These plots had 26% to 57% less digestible forage biomass but greater forage quality than controls. Experimental treatments did not induce long-term changes in forage quantity at either site, but reductions in forage quality persisted up to three years after droughts ended. Our results highlight the resilience of North American Great Plains grasslands to both drought and grazing, but also suggest that these disturbances can have additive and long-term effects on forage nutritive value. Legacy effects of droughts on forage quality and quantity may impact ruminant nutrition for 1-3 years following a drought, and heavy grazing during drought may strengthen the effects of drought on livestock nutrition.

Introduction

The ecosystem services provided by natural grasslands can be disrupted by drought (Smith et al. 2024), and growing season droughts are predicted to become more frequent due to climate change (Knapp et al. 2023). Global change experiments routinely measure effects of simulated droughts on the biomass and community composition of natural grasslands (Smith et al. 2024). Drought-induced changes to grassland vegetation can affect wild and domesticated ungulate ruminants via shifts in both the quantity and quality of forage. For example, drought-induced reductions in forage biomass can negatively impact ruminant performance, and that effect can be exacerbated by concurrent reductions in forage quality (White et al. 2014). Conversely, droughts could maintain or increase forage quality despite drought-induced reductions in forage biomass, leading to weaker bottom-up effects on animal performance (Grant et al. 2014).

Bottom-up drought effects may be further influenced by interactions between drought and land management (e.g. grazing regimes) (White et al. 2014, Deléglise et al. 2015). Due to logistical hurdles, drought manipulation experiments rarely include manipulations of large ruminant grazers. More research is therefore needed to understand when, where and how grazing and drought interact to shape ruminant nutrition. For example, heavy grazing during drought could lead to reductions in aboveground production potential or shifts in plant species composition (e.g., Deléglise et al. 2015), both of which may result in altered forage quantity and quality. Most studies of forage quality and drought do not track recovery for multiple years after the disturbance event, so the legacy effects of drought on forage quality are also poorly understood (White et al. 2014, Deléglise et al. 2015). Legacies of prior year conditions are known to be strong drivers of grassland productivity (Sala et al. 2012), but less work has explored the role of legacy effects on forage quality. To fill these knowledge gaps, we tested the separate and combined effects of rainfall reduction and grazing treatments on forage (grass and forb) availability and nutritive value in grasslands of the northern Great Plains of North America.

Methods

The study was conducted at two field sites in the west-central semi-arid prairies of North America (EPA Level II ecoregion 9.3; Omernik 1987). One site was in eastern Montana (MT) at the Fort Keogh Livestock and Range Research Laboratory (46°20'N, 105°59'W). The other site was at a private cattle ranch (43°18'N, 105°03'W) in the Thunder Basin region of northeastern Wyoming (WY). Mean annual precipitation and temperature are 320 mm and 7.8°C at the MT site and 320 mm and 6°C at the WY site. Most precipitation falls during the growing season (April – October). Floristically, both sites are in a broad ecotone between shrublands of the North American Deserts, and grasslands of the Great Plains. Plant communities commonly include a sparse overstory of *Artemisia tridentata* Nutt. ssp. *wyomingensis* Beetle and Young (Wyoming big sagebrush) and an understory characteristic of northern mixed-grass prairie (Frost et al. 2023).

We manipulated grazing and rainfall reduction in a full factorial (3×5) with a split plot. Main plots (paddocks) were arranged in a randomized complete block design with three blocks per site. Grazing treatments were randomly assigned to three paddocks per block, and the fourth paddock was used to supply water. Grazing treatments were designed around multi-year, regionally relevant drought management strategies. Paddocks assigned to the "heavy" treatment experienced heavy grazing (70% biomass removal) during the drought period (2019-2020) and moderate grazing (50% biomass removal) during the post-drought period (2021-2023). The "stable" treatment received a consistent, moderate grazing intensity (50% biomass removal) across all years. A third "destock" treatment was also included but results are not presented here. Grazing treatments were implemented in early July in WY and early August in MT. Fort Keogh Livestock and Range Research Lab's Institutional Animal Care and Use Committee determined our use of animals was consistent with standard livestock management. Within each paddock, we established six plots (2 × 2 m). Four plots were randomly assigned to rainfall reduction treatments and two were randomly designated as control plots. Rainfall reduction treatments (-25%, -50%, -75%, and -99%) were applied with rain-out shelters (3 × 4 m) positioned over plots from April – October in 2019-2020. Rain-out shelters were removed during grazing treatments. Ambient precipitation in MT was near average in 2019 and 2020, below average in 2021, and slightly below average in 2022 and 2023. In WY, precipitation was above average in 2019, below average in 2020 and 2022, and near average in 2021 and 2023.

To sample forage, we clipped one or two 10 x 50 cm quadrats within each 2 x 2 m plot in May, June, and July for 5-yr (2019-2023). Sampling areas were excluded from grazing during the current sampling year. Forage samples were a composite of living and dead herbaceous material and excluded cactus, woody vegetation, and litter. Forage material was oven dried (60°C, 48 hr), weighed to obtain forage biomass estimates (g × m^{-2}), and ground to pass through a 2-mm screen. From the composite sample, 0.25g subsamples were added to filterbags (F57, Ankom Technology Corp., Fairport, NY, USA) and used for in-vitro organic matter (OM) digestibility analysis via an ANKOM DaisyII incubator (Daisy Incubator; Ankom Technology Corp., Fairport, NY, USA; ANKOM 2017a). Separate subsamples were used for neutral detergent fiber analysis (ANKOM 2017b). In addition, we calculated digestible forage biomass (g × m^{-2}). Species composition data are presented in Frost et al. (2023) and Bloodworth et al. (in review).

For each response variable we ran separate linear mixed models by year and site, since treatment applications and associated hypotheses differed among years, and sites experienced different weather patterns over the course of the experiment. In each model, fixed effects included percent rainfall reduction (continuous), grazing treatment (categorical), month (categorical), and all possible interactions. To account for spatial and temporal non-independence, we included random intercepts for block, paddock nested within block, and plot nested within paddock and block, and we utilized a compound symmetry covariance structure. For each model, we also included May 2019 data from each plot as a fixed effect covariate to account for baseline differences among plots. Whenever two- or three-way interactions with month were significant, we ran separate models by month. We ran models in R 4.2.1 using the nlme package (Pinheiro and Bates 2000).

Results

In Montana, experimental rainfall reduction treatments were associated with lower forage quality and quantity during the first two years. Plots experiencing the most rainfall reduction had 4.1% more fiber content than control plots (Fig. 1; main effect of rainfall reduction 2019 $P = 0.002$; 2020 $P = 0.07$). The quantity of digestible forage declined by up to 27.0% with rainfall reduction in 2019 (Fig. 1; $P = 0.001$). In 2020, digestible forage biomass declined by 46.0-53.5% with rainfall reduction in June and July, but not May (Fig. 1; rainfall reduction*month $P = 0.003$). In 2021, a natural drought year in Montana when we did not impose experimental rainfall reduction treatments, forage quality tended to be higher and forage quantity was lower in plots that had formerly been subject to experimental rainfall reductions, compared to control plots. Forage fiber content was 4.9% lower in plots with the most former rainfall reduction, compared to control plots (Fig. 1; $P < 0.0001$). In May 2021, forage digestibility was 7.4% higher in plots with the most former rainfall reduction, compared to control plots (Fig. 1; rainfall reduction*month $P = 0.008$). Even in the presence of a strong natural drought in 2021, former rainfall reduction treatments were associated with up to 57.2% lower biomass of digestible forage (Fig. 1; $P < 0.0001$). Grazing treatments did not influence forage results in Montana.

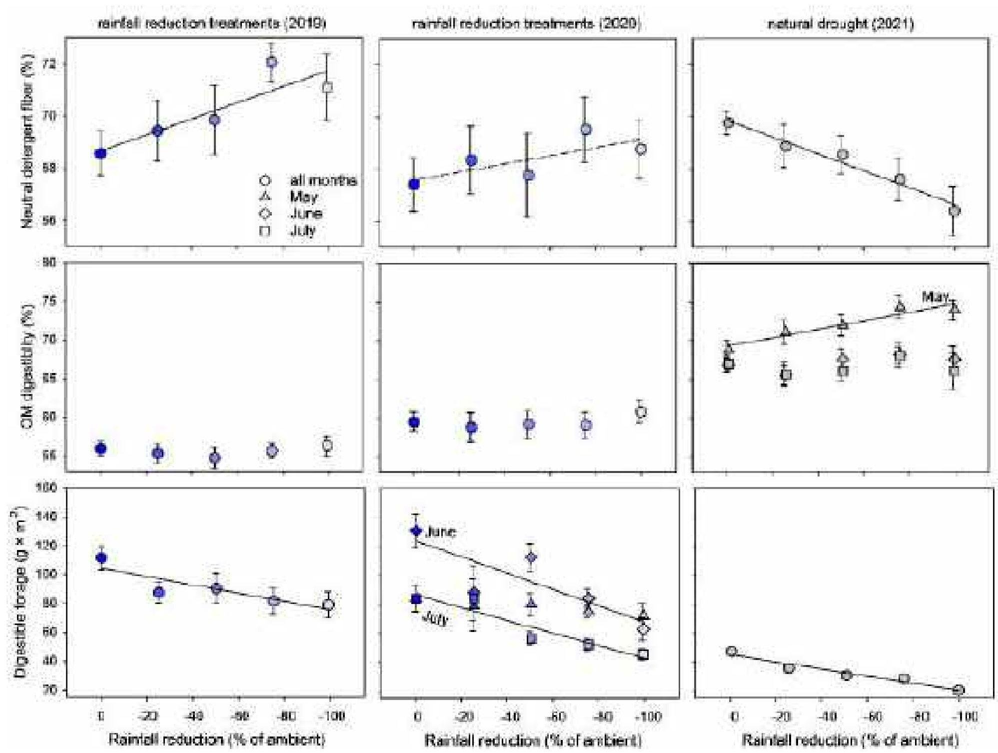

Fig. 1. Effect of rainfall reduction treatments (2019-2020) and a natural drought (2021) on average (±1 SE) forage nutritive value and biomass in Montana. Solid lines indicate significant effects of rainfall reduction ($P \leq 0.05$), and dashed lines indicate marginal significance ($0.05 < P \leq 0.10$)

In Wyoming, our treatments were mostly unrelated to forage quality or quantity during 2019-2020. In 2020, however, digestibility declined with rainfall reduction, but only in the heavy grazing treatment (P = 0.02). In 2020, forage biomass was also 27.7% lower in the heavy grazing treatment than stable grazing treatment ($P = 0.04$). During the first post-drought year (2021), forage fiber content was greater with former rainfall reduction in May, but decreased with former rainfall reduction by July (rainfall reduction*month P = 0.007). Plots that had formerly received the most rainfall reduction also had 26.2% less digestible forage (P = 0.0001).

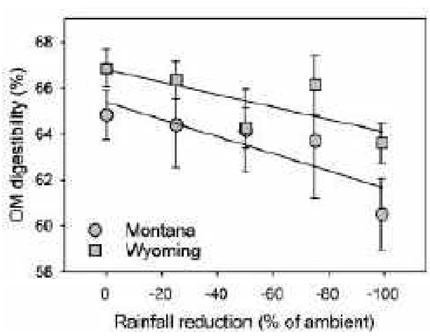

Fig. 2. Legacy effects of 2019-2020 rainfall reduction treatments on 2023 average (±1 SE) organic matter digestibility. Solid lines indicate significant main effects of rainfall reduction (P≤ 0.05)

Several effects of experimental rainfall reduction treatments persisted into 2022 and 2023. In Montana, forage fiber content patterns in 2022 matched those of 2021. Fiber content declined with former rainfall reduction ($P = 0.007$), such that plots which received the most rainfall reduction in 2019-2020 had 3.1% lower fiber content in 2022. At both sites, experimental rainfall reductions in 2019-2020 were associated with lower forage digestibility in 2023 (Fig. 2; MT $P = 0.009$; WY $P = 0.01$). Plots receiving the most rainfall reduction had 4.1-6.7% lower digestibility.

Discussion

Over a 5-yr timespan, we observed strong effects of experimental rainfall reductions and grazing management on both forage quality and quantity in two North American rangelands. Despite major differences in plant communities and weather patterns, responses were surprisingly consistent across our two sites. During experimental droughts, we observed neutral to negative effects of rainfall reductions on forage quality and quantity, as well as some evidence that heavy grazing further reduced forage quality and quantity. After experimental droughts ended, we observed short-term, strongly negative legacy effects on forage quantity. The magnitude of these effects matched or exceeded those observed in other systems (e.g., Oesterheld et al. 2001). We also observed some short-term positive legacy effects on forage quality, which were likely driven by shifts in soil nutrient availability (i.e. higher nutrient concentrations in formerly droughted plots), phenology, and species composition (Frost et al. 2023). From a ruminant nutrition perspective, the strong negative short-term legacy effects we observed on forage quantity may override any short-term positive effects on forage quality.

Grazing and drought shifted plant species composition towards less nutritious species in our study (Frost et al. 2023, Bloodworth et al. in review), leading to the potential for longer-term legacies after extreme disturbance events. Moreover, in perennial dominated systems, multi-year plant resource allocation patterns may lead to complex long-term legacies (Vermeire et al. 2024). We indeed saw evidence that experimental rainfall reductions led to reductions in forage quality at both sites in 2023, a full three years after experimental droughts ceased. Given the already low quality of forage in extensive rangelands, additional reductions could be detrimental to livestock weight gains or necessitate additional supplementation. Our findings emphasize that although northern Great Plains grasslands are resilient to both grazing and drought, these disturbances can have additive and lasting effects on a critical forage resource.

Key words: pasture growth; pasture utilisation; stocking rate

Abstract

Annual pasture growth and utilisation were retrospectively modelled using the biophysical GRASP model for 20 pre-existing breeder herd datasets from across northern Australia as part of a broader study to quantify the effect of pasture utilisation rates on the reproductive performance of extensive beef breeding females. Annual pasture utilisation was more influenced by variation in stocking rate in the central and northern Northern Territory (NT) regions, while variation in pasture growth explained more of the variability in pasture utilisation in the Southern NT and north eastern (NE) Queensland regions. In the Alice Springs region, median pasture utilisation was 1.8 x higher than recommended levels on commercial stations compared to the utilisation rate on the research station where it was 0.7 x recommended levels, despite higher relative rainfall for the commercial herd studies. In contrast, in the Barkly the median utilisation on commercial stations was lower than recommended levels (0.7 x recommended) possibly reflecting the high relative rainfall during those studies. On commercial stations in northern NT and NE Queensland regions, median utilisation was 1.2 and 1.3 respectively x recommended levels, but this was for years with rainfall 1.6 and 1.7 times the long-term median respectively.

Introduction

Safe pasture utilisation is commonly used in a pasture sustainability context as the proportion of pasture consumed by livestock that will maintain the underlying resource base over the long term (Hunt 2008). Northern Australian cattle production systems are typically extensive breeding enterprises with herds free-ranging in large to very large paddocks (five to 500 km²), grazing mostly on rain-fed native pastures. The summer-rainfall dominated climate supports mesic to semi-arid tropical and subtropical savannas, through to arid shrublands and grasslands. Recommended safe levels of pasture utilisation to sustain vegetation and soils are typically in the order of 5 to 25% of annual pasture growth. However, these rangelands are often utilised at rates that exceed safe levels. This work was part of the larger Sweet Spot project that examined the impact of pasture utilisation on breeder herd performance. Here we examine the factors influencing pasture utilisation in the dataset and implications for rangeland management.

Methods

Pasture growth and utilisation (for the growth year between October 1 and September 30) were modelled using the pasture growth GRASP model (Rickert *et al*. 2000) for existing breeder herd datasets at 60 paddocks (sites) across northern Australia as part of the Sweet Spot project. The herd datasets included 77,000 cattle records from 60 paddocks between 1991 and 2022 for a total of 350 site-years. Climate files for each site from SILO were combined with local/site rainfall where available. Pasture utilisation is a result of both pasture growth and animal intake. Intake and growth were calculated within the watered area (defined as all the area within 3 km and half the area between 3 and 5 km from water). Paddock pasture growth was calibrated using total standing dry matter estimated in the paddock and satellite derived green ground cover. Intake was assumed to be 8 kg/adult equivalent/day (McLennan et al. 2020) with an adult equivalent (AE) defined as a 450 kg *Bos taurus* steer walking 7 kilometres each day (McLean and Blakeley 2014). The number of AE was calculated using measured herd performance for each class and time period using the AE calculator (McLean and Blakeley 2014, version 14.63). As safe utilisation rates vary between land types, we used a simple index of utilisation; relative utilisation = modelled annual pasture utilisation/safe (long term average) utilisation for that site. Long term safe utilisation rates for each land type were determined from the literature (e.g. Ash et al. 1997, Hunt 2007). Relative rainfall = actual annual rainfall / median long-term annual rainfall.

Statistical analyses (R Core Team 2024) were performed to determine whether stocking rate or pasture growth was the greater influence on pasture utilisation in the different regions. Data from properties in each region were used for a linear model to assess the relationship between annual percent pasture utilisation and the explanatory variables of log (annual pasture growth) and stocking rate. Partial correlation coefficients for each explanatory variable were generated using the ppcor package (Kim 2015a, Kim 2015b). The dataset was analysed by broad geographical location.

Results

The dataset was skewed towards wetter years, with above median rainfall in 65% of the 350 site-years (Fig. 1a). Median relative utilisation was one in the Southern and Northern NT regions (indicating safe utilisation levels, Fig. 1b), but was less than one in the Barkly Central NT (0.7) and higher than one in NE Queensland (1.2), reflecting stocking rate trials deliberately testing high stocking rates there. The Alice region in southern NT had some very high relative utilisations which were all found on commercial stations (where the median relative utilisation was 1.8 x higher than recommended level) and which were considerably higher than for a local research station (0.7 recommended level), despite higher relative rainfall for the commercial sites (1.6 vs. 1.1 respectively). In contrast the Barkly median utilisation on commercial stations was lower than the recommended level (0.7 x recommended) possibly reflecting the high relative rainfall during those studies (1.4 x median). On commercial stations in Northern NT and NE Queensland regions, median utilisation was 1.2 and 1.3 x recommended levels, but this was for years with rainfall 1.6 and 1.7 times the long-term median.

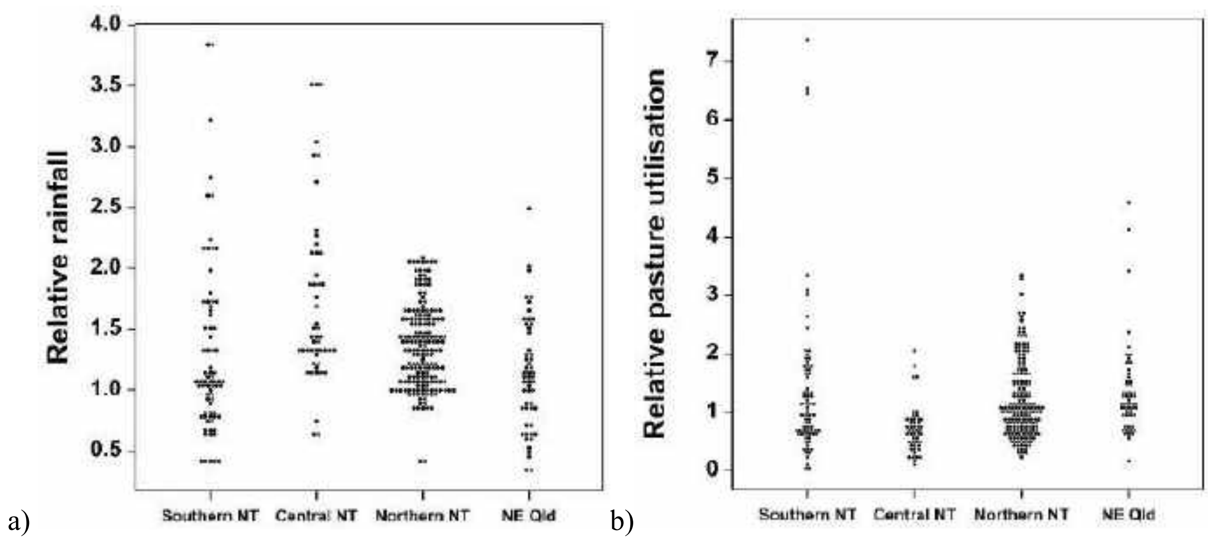

Figure 1: Variation in a) relative rainfall, 1 = median rainfall and b) relative simulated pasture utilisation, 1=safe utilisation, across regions of northern Australia on the Sweet Spot sites

Pasture growth explained more of the variation in pasture utilisation in the Southern NT and NE Queensland regions (Table 1, Fig. 2) and stocking rate explained more of the variation in annual pasture utilisation in the Northern NT and Barkly regions (Table 2, Fig. 2).

Discussion

This dataset includes data from research herds used in cattle production studies, grazing trials for testing different stocking rates and grazing systems, and studies on collaborating commercial cattle stations. This work involves a meta-analysis of pre-existing datasets where the individual datasets are inherently idiosyncratic in nature, and the regional breakdowns were not balanced for commercial vs. research station, level of infrastructure development, land types represented, or the proportion of dry vs. wet years. Whilst the dataset was not necessarily representative of pasture utilisation rates across the broader industry it was suited to the broader Sweet Spot study where a range of pasture utilisations was needed to compare with breeder performance. Regional comparisons of the pasture utilisation results in isolation can only be made in light of the characteristics of the varying datasets within each region. For example, the Northern NT and NE Queensland regions were heavily represented by stocking rate trials deliberately examining moderate to high utilisation. This compares to the Alice Southern NT region where the research station was deliberately stocked to achieve safe utilisation in most years. Rather we examine the factors influencing the variation in pasture utilisation in the dataset and implications for rangeland management.

The modelling of pasture growth and utilisation for this study was at the paddock or watered area scale. Rather than try to model different land types separately, we used paddock scale satellite derived green ground cover and TSDM observations to calibrate average growth across all land types in the paddock. This will inevitably average across different land types that will potentially respond differently to rainfall, depending on soil water holding capacity and fertility and pasture species composition. Similarly, land type preference and use in relation to distance from water means that the actual spatial distribution of pasture utilisation within paddocks would have varied considerably. This has been partly accounted for by assuming cattle grazed only within approximately 4km from water, when pastures are not limiting within that part of the paddock which is consistent with research findings (e.g. Hodder and Low 1978). However, in very high utilisation years when utilisation was calculated to be more than 80% of growth, as was found on several occasions in the Alice and Queensland sites, it is likely that cattle walked further from water and / or supplemented their diet with browse. These highest utilisation years were due to very low pasture growth in low rainfall years, (<250kg/ha for Alice and <650kg/ha for North Queensland) combined with moderate to high stocking rates.

Key words: Northern Western Australia; beef enterprise; irrigated forage; finishing

Abstract

The northern Western Australian (WA) beef industry is characterised by a reduction in dry-season forage quality leading to weight loss in livestock and reduced market readiness. A potential solution is the use of irrigated forage to provide a reliable source of energy and protein to finish cattle before sale. The feasibility of this feeding strategy was simulated using the Crop Livestock Enterprise Model (CLEM) and compared with the baseline of the usual practice of grazing on dry native pasture. Calving occurs during the wet season and weaning and mustering during the dry season, with a finishing scenario for castrated males (steers) based on feeding irrigated forage during the dry season. The CLEM results showed an improvement in livestock productivity under this scenario, with higher live weight (LW) at sale due to faster weight gain while fed the irrigated forage. Furthermore, selling a higher proportion of animals at an earlier age, could potentially reduce methane emissions (and thereby create a more sustainable system) or there is the possibility of diversifying the market to include animals with higher LW but at an older age. Overall, integrating cattle production with irrigated pasture/forage, presents a significant opportunity to enhance the efficiency of beef production.

Introduction

Despite its economic importance, the beef industry of northern Western Australia (WA) experiences some challenges such as limited market opportunities and relies heavily on live exports (Chilcott et al. 2018). The climate is one of distinct wet-dry (tropical) conditions with a reduction in forage quality during the dry season resulting in weight loss in cattle. This results in animals failing to reach the target sale weight for market, such as the live weight (LW) of approximately 350 kg for two-year-old steers intended for live export for some markets like Indonesia (MacLeod et al. 2018), and as a result they might be sold at a lower price. One potential solution is to put cattle onto high-quality pastures as an improved source of energy and protein to enhance weight gain (Webster et al. 2024). Feeding products from irrigated crops and forages, such as sorghum silage and cotton seed and direct grazing of irrigated pasture, can be a valuable source of energy and protein offering opportunities to target broader markets, implement effective herd management strategies, provide a reliable feed source during dry seasons when pasture availability is limited, and diversify the business through fodder sales (Moore et al. 2021).

The economic benefit of integrating irrigated crops and forages into the beef cattle enterprises through increasing total carrying capacity and increasing the weight at sale has been reported (MacLeod et al. 2020). This study aimed to evaluate the effective utilization of irrigated forages in a beef finishing system to increase the proportion of animals that meet market specifications, and thereby to maximize productivity. The inclusion of irrigated pasture in the feedbase was assessed against a standard native pasture base scenario, focusing specifically on castrated male animals.

Methods

Scenarios

In this study, two scenarios were considered: 1) The baseline scenario where the herd grazed only native pastures, and 2) An irrigated feed scenario in which weaned calves were moved to irrigated pasture during May in the dry season. For both scenarios calving occurred during the wet season (November to April), weaning at 5 months (twice a year, May, September), with phosphorus supplement during the wet season. In the baseline scenario, animals received a urea supplement during the dry season, and hay was provided during the first two months after the May weaning (June and July).

CLEM modelling

The case study farm with each feeding scenario was simulated with the Crop Livestock Enterprise Model (CLEM, Version 2023.3.7172.0, Liedloff et al. 2024); integrated with the APSIM Next Generation (APSIMNG; Holzworth et al. 2018) framework. The simulation was set up to represent a small property, on clay soils, with approximately 2,250 breeders and with bulls included at 4% of breeding herd numbers. Feed resources were described in separate input files for native pasture (modelled with GRASP; McKeon et al. 2000) and irrigated pasture/forage (modelled with APSIM; Holzworth et al. 2014). The productivity of individual animals was simulated in CLEM in response to feed quantity and quality. Herd management activities were implemented to represent the farm for each scenario. Mating was enabled from January to May with conception based on breeder condition. Breeders of 10 years were culled each May, and bulls purchased as needed in April. Individuals who meet the LW criteria for sale were sold in either May or September. All simulations were run over a period of 12 years (from June 2010 to June 2022).

Descriptive analysis

The biophysical outputs of each scenario were reported by CLEM and summarised using the R environment. For each resource (e.g. weight gain or average quantity of beef sold), descriptive statistics were then calculated, and metrics such as growth rate of individuals were plotted using the “ggplot2” package.

Results

Based on our CLEM simulation results, livestock productivity was higher in the irrigated pasture scenario compared to the baseline (Table 1). In addition to the increased quantity of beef sold (kg LW), a higher percentage of castrated animals reached the sale weight at an earlier age (before 12 months) under the irrigated pasture scenario compared to the baseline (94.6% vs. 83.7%) (Table 1).

Table 1. The difference in steer sales and weight gain between CLEM simulations using only native pasture and feeding with irrigated forages for a representative northern Australia property.

Biophysical parameters	Simulation	
	Native pasture	Irrigated forage
Average annual castrated beef sold (kg LW)[1]	136,229	156,950
Average weight (kg LW) of castrated males, age 7-11 mo., September sale	242.0 ± 27.2 (n=5045)	278.0 ± 34.8 (n=5749)
Percentage of castrated males, age 7-11 mo. sold, September sale	83.7	94.6
Average weight (kg LW) of castrated males, age 15-20 mo., September sale	263.0 ± 11.7 (n=212)	318.0 ± 14.0 (n=101)
Average monthly weight gain of castrated males, age 5-10 mo. (kg LW)[2]	14.03	22.02
Average monthly weight gain of castrated males, age 15-20 mo. (kg LW)[2]	1.7	14.7

1. LW= Live weight.
2. These calculations were based on a weighted average due to the unequal number of animals per month. The calculation did not consider the weight gain during the final month, which was the time of sale.

As expected, the average monthly weight gain (Table 1) and average weight (Figure 1) increased when feeding growing males with high-quality pasture forage, with better performance for castrated animals at older ages (Figure 1B). This resulted in achieving the LW target for live export to a much greater extent under the irrigated pasture scenario compared to the baseline.

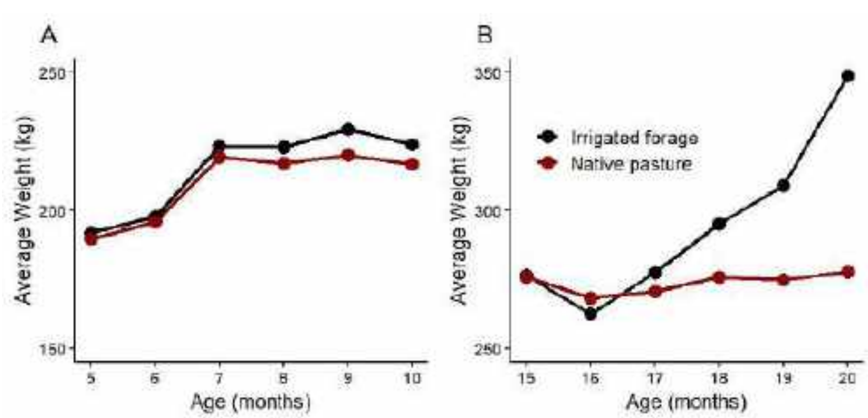

Figure 1. Difference in average liveweights (kg) for castrated animals between the native pasture and irrigated pasture/forage scenarios, A) immediately after weaning (ages 5–10 months) and B) the following year (ages 15–20 months). Note: A maximum gain of 0.83 kg/day (A) was observed at the start of the dry season (May-June) when native pasture quality remained good, and urea (throughout the dry season) and hay supplementation (June-July) were provided. This growth rate was expected, as the weaned castrate calves were in their active growth phase and had been weaned at a heavy weight. A similar trend of liveweight gain (with seasonal effects) for heifers (e.g., Fordyce and Chandra 2019) and weaners (Tyler et al. 2012) has been reported in northern Australia.

Conclusion

The use of irrigated forage was shown to increase the productivity of northern cattle herds through an increase in the average weight of animals at sale, consistent with previous studies (MacLeod et al. 2018; Monjardino et al. 2015; Webster et al. 2024). Our results also indicated that there is a potential opportunity to finish steers with alternate quality feed sources and sell a portion of them at an early age or hold them to achieve heavier weights at sale. Additionally, due to the differing rates of weight gain in 1-year-old and 2-year-old steers (Figure 1), the time of introducing animals to irrigated pastures is crucial for optimizing the use of this feed resource. For instance, selling stock at an earlier age could lead to a reduction in the enteric methane emissions of the herd, contributing to a more sustainable livestock system. On the other hand, achieving heavier weights provides opportunities for market diversification and helps meet the target LW for live export (MacLeod et al. 2018). However, a comprehensive assessment of the whole beef cattle enterprise is necessary that will consider factors such as market demand and the logistics of transporting animals for live export, including associated costs for trucking (i.e. larger animals will require more space for transport).

Overall, recommendations should be made with caution, as these results need to be economically evaluated to determine the net profit of using irrigated forage, especially considering the high capital costs associated with irrigation developments. Additionally, this study focused on castrated males (steers) over a short period, but the findings could be extended to other categories of livestock or different age groups and timeframes. Other factors, such as the size of irrigated land exploited and incorporating the animals into a feedlot system as well as considering other selling rules such as out of season to support the supply chain when there is a shortage, could also be evaluated using the CLEM framework. The next phase of this project will economically evaluate the findings of this study, as well as explore additional production scenarios that could contribute to the profitability and sustainability of the beef cattle industry in northern WA.

Use of integrated crop-livestock systems to reduce economic risk to rangeland grazing systems

Windh, JL[1]; Parsons, J[2].

Key words: cover crop grazing; integrated crop-livestock systems; rangeland grazing; grazing economics

Abstract

The economic sustainability of rangeland livestock operations requires that the land resource be properly managed while also optimizing the supply of forage produced and grazed. Keeping this balance of range health and adequate grazing supply, and therefore animal production, is dependent on a producer's ability to adapt to stochastic shocks, such as drought or delayed growing seasons; one such adaptive mechanism is to use alternative forages, such as cover crops, as a supplementary grazing source.

Using a simulation modelling approach on 20-years of rangeland production data from the Sandhills ecoregion of Nebraska, USA, a mixed-grass prairie in the central plains of North America, we analysed the variation in annual production risk to a grazing operation associated with having a set, non-flexible grazing plan. We then analysed how that production risk changes when a spring-grazed cover crop of cereal rye is added as an early-season grazing alternative. Within the model, forage resources of rangeland, cover crop, and hay were available to be used, with hay only being utilized once the other forages were no longer available. The model determined when to graze the cover crop and rangeland in order to maximize the total grazing days, based on the forages' within-season growth rates.

Our results indicate that there are compounding benefits to rangeland forage production by delaying grazing even by a short time, with a one day of grazing delay resulting in multiple days of additional forage later in the season. However, we also find that a spring-grazed cover crop is not an appropriate alternative forage to consistently reduce production risk in the Sandhills. This highlights the importance of having a diverse portfolio of forage types available to reduce different drivers of risk. Production risk to Sandhills graziers should be re-evaluated using a late season cover crop.

Introduction

The integration of livestock grazing into cropland is not a new concept; it was, however, historically more popular in the United States' Midwest than it is today, with major decreases noted in the 1925-1945 period (Smart *et al.*, 2021). More recently, as a response to multiple factors, including cover crop use on winter croplands and as potential mitigation to climate variation affecting livestock forage supply, integrating livestock into cropping systems has seen a resurgence in popularity (Bowman *et al.*, 2024). This increase in popularity has been complemented by an increase in studies focusing on integrated crop-livestock systems, including studies on soil health, animal production, and agronomic benefits, but a systems-level evaluation investigating how grazing cover crops may affect other aspects of a year-round grazing system was lacking. Several studies based in annual grassland systems of Australia (Thomas *et al.*, 2015; Thomas *et al.*, 2012; Dove, 2018) did evaluate the system-level impacts of grazing a dual-use crop, or a cash crop that is resistant to grazing during a portion of its growth, and found production benefits as well as the risk management benefits associated with diversified systems.

Economically, modelling livestock production within cropping systems is relatively straight-forward. The agronomic modelling of a monocrop can be algebraically determined, and livestock weights are easily tracked; Coufal (2019) modelled the farm-level benefits of grazing a cereal rye cover crop in Nebraska using this methodology. Production-level economic studies for rangeland systems are more challenging and uncommon in the literature, one reason for this is the challenges with modelling production for heterogeneous landscapes without distinct spatial boundaries. Rangeland production is, instead, typically tracked using early- and late- season biomass measurements and then correlated with climatic and grazing variables (Smart *et al.*, 2007; Stephenson *et al*., 2019) and economic studies are largely derived from animal weight data (Windh *et al.*, 2020).

In this study, we modelled production of a cereal rye cover crop using an algebraic set of equations, and we modelled a mixed-grass rangeland pasture using a sigmoid growth function for the individual cool- and warm-season grass components. We then evaluated the production-level impacts of delaying grazing to the rangeland system in the Sandhills of Nebraska, USA, by grazing the spring cover crop.

Methods

Modelling the growth of cereal rye model followed the mathematical system of equations laid out in Coufal (2019) and can be seen in detail in Windh (2023). The model was adapted to our study area at the University of Nebraska-Lincoln Barta Brothers Research Ranch near Rose, Nebraska, USA using climatic data from an on-site weather station. The model was most limited by the availability of soil moisture data. The equations follow the growth of rye on a daily time step from germination through maturity, with temperature and water stress limiting growth by an adjustment factor. The daily time-step model was important for our ability to model re-growth while grazing was occurring in our final simulation model.

Rangeland grass biomass data from the Barta Brothers Ranch was used to inform the rangeland production model. Current year herbaceous biomass was clipped from within grazing exclosures twice annually, once in mid-June to correspond with peak cool-season production and once in mid-August to correspond with peak warm-season production. Data was collected annually from 2000 to 2020, separated by functional group, and the exclosures were moved annually after the final biomass collection.

Voisin (1954) modelled the "kinetics" of grass growth and showed how marginal growth rates can be used to determine the optimal length of rest, post-grazing, before a pasture can be grazed again. Later, Cacho (1993) readdressed this topic and showed that a sigmoid curve has a better fit than other mathematical models to sets of both grazed and non-grazed grass biomass data. Following from these, we fit our data to a Gompertz growth curve; the Gompertz curve (Equation 1) is an asymmetrical, four-parameter, sigmoid equation:

$$x = Ae^{(-b)e^{-kt}}$$

The output, x, is grass biomass in lbs/acre. A is the maximum potential growth during the growing season; this defines the asymptote of the curve and is set based on measured end-of-year biomass data. b is the displacement of the curve on the x-axis. The displacement is necessary because grass growth does not begin when t, which in this case is cumulative growing degree days (GDD) with a base temperature of 40˚F, equals zero. An accumulation of several days with GDD greater than zero are required to stimulate grass to begin growing. In this equation t is growing degree days, rather than time, in order to compare multiple years of growth directly. Finally, the k parameter is the growth rate of the grass. We fit the data to the curves using known data to inform A, b, and t, and used the *easynls* package in R to determine the best fit for k, resulting in 21 annual growth curves. The derivatives of the curves gave us the daily growth rates for the simulation model.

Using the cereal rye and rangeland production values, we created a simulation model to show how the cereal rye could complement the rangeland grazing. We wanted to model how to best use our available forage portfolios on a daily time-step to 1) maximize rye use, 2) minimize hay needs, and 3) maintain rangeland health (i.e., prevent overgrazing). We modelled the simulation under three scenarios, 1) terminating rye on May 20 to plant a cash crop, 2) allowing rye grazing until it fully matures and it's quality as forage is low, and 3) a no-rye scenario to evaluate the other two rye contributions.

We developed a simulation model that follows the behavior of a cost minimization model; however, the output of interest is how each forage is selected for daily use, rather than the "minimized cost".

$$min\, C_t = \sum_{t=0}^{T} p_F x_F$$

where F is the three available forages: rye, rangeland, and hay, t is the daily timestep parameter, x is the daily (t) use of the selected forage (F), and p is the "price" set on each forage for the purpose of creating the desired behavior. p_{rye} is set as the lowest value to induce the model to use up the entire supply of rye biomass available. p_{hay} is set as the highest value to ensure the model only selects it as a last resort. $p_{rangeland}$ is set to some intermediate value, such that it is used after the rye but before the hay. Three constraints are used to emulate the properties that make the model realistic to an operation in the Sandhills of Nebraska: 1) the forage growth constraint, which used the cereal rye and rangeland production models to simulate regrowth post daily grazing events; 2) the daily use constraint, which constrains daily use of any combination of feed to 1 animal unit day worth of forage; and 3) the rangeland health constraint, which prevents the rangeland from being grazed below 650 lbs per acre. Further mathematical configuration of the model can be referenced in Windh (2023).

Results

Production models

The first surprising result was that cereal rye yields were very low in the location of our study; annual yields were 450 to 600 lbs/acre, whereas yields if 1700 lbs/acre are more common elsewhere in Nebraska. Yields of this magnitude are unlikely to provide any benefit to livestock producers as a grazing cover crop, unless there is sufficient land area to allow for stocking rates of 3 or more acres per animal unit (AU). Due to this unexpected result, we set the stocking rate of our simulation to 3 acres per AU.

The rangeland production curves, on the other hand, yielded quite varied results based on the year modelled (Figure 1). The Gompertz curve was successful in fitting curves to total annual production as well as annual warm-season production, however it was unsuccessful in fitting a curve for cool-season production due to the first data point

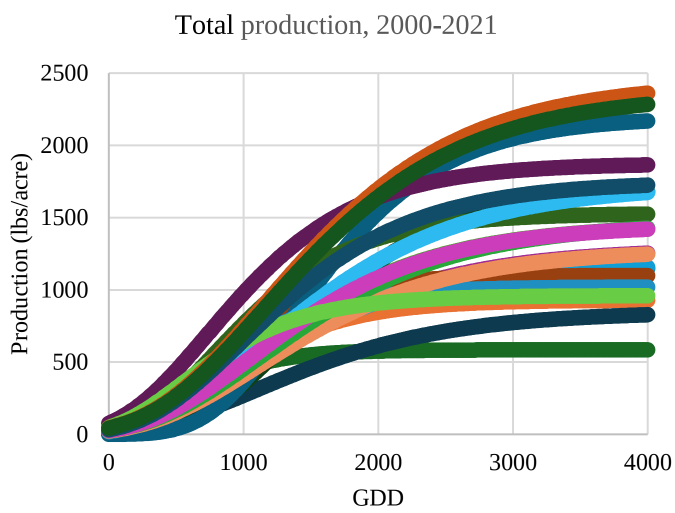

Figure 1. Total production curves derived through estimation with the Gompertz curve. Each line represents total production within one year between 2000 and 2021.

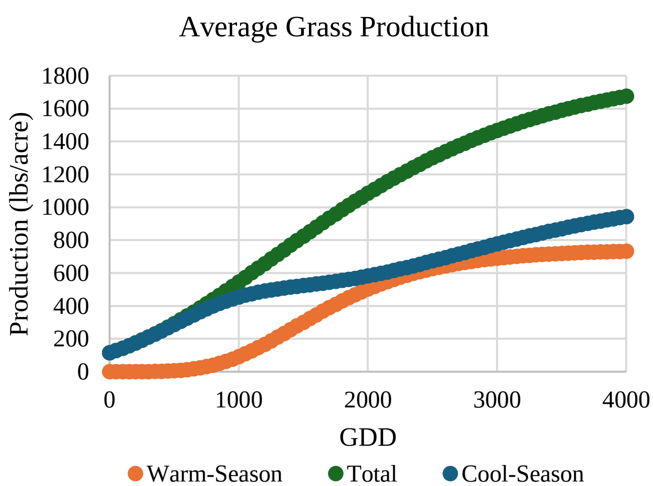

Figure 2. Average total, cool season, and warm season production curves across years 2000-2021

being from the peak cool-season production time. We were, however, able to take the difference in the total and warm-season curves to derive a cool-season curve with two-growth periods, which is consistent with the literature on cool-season grass production (Figure 2).

As mentioned, the soil moisture data was the limiting factor for modelling rye growth; due to this we ended up with 9 years for which we could simulate the full grazing system. Of those nine years, four of the years did not require any hay in addition to the cereal rye and the rangeland. The rye grazing was able to provide between 19 and 27 days of grazing in the cash crop model, and between 22 and 38 days in the no-crop model. We used the four years that did not require hay feeding to evaluate any benefits provided by the rye.

In the cash crop model, the rye is terminated on May 20 and rangeland grazing cannot occur before May 15; therefore, in this simulation the rye can only delay rangeland grazing by a maximum of 5 days. We wanted to evaluate the impact to the rangeland of delaying grazing, and while 5 days did not seem like much, it had substantial results. Between 77 and 205 lbs/acre of rangeland forage were available in excess of the 650 lb/acre threshold at the season's end; at a stocking rate of 6.66 acres/AUM that corresponds to between 19 and 52 additional grazing days as a result of a 5-day delay. More complete results can be found in Windh (2023, page 56).

Discussion

The Sandhills of Nebraska are one of the largest intact swathes of rangeland in the world, our cereal rye production results suggest that poor farming potential may have contributed to this preservation. Regardless, we can see small changes in production practices, such as delaying turnout, can yield large results. Dove (2018) found a 40% increase over the number of crop-grazing days delaying the livestock grazing. Our returns are substantially higher (400% to 1000% increase), but our stocking rates are quite conservative, especially with the 3 acres of rye per animal.

Within the production models, it would be interesting to know what caused the low cereal rye production values. The authors hypothesize that a late spring warm-up may be the cause, or possibly the soil water holding capacity of the regions' namesake sandy soils contributed to increased water stress. The cause would be interesting to investigate before producers, with more at stake, tried for a failed crop in a similarly unsuitable area. Within the rangeland production curves, further research is necessary to correlate the four parameters of the Gompertz equation with climatic drivers. Having some predictive context to the curves could clue producers into high production yields earlier in the season, or give forewarnings of climate-related forage shortages.

Despite our model not working as smoothly as one would hope, the benefits of integrating livestock into cropping systems have been shown in nearly every aspect of the system. Manure and urine add nutrients to the soil while hoof action contributes negligible soil compaction (Blanco-Canqui, 2020), cash crop yields are unaffected or increased (Bowman *et al.*, 2024), and the grazing creates another enterprise with which crop producers can diversify their operations. Further research is required to understand the full mechanics of these grazing systems, and how they work across ecoregions, but preliminary research shows it's a promising option.

Key words: economic, herd, modelling, safe stocking rate, infrastructure

Abstract

In the semi-arid rangelands of Central Australia, research undertaken at the Old Man Plain Research Station (OMP) has shown that managing stocking rate at a safe utilisation level allows land condition improvement given two La Niña years in a row. The first year provides a high rate of vegetation growth and consequent seed and the second-year results in a recruitment event from the first year's seed bank. The aim of this paper is to contrast the economics of OMP grazing strategies to an industry business-as-usual scenario. A bioeconomic model has been developed which encompasses a pasture growth model; the GRASs Production (GRASP) model linked to herd structure modelling using Breedcow and Dynama. The herd performance and other baseline data was derived from industry consultation, whereas the OMP data was derived from published data from the research station.

The analysis shows that there are economic incentives to run safe stocking rates. Besides the unequivocal environmental (land condition) benefits of running a safe stocking rate, the economic benefits are dependent on the initial status of the station and how it transitions to a safe stocking rate. The analysis concludes that there are economic benefits of running safe stocking rates, however implementation should be carefully managed by pastoralists to maintain a positive cash flow.

Introduction

Researchers have described key strategies for maintaining productivity in Northern Territory's rangelands (Walsh et al., 2014; Walsh and Cowley, 2016). One of the main principles is rigorous control over total grazing pressure by controlling animals' access to water supplies through self-mustering yards (SMY) and other infrastructure. This principle permits stocking rate adjustments in response to seasonal conditions, and most significantly, implementation of safe stocking rates (SSR). A safe stocking rate (SSR) is described as the stocking rate that allows for land condition maintenance or improvement over time. Usually, the SSR is calculated as the safe utilisation of median long term pasture growth / intake (Johnston *et al.* 1996).

The Northern Territory Department of Agriculture and Forestry (NT DAF) have been testing the application of SSR on Old Man Plains Research Station (OMP), near Alice Springs, Australia, over the last 15 years. Applying safe stocking rates has facilitated land condition improvement at OMP (Materne and Cowley 2023), increasing the cover of forage across the landscape (Bastin et al. 2024). The application of a SSR on OMP has resulted in livestock performance that is consistently higher than other properties in the region (Materne et al 2021). Properties in the Alice Springs region are typically large (average 3799km^2) and poorly developed with an average 28 watering points per station (Conradie 2014). The result of this underdevelopment leads to only 50% of the average station being within a 4km radius from water (watered area) where cattle usually graze (Hodder and Low 1978). This leads to uneven grazing pressure across the landscape and high grazing pressure surrounding waters, thus investment is infrastructure is key to further spread and control the grazing pressure

The economics of applying SSR on a commercial station has not been yet investigated. The present study aims to evaluate the economic and environmental benefits of implementing self-mustering yards (which provide control over total grazing pressure via controlling animals access to water), while running a SSR. These interventions are expected to permit pastoralists to manage stocking rates more efficiently, reduce overgrazing, and help ensure sustainable beef production in Central Australia.

Methods

In this study we applied a two-step modelling approach given the complexity of integrating the models. Firstly, pasture growth and Total Standing Dry Matter (TSDM) when grazed by cattle was modelled using the GRASP model (GRASs Production; McKeon et al. 2000; Rickert et al. 2000) which has been calibrated by NT DAF to OMP land types and land condition (Materne and Cowley 2023). The pasture growth modelling results of the land conditions and stocking rates on OMP encompassed 100-year data sets using Alice Springs Airport rainfall (LongPaddock, 2024). The modelling considered 2 land conditions (B and C – see Walsh et al. 2014) with three different management scenarios (Table 1) and 7 different constant stocking rates from 0.5 to 12 adult equivalents (AE - McLennan et al. 2020) per km^2. This provides 42 x 100-years results.

Secondly, a herd bioeconomic model has been developed which uses the relevant modelled pasture availability from the different scenarios noted above. Given the herd modelling results, the model selects the pasture growth jumping from one of the 100-year results to the most appropriate one, given the modelled land condition and stocking rate. The herd structure modelling is based on Breedcow and Dynama (Holmes et al. 2017) which were modified to allow for herd variations and un-mustered cattle (i.e. phantom herd) (d'Abbadie et al. 2024).

An initial herd and station condition was developed after discussions with both NT DAF experts and pastoralists. From the initial condition, three scenarios have been run: (a) BAU: This scenario performs as the contrafactual in which the station's business as usual (BAU) has developed across time with almost no adoption of practice change. The objective of this scenario is to reflect current poor-performing practices. This scenario was contrasted with two improved management practices, T and TS. (b) T: This scenario builds on the BAU scenario and includes the development of a network of SMY which enables a higher mustering efficiency and better herd management. (c) TS: This scenario builds on the T scenario and runs with a SSR in the watered area. The lower stocking rates will reduce pasture utilisation, improve land condition and increase animal performance.

Table 5: Main variables considered in the modelling for the initial condition and the three scenarios considered: business-as-usual (BAU), self-mustering yard development (T) and self-mustering yard development and safe stocking rate (TS)

Variables	Initial Condition	Expected status after 20-years		
		BAU	T	TS
Herd numbers mustered (AE)	5000	5000	5000	2213 - 3218
Target Stocking Rate (AE/km^2)	5	5 with destocking	5 with destocking	2.2 + 1
Weaning Rate (%)	50%	60%	70%	83.50%
Mortality rate (%)	10%	5%	5%	0.50%
Annual LWG steers (kg)	110	110	130	150
% turnoff females	15%	15%	37%	50%
% turnoff males	85%	85%	63%	50%
Land Condition	C	Maintained	Maintained	Improved to B
% water points with self-mustering yard	20%	50%	100%	100%
Mustering Efficiency	50%	80%	95%	95%
Phantom herd	50%	20%	5%	5%

The simulated station is located in Alice Springs region and was assumed to be in poor condition (land condition C- see Walsh et al. 2014) and has 1006 km^2 of watered area. It was assumed that the land condition improvement will occur when there is both a double La Niña event as the station is carrying a safe stocking rate within the watered area, so that the stocking rate increases by 1 AE per km^2 (Bastin et al. 2024). The model encompassed 20 consecutive rainfall years for each scenario, with the initial year varied from 1987 to 2004 to assess sensitivity. The model used the last 20-year average South Australian cattle prices (MLA 2024), and variable costs were discussed with pastoralists. Droughts were assumed to have no effect on prices. Fixed costs were based on current benchmarks for the region (McLean et al. 2024) and remained constant throughout the modelling. Infrastructure costs were set at $30,000 per SMY. Each scenario included an infrastructure development plan implemented in year one to understand the economic merits of infrastructure development. Scenarios were compared using net margin and net present values (NPV) with a 10% discount rate.

Results

Figure 1 shows the carried cattle for the 17 runs for each scenario. Both the BAU and T scenarios maintain a stable stocking rate over time. In the T scenario, the stocking rate stabilizes after five years due to the improved mustering efficiency from the SMY network, which helps to both control the herd and reduce numbers to desired levels. Additionally, the T scenario exhibits lower variability compared to the BAU scenario. In the TS scenario significant destocking occurs during the first five years, followed by an increase in carried cattle as land condition improves, typically after ten years on average. This improvement can occur between five to thirteen years, depending on the occurrence of a double La Niña event.

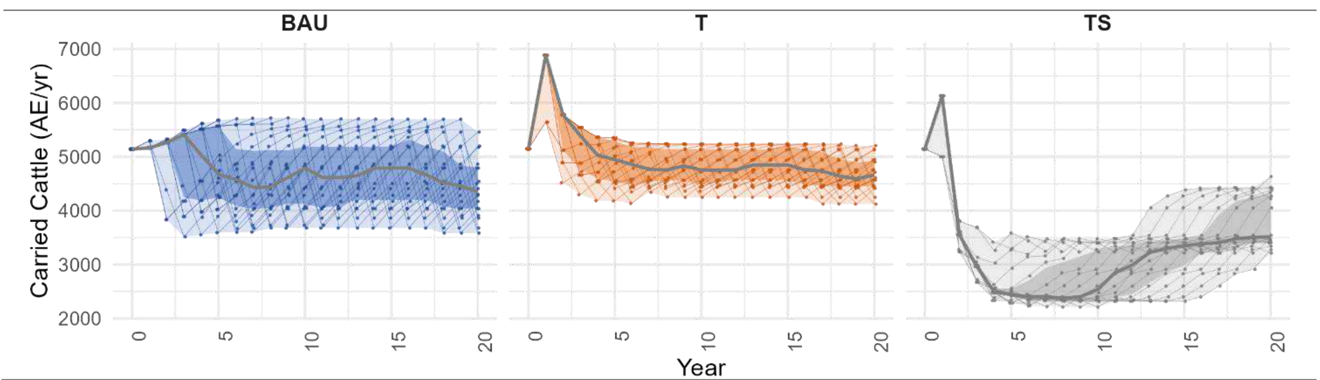

Figure 1: Yearly herd size (without considering phantom herd) for the business-as-usual (BAU), self-mustering yard development (T) and self-mustering yard development and safe stocking rate (TS) scenarios considering the

median in black and the 50% confidence interval in dark shaded colour. All 17 simulations with different starting years shown for each scenario.

The BAU scenario shows the largest variability in net margins over time (Figure 2), from the need to destock during prolonged droughts. Despite occasional highs from destocking during droughts, the overall net margin remains negative. A limitation of all scenarios is the fixed costs, which remain constant and do not adjust seasonally or in response to cash flow constraints.

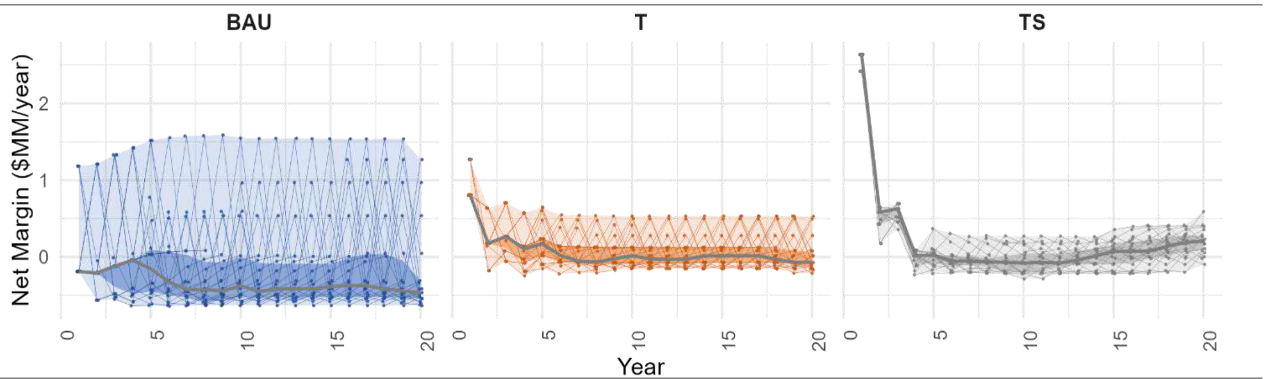

Figure 2: Yearly net margin for the business-as-usual (BAU), self-mustering yard development (T) and self-mustering yard development and safe stocking rate (TS) scenarios considering the median in black and the 50% confidence interval in dark shaded colour. All 17 simulations with different starting years shown for each scenario.

The T scenario is profitable in the first five years, with destocking of the phantom herd funding the trapyard developments. This scenario also requires destocking during droughts. After year five, cash flow averages around zero. Compared to the BAU scenario, the T scenario generates approximately $2.27 million extra in NPV (at 10% discount rate) over 20 years, with a return on the investment required to install the self-mustering yards of around 474%. In the TS scenario, peak cash flow occurs in the initial years due to destocking, which funds the self-mustering yards. From years five to thirteen, cash flow remains around zero. When the double recruitment event occurs, net margin increases as more cattle can be carried. Implementing safe stocking rates alone adds approximately $1.44 million in value, assuming the SMY are already in place.

Discussion

The results indicate that implementing SSR offers long-term economic benefits by reducing pasture utilization and eventually improving land condition, pasture growth, and animal performance. However, adopting SSR can lead to poor cash flow from the 5 to 10 years following the income gained from destocking and gaining control over total grazing pressure (TGP). This "valley of death" may deter pastoralists from adopting this strategy. To navigate this period, financing options could include the cash income from destocking, which could be deposited in banks to earn interest or used as needed. Additional income sources might include carbon credits, biodiversity credits, or investments from public donors interested in supporting enterprises that enhance and maintain land condition and biodiversity. Future research should explore additional infrastructure developments, such as more water points, and analyse the sensitivity of these interventions to varying initial conditions in this environment.

The results also highlight the benefits of investing in infrastructure such as SMY in that it improves TGP management, allowing for greater control over animal performance and significantly increases mustering efficiency. This presents an opportunity for pastoralists to leverage infrastructure development to better manage grazing pressure and potentially spread cattle with new or redeveloped water points. Consequently, the more cattle on the property, the greater the opportunity to capitalize on those above-SSR numbers. It is important to note that the BAU scenario's economics are poor, with net margins consistently below zero. A limitation of this modelling is the lack of tactical adjustments to fixed costs in response to extended dry periods. As a result, costs remain unchanged regardless of income levels, leading to negative cash flows, and as such alternative sources of income are likely to be required in order to implement the proposed changes.

Key words: Zebu; Rangeland; Madagascar; Livestock; fire.

Abstract
Madagascar's poverty is partly linked to inadequate livestock nutrition and inefficient use of grassland, which covers more than half of the country's surface. Prioritising zebu nutrition and efficient use of native forage species can lead to substantial improvements.

This project involves 90 households and is working to improve zebu breeding around three protected forests in Madagascar: Ankafobe, Ibity and Itremo. The initiative focuses on pasture productivity, forage grass management and livestock nutrition. It includes demonstration farms, experimental pastures and forest plots with a fire management plan. Monitoring focuses on cow performance, forage production, grazing capacity and biomass productivity.

Across the project sites, nitrogen deficiency and low phosphorus and potassium levels are common. The successful silage production (1881 kg/ha) resulted from combining Supergraze 1000 forage sorghum with legumes in Ibity. Households fed zebus with silage and hay for the first time. In Ibity, milk production tripled, while in Itremo and Ankafobe, beneficiaries focused on calf production, achieving annual calving rates of 63.4% and 58.0%, respectively. Initially, 123 grass species were inventoried around experimental pastures. After fire and grazing, grazing capacity decreased from 1.4 ha to 0.7 ha/zebu/year, and biomass production varies between 300 and 800 kg/ha.

Madagascar remains famous for subsistence farming with long-term decline in livestock, but there are significant opportunities for integrated crop-livestock production and the sustainable use of grassland while preserving biodiversity.

Introduction

In Madagascar, grasslands are vital to the rural economy, especially for livestock farmers who rely on native forage grasses to feed their animals (Bosser 1969; Randrianarimanana et al. 2024). However, these pastures face significant challenges. Annual bush fires, often set to renew pastures, disrupt local ecosystems, threaten biodiversity, and degrade soils (Kull 2002). Additionally, population growth increases pressure on the remaining land and forage quality, heightening the demand for natural resources (WorldData.info February 2025). It is increasingly important to balance the interests of local communities with biodiversity conservation by adopting sustainable natural resource practices. Innovative solutions for managing native forage grasses and improving animal husbandry practices, particularly in feeding, could help balance animal production with the preservation of protected areas (Kew 2021). This study aims to propose solutions to enhance zebu nutrition by leveraging botanical knowledge, agricultural science, and fire management expertise.

Methods

The project collaborates with local communities living around three protected areas in Madagascar's central highlands: Ankafobe, Ibity, and Itremo. These communities have built trusting relationships with international researchers for over two decades. The project operates on the principle that farmers learn best by applying techniques observed at demonstration sites, ensuring the effective transmission of methods tailored to local conditions.

- The project is collaborating with 30 Malagasy zebu-owning households to initiate pilot activities in their villages.
- A demonstration farm per site has been established with 4 female zebus to monitor milk production, body condition, calving rates, grazing effects in the experimental pasture, and other farm activities.
- A demo barn was constructed at each site using a simple, replicable model with locally available materials.
- The project includes 2 hectares of fenced experimental pasture: 1 hectare protected from fire and 1 hectare burned, to compare grass species diversity, frequency, biomass production, and grazing management using the project zebus.
- Additionally, a one-hectare field has been set up for planting other forage crops, such as Sorghum sp., for silage production, combined with leguminous crops.
- The project also utilizes available crop residues for storage and use during the dry period.

Results

As the project aimed to enhance zebu nutrition through new techniques, the following metrics were recorded: fodder production, animal production from zebu breeding on the demonstration farm and among beneficiary farmers, including milk production, zebu body condition scores, and annual calving rates.

Forage production

The project and beneficiary households produced 770 kg/ha of Supergraze 1000 (SS1000) sorghum silage and 2704 kg of native grass hay during the last year of the project. The main crop residues used are peanut, bean and corn stalks, urea-treated rice straw to feed zebu, and sweet potato stalks to improve silage quality.

The following photos show the research activities carried out in each experimental pasture, including inventories and monitoring of the frequency and diversity of native grass species, and the rotational grazing method

Figure 1: Inventory of grass species in the experimental pasture

Figure 2: Rotational grazing with project zebus on experimental grazing land

For the pasture biodiversity, 133 species from 31 families and 95 genera including grass and forb dominated by *Poaceae, Asteraceae, Cyperaceae, Fabaceae, Orchidaceae, Rubiaceae*. Pasture quality annual biomass production is about 2,700-8,356 kg/ha depending on the fire regimes. The average biomass productivity for the 3 sites during the project is as follows:

- For unburned pasture: 2850 kg/ha in year 1 (2022), 4418 kg/ha in year 2 (2023) and 9765 kg/ha in year 3 (2024).
- For burnt pasture: 3851 kg in year 1, 2981 kg/ha in year 2 and 4985 kg/ha in year 3.

The average species per plot region is about 9 -13 for Ankafobe, 8 - 13 for Ibity and 3 - 6 for Itremo in 2024. In terms of soil quality, across all sites, the soil analysis exhibit very low levels of nitrogen, phosphorus, potassium, and calcium. Additionally, all sites show high iron toxicity, with Ankafobe being particularly affected.

Zebu production

Figure 3 illustrates the changes in calving rates for both beneficiary and project zebus over the three years of project implementation, compared to the baseline.

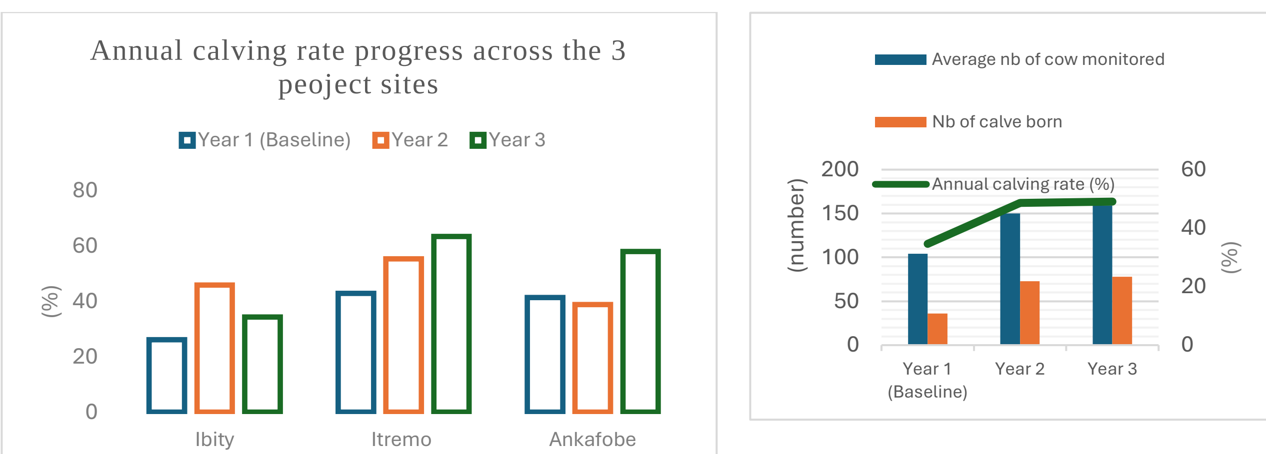

Figure 3: Change in percentage zebu calving rate over 3 project years compared with the pre-project baseline level, number of cows monitored, and number of calves born.

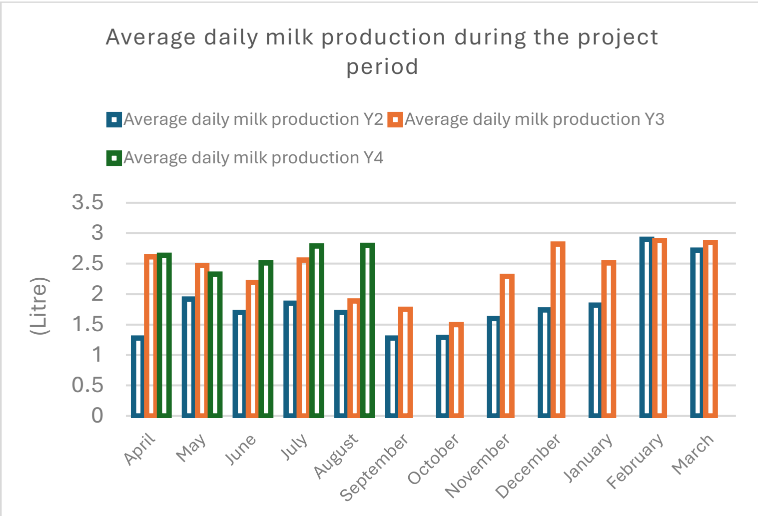
Beneficiaries in Ankafobe and Itremo had higher calving rates than those in Ibity, indicating a preference for more calves over milk production (Figure 4). This suggests that weaning around two months after calving encourages zebus to prepare for the next reproductive cycle.



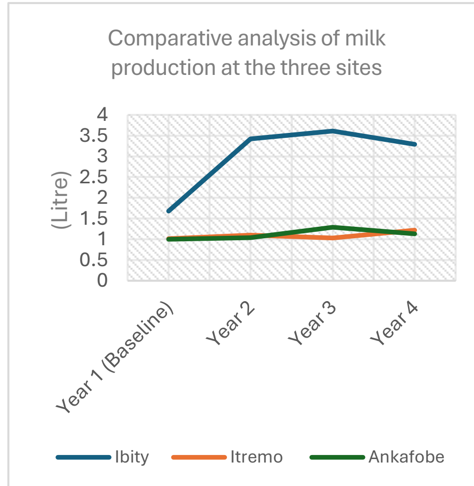


Figure 4: Average daily milk production over the 3 years of the project compared with the pre-project baseline level.

Farmers are gaining experience each year (Figure 4). Despite only having data for the first four months of year 4 (end of the project), it is evident that farmers have mastered feed stock management, ensuring sufficient feed for the dry period.

Discussion

Reducing rural poverty in Madagascar through the development of cattle farming, particularly in terms of feed, is entirely achievable. Effective pasture management using native grasses, through conservation techniques like haymaking and controlled grazing fire management, are among the best strategies, despite their challenges. In Madagascar, the focus should be on improving extensive grazing land, which is still in a legal vacuum: it is neither officially untitled property, nor land with a defined legal status (Ranjatson P et al 2021). Additionally, utilizing available resources such as crop residues to ensure consistent feeding during dry periods is beneficial. Incorporating high-nutrient, climate-tolerant, soil-covering forage species like sorghum is also highly recommended to quickly address feed deficits in native grasses. To improve soil quality, it is crucial to educate farmers on using zebu manure to create compost for their crops, as well as employing crop rotation and association techniques to alleviate land requirements, cover the soil, and increase yields for both food and feed on the same field. Decreasing the frequency of fires will reduce soil sensitivity to heavy rainfall, thereby minimizing the risks of erosion and soil degradation (Masse et al 1997, Louppe D 2004). The degraded soil quality negatively impacts the floristic and nutritional composition of the pastures, likely leading to soil erosion. The forage grasses that grow in these conditions are also expected to have low nutritional value (Rasambainarivo 1997).

Integrating zebu breeding into farming practices will further facilitate this approach. These new practices for the community will also contribute to the protection of biodiversity around protected areas.

Acknowledgements

We would like to express our deep gratitude to all the institutions and partners who made this project possible. Many thanks to the UK Government and the Darwin Initiative for funding the project, and to NERC for supporting travel. We are also grateful to the Royal Botanic Gardens Kew and the Missouri Botanical Gardens for implementing the project at the three sites of Ankafobe, Ibity and Itremo. Your support and collaboration were essential to the success of this project.

Multinational Ground Beef: Global integration of beef production systems and implications for the sustainability of rangelands

Barry, S

University of California Cooperative Extension, San Jose, California

Key words: Grazing; beef cattle; global trade; rangeland management

Abstract

In many parts of the world, including the USA, the beef supply chain engages many small-scale producers raising cows and calves on rangelands. This part of the beef supply chain is a social-ecological system where raising cattle is tied to livelihoods, land, natural resource and agricultural uses, and ecosystem processes. To produce and market beef products this system relies on transportation and markets to bring cattle to fewer and larger operations for finishing, and to a handful of beef processors for slaughter and wholesale marketing. With the inclusion of imported lean beef from South America and Oceania, US beef production is a globally connected system that impacts the sustainability of rangelands and their ecosystem services across continents. Using livestock identification inspection data and survey, this research describes California's beef production system. Managing rangeland resources for multiple ecosystem services, California's beef cattle producers seasonally move calves from rangelands often to intensive feeding operations. Fat-trim, a by-product of intensive feeding creates a demand for lean beef from grazing land cattle (including imports).

The demand for beef, dairy and mutton is projected to nearly double with the world population reaching 9 to 11 billion by 2050. Whereas increases in beef production have been primarily achieved through intensive livestock production systems, extensive systems exist in parallel and can be integrated with intensive production systems to increase production. Integration can contribute to sustaining rangelands and their ecosystem services. Data and communication technologies that support livestock records, markets, and price discovery afford more opportunity to integrate production systems at local, national, and even international levels and influence sustainability.

Introduction

The global beef industry faces unprecedented challenges as demand is projected to double by 2050, driven by population growth to 9-11 billion people (FAO 2023, OECD/FAO 2021). While intensive livestock systems have historically led production increases, extensive rangeland systems continue to play a vital role, particularly in supporting ecosystem services and rural livelihoods (Herrero et al. 2020). These systems are increasingly connected through sophisticated market mechanisms and international trade networks.

Rangelands, which cover approximately 60% of global agricultural land, represent a critical resource for food production while providing essential ecosystem services (FAO 2018). In the United States (US), small-scale producers managing these landscapes form the foundation of the beef supply chain, with most operations maintaining fewer than 50 head of cattle (USDA 2017). These producers rely on marketing infrastructure, including saleyards, to connect their operations with larger finishing facilities and processing plants. The US ground beef market exemplifies the global nature of modern beef production. Lean ground beef from grass-fed cattle in South America and Oceania is blended with fat trim from grain-fed animals finished in feedlots in the US to meet the US demand for lean ground beef (Ernst et al. 2020; Cheung and McMahon 2017).

Methods
This study analyzed California's brand inspection data collected from 2017-2021 following Barry's (2021) methodology. Brand inspections, required by law to verify ownership and prevent theft, occur during key cattle movements including sales, interstate transfers, slaughter, or entry into feeding operations. The brand inspection data included: type of transaction (e.g., sale, transfer, slaughter), cattle characteristics (e.g., breed, age, and sex class), geographic information (e.g., origin and destination of livestock), ownership changes, and number of head per transaction. Inspections occur at various points in the production chain, including saleyards, feedyards, meat processing facilities, and ranch locations.

Additional data on multinational ground beef production was gathered from industry reports and trade statistics. The analysis focused on the seasonal patterns of cattle movement, integration between production systems, market infrastructure supporting movement, and international trade flows in beef products.

Results
California Cattle Movements Analysis of California brand inspection data reveals significant seasonal movement patterns that support integrated production.

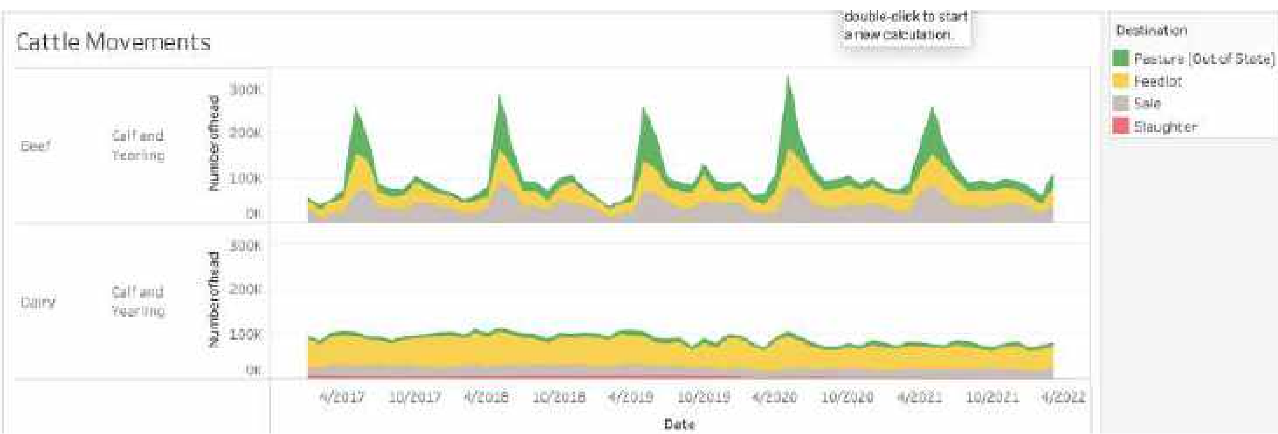

Fig. 1. Calves and yearlings (number of head) moving from California grazing lands (beef) and dairies or feed yards (dairy) from January 2017 to April 2022.

Over 560,000 head (43%) of beef calves and yearlings are moved off California's rangelands during a 12-week period each year in late spring to summer. This seasonal movement is in sharp contrast to the 1.2 million head of dairy calves, which are also moved through production systems to contribute to beef production, but with little indication of any cyclical or seasonal pattern (Fig. 1). A smaller movement occurs in fall with 15 percent (199,000 head) of beef cattle calves moved. Cattle movement data from California provides evidence that grazing cattle move from rangelands based on forage resources.

Market Integration The data shows most ranchers in California, from small-scale producers (1 to 50 head) to larger producers (more than 5,000), participate in the integrated beef production system:

- Fewer than 1% of steers and heifers go directly from rangeland to meat processing.

- Small and medium-sized producers marketed over 85 percent of their cattle through saleyards.

- Steers and heifers sold at saleyards were purchased by large-volume buyers and moved into intensive production systems for finishing.

The production of multinational ground beef demonstrates market integration. The U.S. beef production system does not produce enough lean beef to meet demand for lean ground beef. Growing efficiencies in beef production in the US have resulted in fewer beef cows in the U.S. so there are fewer cull cows and bulls. Additionally, grinding up fed cattle for ground beef no longer makes economic sense, because of the high value of beef cuts. The blending of product from different systems and countries (Table 1) not only optimizes resource use and is facilitated by trade, linking rangelands in developing nations to consumer markets in industrialized countries (Table 1).

Table 1. Production systems contributing to multinational ground beef sold in the United States

Production System	Class of Cattle	Location	Contribution to Multinational Ground Beef
Extensive grazing rangeland	Beef cull cows and bulls	US, Canada	Lean meat
Intensive grain feeding	Dairy cull cows	US	Lean meat
Extensive grazing rangeland and improved pasture	Beef stockers and cull cows	Australia Uruguay Nicaragua	Lean meat
Intensive grazing improved pasture	Dairy cows and bull calves	New Zealand	Lean meat
Feedlot raised and finished	Fed cattle (dairy)	United States	Fat trim
Extensive grazing rangeland raised; Feedlot finished	Fed cattle (beef)	United States	Fat trim

Discussion

The movement patterns revealed in California's cattle production system exemplify how local rangelands connect to global beef supply chains through complex market integration. Small-scale producers managing rangelands play a vital, yet often overlooked role in this system (Huntsinger & Oviedo 2014). The seasonal movement of cattle off California's rangelands aligns with traditional ecological knowledge about forage quality and quantity (Becchetti et al. 2016). Producers time their marketing decisions to match both environmental conditions and market opportunities. This flexibility, supported by market infrastructure like saleyards and transportation networks, enables producers to optimize both production and conservation objectives (Barry 2021). Climate change may alter the timing and reliability of forage production (World Bank 2020). As Nori and Davies (2007) argue, access to diverse marketing channels helps producers manage risk from environmental variation. The seasonal movement patterns observed in California suggest producers use market integration to adapt to both ecological and economic conditions.

In Australia, extensive grazing systems dominate beef production, with large tracts of land supporting cattle in arid and semi-arid regions. Producers rely on rotational grazing and seasonal adjustments to balance livestock needs with forage availability, similar to California ranchers. Australian producers participate in global beef trade, with a significant portion of their beef exported to markets in Asia and North America. This integration and a National Livestock Information System facilitates economic sustainability and encourages adherence to environmental standards, including the preservation of biodiversity in grazing landscapes (McIvor et al. 2011; Howden et al. 2008).

In Uruguay, beef production is deeply integrated with global markets, particularly in Europe and Asia. Uruguay's producers manage grazing lands with a focus on sustainable intensification, employing rotational grazing and native grassland conservation techniques. The Uruguayan government has actively supported sustainability through policies that incentivize ecological grazing practices, carbon footprint reduction, and traceability systems. The "National Livestock Information System" ensures that beef exported from Uruguay meets stringent environmental and food safety standards. These efforts have positioned Uruguay as a model for balancing production efficiency with ecosystem health (Modernel et al. 2016; Ernst et al.,2020).

The role of saleyards in facilitating market integration deserves special attention. These facilities serve as crucial nodes connecting small-scale producers to larger markets (Sayre et al. 2013). Buyers sort, price, and match cattle to feed resources and markets; they consolidate cattle allowing a producer with even only one head to participate in a global market.

The sustainability implications extend beyond individual operations. Research by Huntsinger and Oviedo (2014) shows how grazing on California's rangelands provides ecosystem services including biodiversity conservation, fire fuel management, and watershed protection. The economic viability supported by market integration helps maintain these extensive grazing systems rather than converting lands to more intensive uses (Cameron et al. 2014).

Looking forward, new technologies like blockchain could improve supply chain transparency and help communicate conservation values to consumers (MacLeod & McIvor 2006). Blockchain technology provides a decentralized, secure way to trace the origin, movement, and management of livestock through integrated production systems. For example, blockchain can document every step of a beef product's lifecycle, from rangeland grazing to feedlot finishing and eventual processing. This level of traceability ensures transparency, allowing consumers to make informed decisions and enabling producers to differentiate their products based on sustainability criteria (Tian 2016, Ernst et al. 2020). In Uruguay, government-mandated traceability systems already demonstrate how this technology can support premium market positioning by verifying grass-fed origins and sustainable practices (Modernel et al. 2016). Expanding blockchain globally could facilitate fair pricing for ranchers managing their grazing lands sustainably, incentivizing practices such as rotational grazing and biodiversity conservation.

Conclusions

Global market integration, particularly through ground beef production, creates demand that helps sustain these extensive grazing operations. As Capper (2012) notes, different production systems complement each other - intensive feeding creates fat trim that requires lean meat from grazing operations for optimal ground beef production. This market integration extends beyond domestic boundaries, with lean beef imports from countries like Australia and Uruguay complementing US production (USDA 2021).

The global integration of beef production systems connects diverse production systems; it provides economic opportunities that enable producers to maintain extensive grazing operations while supporting ecosystem services. As Reid et al. (2008) argue, maintaining working landscapes requires understanding and supporting the mechanisms that make them economically viable.

Effective tools for optimal pasture management

Bauer, L*; Carriquiry, E*

*Instituto Plan Agropecuario, Br Artigas 3802, Montevideo, CP 11700, Uruguay.

Key words: Pasture Management, Meal Plate Index, Species composition**.**

Measuring Pasture Availability

Effective pasture management is fundamental for livestock farmers to ensure the sustainability and productivity of their operations. The initial step is to quantify the available biomass at various times throughout the year. This can be achieved by using a calibrated ruler to measure pasture height.

Calculation of the Meal Plate Index

Once the average pasture height is determined, farmers can calculate the Meal Plate Index. This index correlates the pasture available with the pasture required for the current livestock load, effectively indicating the adequacy of the “plate” to meet daily forage demand.

Case study: Las Tres Marías Ranch

At this ranch, pasture measurements were taken seasonally over four years to calculate Plate Index. For instance, in winter 2021, the initial measurement was 2 cm, the Meal Plate Index confirmed the necessity of reducing the livestock load, opposite to the farmer´s visual estimation that the pasture was enough for the season.

Observation on Species Composition

In paddocks with appropriate rest periods and limited grazing days, an increase in frequency and vigor of C4 species, such as *Paspalum dilatatum* and *Coellorachis selloana,* was noted, especially during summer. In damp fields, the last three springs monitoring sessions revealed a high frequency of *Poa lanigera*, a winter species preferred by livestock but highly sensitive to management practices.

Key Management Practices

Livestock farmers should focus on average pasture height, height at animal entry and exit, occupation and rest periods, and livestock load. This knowledge helps in making informed decisions to enhance pasture resilience and livestock productivity.

Introduction
This case study examines three years of data collected at Las Tres Marías Ranch, focusing on the Meal Plate Index (IsPC), pasture height, and species composition. The objectives were to analyze how ranchers manage uncertainty, adapt to variability and base their decisions on balancing stocking rates, pasture availability, weather conditions, and daily management practices, all of which contribute to meat production and profitability.

Methods
Pasture height was measured using a calibrated ruler designed by researchers (Santiago Lombardo et. al, 2021). This method leverages the strong correlation between pasture height (in centimeters) and dry matter availability (kg/ha), enabling precise estimation of forage availability for livestock.

Given the heterogeneity of the native grasslands, a systematic sampling approach was developed to account for variability in species composition, soil types, and topography (meadows vs. hills). Prior to measurements, a detailed survey identified distinct plant communities, ensuring accurate sampling routes.

Measurements were taken at 20-step intervals along predetermined paths. The sampling intensity was adjusted based on paddock size:

- 80 measurements for paddocks >100 hectares
- 40 measurements for paddocks <100 hectares
- 20 measurements for cultivated pastures

Data were collected seasonally, with four measurement rounds per year. In parallel, livestock requirements were determined based on the research from the leading agronomist Martin Do Carmo (2019) of forage consumption for various livestock categories. By comparing forage availability with livestock demands, the Meal Plate Index (IsPC) was calculated, providing a forage balance metric for decision-making.

Results

The Meal Plate Index (IsPC) illustrates the forage balance, with visual indicators resembling traffic lights:

- **Brown zone:** More than 1,2, mature pasture exceeding livestock load.
- **Green zone**: Between 0,8 and 1,2. Adequate forage for livestock
- **Yellow zones**: Between 0,6 and 0,8. Alert of not reaching the objectives.
- **Red zones**: Below 0,6. Increasing risk of forage deficits

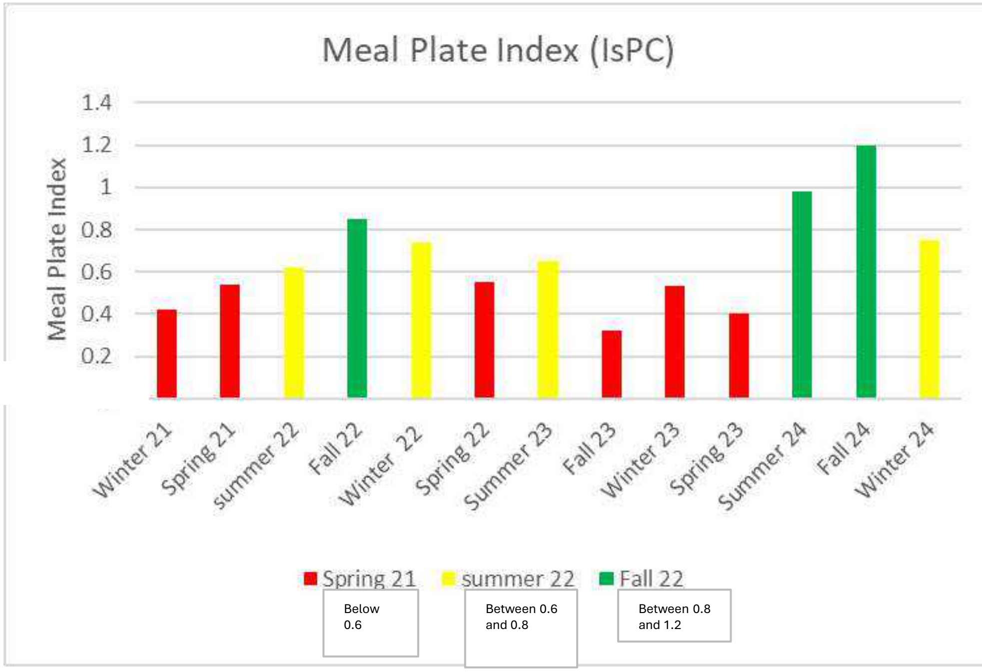

Figure 1: Meal Plate Index (IsPC) in every season that lasted the project in Las Tres Marias Ranch,

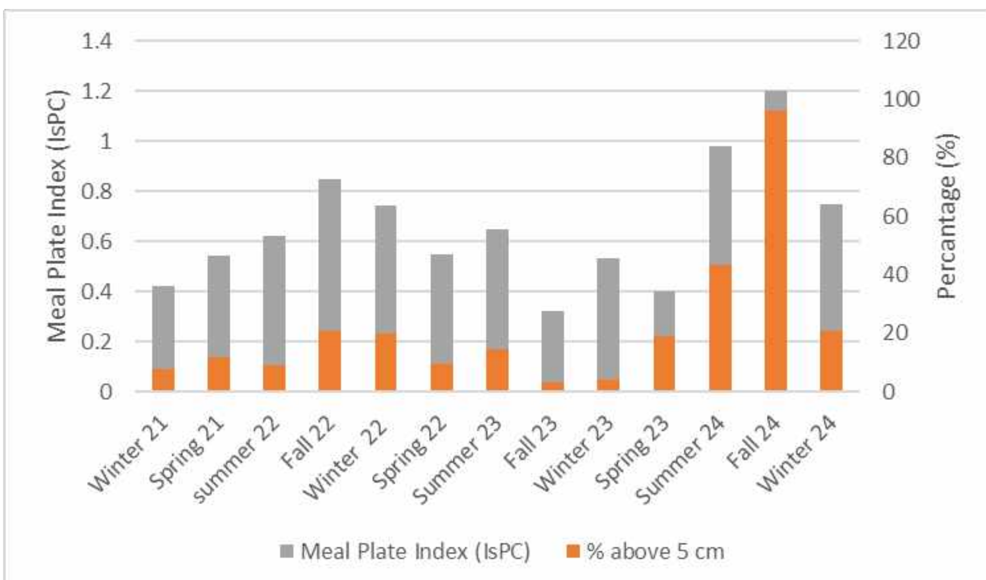

Figure 2: Meal Plate Index along with the % of grass above 5 centimetres.

The colours of the bars in Figure 1 align with the traffic light system previously mentioned: red bars indicate a risk of forage deficit, while green bars represent adequate forage availability for the livestock.

Discussion

Figure 1 illustrates the evolution of the Meal Plate Index (IsPC) over the three-year project period. Initially, the IsPC was notably low, reaching its lowest value during Fall 2023, an expected result due to a hard drought that persisted that year. A comparison of Fall 2023 data across graphics reveals that this period also had the smallest percentage of pasture area with grass taller than 5 cm.

Conversely, the highest IsPC was recorded in Fall 2024, with a value of 1.2 and 96% of the ranch exceeding the 5 cm grass height threshold. This improvement was primarily attributed to the favorable rainfall conditions during that season.

Analysis underscores a critical threshold: maintaining a high percentage of pasture with grass taller than 5 cm significantly influences both physical and economic outcomes.

The findings indicate that the Meal Plate Index is not inherently tied to seasonal patterns but is strongly correlated with the proportion of the ranch maintaining grass height above 5 cm. This emphasizes the importance of measuring grass stock and utilizing this indicator to inform ranch management and decision-making processes.

Forage Utilization and Meat Production

Figure 3 correlates meat production per hectare with the Meal Plate Index (IsPC) over three years. The data suggest a relationship between maintaining pasture height above 5 cm and achieving favorable IsPC values in the green zone, ultimately supporting higher meat production.

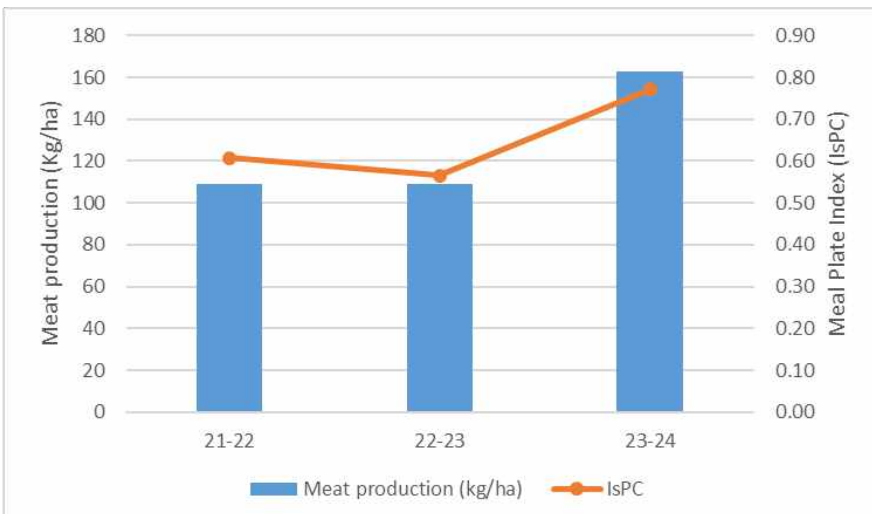

Figure 3: Meat production per hectare and Meal Plate Index (IsPC)

Species Composition Observations

An unused paddock with tall, mature grassland was transformed through targeted grazing management. A water trough and a protein supplement were introduced, and 400 cows rotationally grazed the area in small paddocks. This intervention rejuvenated the grassland:

- Mature grasses were consumed, allowing light to reach the soil.
- Initial colonization by herbs and small weeds protected the soil.
- Over time, native and non-native species (e.g., ryegrass) flourished, creating a more diverse and productive pasture.

The rejuvenated grassland provided high-protein forage in its juvenile state and evolved into a mix of cool- and warm-season grasses, demonstrating the potential for converting underutilized areas into high-quality forage systems through strategic management.

This tool had a significant impact on the Meal Plate Index (IsPC) as the pasture area increased. The newly gained hectares were predominantly of good quality, enhancing the forage available to meet the same requirements.

Conclusions

The Meal Plate Index (IsPC) has proven invaluable for quantifying forage availability and guiding management decisions. Over the three years, the project demonstrated the importance of measuring grass stock and incorporating it into decision-making processes.

Weather played a significant role, with a severe drought in the first two years followed by favorable rainfall in the final year. This variability underscored the importance of adaptive management and maintaining sufficient paddocks with grass taller than 5 cm. Understanding plant communities, their rest periods, and strategic utilization is critical for optimizing forage production and profitability.

Balancing livelihoods and grassland sustainability: an analysis of biomass, stocking density, and income in Mongolian pastoralism

Bo, H[1]

[1] Department of Applied Economics, University of Minnesota, Saint Paul, USA

Key words: Pastoralism; income; biomass; livestock; Mongolia

Abstract
Mongolian pastoralism, a vital traditional livelihood, faces challenges from increasing livestock numbers, grassland degradation, and socio-economic disparities. This study explores the relationships between biomass, stocking density, and livestock-based income among Mongolian pastoralists, using a pooled dataset from socio-economic surveys and ecological data from 2010 to 2019. A two-stage least squares (2SLS) regression framework is employed, with biomass as an instrumental variable for stocking density. The results reveal that biomass positively correlates with stocking density, while stocking density is negatively associated with net income, suggesting overgrazing and heightened resource competition. Other variables such as livestock number and household size are positively associated with net income, highlighting their critical role in sustaining pastoral livelihoods. Cluster analysis further shows variations based on biomass and income levels. Low-biomass regions rely more on cashmere yield, while high-biomass regions face constraints due to competing land uses. Wealthier households managing larger herds can mitigate income losses, whereas poorer households experience more significant losses due to weakness in competition. Policy recommendations include regulating livestock numbers to prevent overgrazing and promoting cashmere productivity in low-biomass regions. Future research should focus on dynamic panel data analyses and policy evaluations for sustainable livestock management.

Introduction

Mongolian pastoralism is a traditional livelihood deeply intertwined with the region's ecological systems and socio-economic structures. Despite its resilience over millennia, this practice faces increasing pressures from growing livestock numbers, grassland degradation, and socio-economic disparities, exacerbated by market demands for products like cashmere. Studies have highlighted the environmental consequences of overgrazing and the socio-economic challenges faced by pastoralist households, yet there remains a gap in understanding the intricate relationships between biomass availability, stocking density, and household income. Specifically, the interplay of ecological constraints and socio-economic factors in shaping pastoral livelihoods has been under-explored from an economic perspective.

This study seeks to fill this gap by examining what relationships biomass, stocking density, and other socio-economic variables have with livestock-based income among Mongolian pastoralists. By leveraging a pooled dataset from household socio-economic surveys and ecological data spanning 2010 to 2019, this work employs regression analyses to investigate these relationships across ecological and income clusters. The objectives are to assess the role of biomass in associating stocking density and income, explore the disparities among households based on wealth, and provide insights for sustainable livestock management and policy development in Mongolia's pastoral systems.

Methods

This study integrates data from three sources to form a pooled dataset (See details for each variable in Table 1). The primary dataset originates from the Household Socio-Economic Survey (HSES) conducted in Mongolia in 2010, 2013, 2016, and 2019. Only households actively engaged in livestock production in the 12 months preceding the survey were included. The Rangeland Production Model (RPM) is a gridded ecosystem model. It integrates the Century ecosystem model to estimate herbaceous biomass production given climate, nutrient availability, and soil properties (Kowal et al. 2021). The rangeland area size for each province used to calculate stocking density is also derived from RPM. Cashmere market price and total livestock number data by province are sourced from the National Statistics Office (NSO).

Table 1. List of the final selected variables and their definition

Data source	Variables	Description	Unit
HSEH	Net income	Yearly net income for each household from doing livestock husbandry (net income = selling animal/products - expenditure on animals)	Tugrig*
HSEH	Household size	Number of household members in each household	People
HSEH	Livestock number	Total livestock number for each household converted to goat unit (GU)	Heads of GU
HSEH	Cashmere yield	100 grams of cashmere per goat in the household for each year	100g/goat
HSEH	Other income	Pension and benefits other than revenue from livestock production	Tugrig
HSEH	Location	Dummy to indicate whether the household is located in a settlement or the countryside	Code: 0. Countryside 1. Settlement
HSEH	Water condition	Dummy to indicate main water source types, divided by whether water sources are fixed in location or not. Examples of fixed water are centralized water supplies, dug wells, and springs. Unfixed water includes tanker trucks, rainwater, surface water…etc.	Code: 0. Unfixed 1. Fixed
NSO	Cashmere price	The average market price of cashmere per kilogram in each province for each year	Tugrig/kg
RPM	Biomass	The average potential biomass production in grassland for each province in a specific year	Kg/ha
NSO and RPM	Stocking density	Total number of goat units per hectare of each province's rangeland area in a specific year.	GU/ha

*Tugrig: Mongolian currency. One US dollar is roughly equivalent to 3500 Mongolian tugrig

Biomass does not have a direct relationship with income but influences it indirectly through livestock, which depends on forage availability (Herrero et al. 2013). The quantity of grassland biomass, measured in kilograms per hectare, determines the forage availability of the grassland, which directly impacts stocking density, the total number of livestock units a grazing area can support. Biomass serves as the basis for estimating potential stocking density and acts as an instrumental variable (IV) because it is exogenous determined by environmental and climatic factors, and is strongly correlated with actual stocking density (correlation coefficient = 0.62). Meanwhile, actual stocking density is treated as an endogenous variable, influenced largely by biomass and potentially by other management and environmental factors. I assume this structure stands and employed the two-stage least squares (2SLS) method. The model is described in equations (1) and (2). I used logarithm to treat heteroscedasticity on both the dependent variable and two major independent variables, biomass, and livestock number[11].

In the first stage, regress the endogenous variable of stocking density on the instrumental variable biomass to get the predicted values of stocking density (donated as $\widehat{SD_{Jt}}$). μ is the error term.

$$\widehat{SD_{Jt}} = \pi_0 + \pi_1 \, log\big(biomass_{jt}\big) + \mu_{jt} \qquad (1)$$

In the second stage, the dependent variable $log\ (Net\ income_{it})$ is regressed on the predicted stocking density from the last stage with other variables. Where the dependent variable is the net income of livestock production for a household i at province j in year t. Cashmere price, stocking density, and biomass are at province j in year t.

$$\begin{aligned} log\ (Net\ income_{jit}) & \\ = \beta_0 &+ \beta_1 \, log\big(livestock\ number_{jit}\big) + \beta_2 \widehat{SD_{Jt}} + \beta_3 household\ size_{jit} \\ &+ \beta_4 cashmere\ price_{jt} + \beta_5 other\ income_{jit} + \beta_6 water\ condition_{jit} \\ &+ \beta_7 cashmere\ yeild_{jit} + \beta_8 location_{jit} + \epsilon_{jit} \qquad (2) \end{aligned}$$

Cluster analysis further is applied to this model. One cluster is based on biomass level and ecozones, another cluster is created based on net income and household size. Each cluster contains three groups to represent biomass and wealth status from low to high.

Results

The main results from equations (1) and (2) are summarized in Fig. 1 which are the coefficient (dots) and their confidence intervals (lines across dots). All results are significant. Except for stocking density, all other factors are positively related to it. Livestock number is most positively associated with net income. In the first stage regression, the relationship reveals that a 1% increase in biomass corresponds to a 0.005 GU/ha (0.507/100) increase in stocking density. Predicted stocking density, however, shows a negative relationship with net income in the second-stage regression. The coefficient indicates that an increase of 0.1 GU/ha in stocking density is associated with a 1.8% decrease in net income from livestock production.

[11] When doing the log transformation, I add 1 to handle zero values in those variables. By adding 1 does not change final interpretation since both net income, livestock number and biomass are large values.

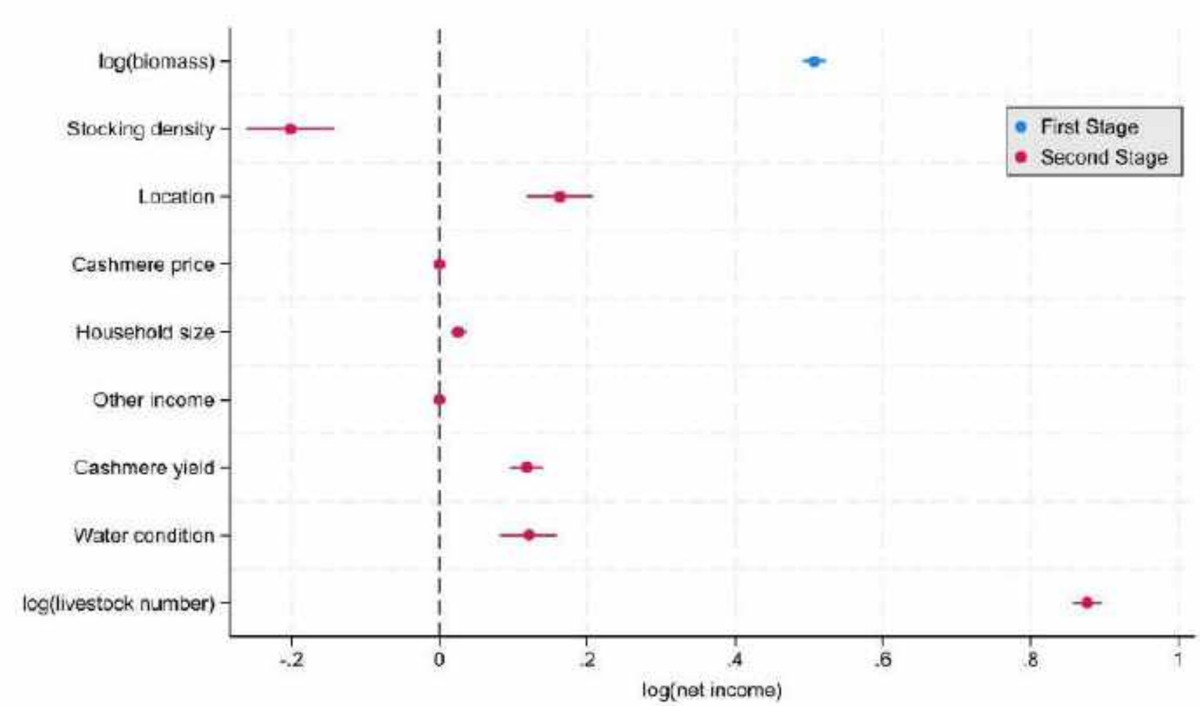

Fig. 1. General results from IV regression. Factors correlated with net income

Most results are also significant in all cluster analyses. I chose the most important variables and the main takeaway in each cluster group to be reported in Table 2. The first stage column reports the relationships between biomass and stocking density and the second stage column displays the relationship between predicted stocking density and the net income of livestock production.

Table 2. The main results from IV regressions by each biomass or wealth cluster group

Cluster group	First stage (Log (biomass) on stocking density)	Second stage (Stocking density on net income)	Interpretation of main results
Low-biomass	0.41	-0.232	Income response to cashmere yields more than other variables
Middle-biomass	0.888	0.367	Stocking density correlates positively with net income
High-biomass	-2.544	0.122	Stocking density is potentially constrained by the availability of or access to grazing land
Low-wealth	0.478	-0.169	Decreased net income is associated with stocking density increase
Middle-wealth	0.55	-0.076	Net income increases by higher biomass but possibly unreliable results due to low R squared
High-wealth	0.6	-0.03*	Stocking density is not related to net income

Note: Numbers are coefficients and * means statistically insignificant

Discussion

In the general results, the positive relationship between biomass and stocking density shows the basic idea that the more biomass, the more livestock the rangeland can support. This declining relationship between stocking density and net income is likely due to the increased demand for grass resources and heightened competition among livestock for adequate forage, reducing the per-unit livestock production. This negative association further suggests overgrazing which is a classic example of the tragedy of the commons, a concept articulated by Garrett Hardin in 1968. Increasing stocking density often leads to overgrazing since it exceeds the carrying capacity of grassland (Piipponen et al. 2022), then the degraded rangelands due to overgrazing disrupt the balance between livestock and their environment, leading to decreased livestock productivity and income, harming all users in the overgrazed areas (Silayi et al. 2024).

When breaking down the relationships by different clusters, the results suggest that regardless of the wealth status, increasing stocking density is related to less net income for livestock production. However, richer households can cope with it by keeping the larger scale of herds and having access to the market and more resources. Poorer households with less livestock will have a larger loss in net income since they are too weak to compete with richer households.

Low-biomass cluster suggests that overgrazing has happened but not for middle-biomass regions. The negative association between biomass and stocking density could mean some constraints prevent animals from grazing on land in the high-biomass group. Given the high biomass regions have the highest forest, cropland cover, and population density, lands may be turned to other uses than rangelands so fewer pastoralist households live in those areas resulting in less stocking density whereas the biomass is high.

All results suggest that livestock numbers should be regulated from overgrazing yet Mongolia currently does not have a systematic policy to control livestock numbers (ADB 2018). A higher positive association between cashmere yield and net income in low-biomass areas highlights that the decision-making in production and policy should help pastoralists focus on improving cashmere productivity instead of increasing the quantity of goats. Future studies should build on this study by using panel data to analyze effects between biomass, stocking density, and economic returns in a geographic spilite and dynamic format. Further policy analysis on livestock management and its impact is requested from this paper.

Effect of dietary combinations on productivity and greenhouse gas emissions in lambs

Dong, Y[1]; Wang, D[2]; Guo, C[3]

[1]College of Grassland Science and Technology, China Agricultural University,dongyao0624@163.com;[2] College of Grassland Science and Technology, China Agricultural University, shandongwangdeping@163.com;[3]College of Grassland Science and Technology, China Agricultural University, 2627238862@qq.com

Key words: Forage combinations; methane; Production performance, Apparent nutrient digestibility

Abstract

Livestock farming is one of the main sources of global greenhouse gas emissions, particularly methane produced during the digestion process of cattle and sheep, which not only harms the environment but also results in feed energy loss. Therefore, it is essential to understand the patterns and influencing factors of livestock greenhouse gas emissions to improve feed energy efficiency and protect the environment. By feeding different combinations of roughage, production efficiency can be increased and pollution reduced. Different forage compositions lead to varying greenhouse gas emissions in lambs. Understanding the response of productivity and greenhouse gas emissions to dietary combinations, exploring green regulation methods, and focusing on low-carbon emission reduction technologies are crucial for reducing methane pollution, improving feed utilization, ensuring animal health and product safety, and promoting sustainable livestock farming. This study selected 24 healthy lambs of similar weight, randomly divided into four groups of six, and fed different combinations of diets: natural hay, oat hay + natural hay, alfalfa hay + natural hay, and alfalfa hay + oat hay. Feed intake, weight changes, and greenhouse gas emissions were measured during the experiment.

The results showed: (1) Under ad libitum feeding conditions, the dry matter intake of the alfalfa hay + oat hay group and the natural hay group was significantly higher than that of the other two groups ($P<0.05$); the protein intake of the oat hay + natural hay group was significantly lower than that of the other three groups ($P<0.05$). (2) The average daily weight gain of lambs in the alfalfa hay + natural hay group was significantly higher than that in the oat hay + natural hay group ($P<0.05$) . (3) The trend of CH4 emissions in lambs was similar to that of CO2, with the natural hay group significantly higher than the other three groups, and the emissions in the alfalfa hay + oat hay group being the lowest; the N2O emissions in the alfalfa hay + oat hay group were also significantly lower than those in the oat hay + natural hay group. This indicates that feeding natural hay significantly increases the greenhouse gas emissions of lambs .

Introduction

Livestock consumption is projected to increase by 70% by 2025 due to global population growth, urbanization, and rising incomes (FAO 2017). Meeting this growing demand will require significant improvements in animal productivity and feeding efficiency. Efficient animal feeding involves producing economically viable and safe animal products while utilizing natural feed resources effectively an Consequently, animal welfare and health, product quality and safety, and greenhouse gas emissions are critical considerations when developing strategies for precision animal husbandry. Enteric methane emissions from ruminants not only represent an energy loss from their diet (Tseten et al. 2022; van Wyngaard et al. 2018), but also contribute significantly to global warming (Yang et al. 2021). While ruminants emit carbon dioxide (CO_2) through respiration and feed fermentation, this CO_2 originates from biogenic carbon in feed (e.g., plant biomass) and is not classified as a human-induced GHG in national inventories (IPCC, 2021), as it is part of the natural carbon cycle. In contrast, nitrous oxide (N_2O) is closely linked to nitrogen conversion in faeces and urine. Although N_2O emissions are typically lower than CH_4 in ruminants, its high global warming potential (298× CO_2 equivalent) makes it a critical contributor to climate change (IPCC, 2019). Exploring the effects of different forage types on CH_4 and N_2O emissions is essential. Such research can help reduce the environmental footprint of ruminant production while improving energy and nitrogen utilization efficiency, ultimately enhancing animal productivity.

Forage plays a critical role in ruminant feeding systems due to its affordability and abundant dry matter supply. However, its low feeding value makes it insufficient to meet the nutritional requirements of animals for production when used alone (Du et al. 2019). To address this limitation, researchers have explored supplementing natural pasture-based diets with legumes, which are rich in protein and energy (Graham and Vance 2003). Some studies have demonstrated that the use of legumes as a source of roughage in ruminant diets can reduce methane emissions (Alecrim et al. 2024; Quintero-Anzueta et al. 2021). Compared to grass forages, legumes are characterized by lower structural carbohydrate content, faster physical breakdown, and quicker rumen fermentation (Niderkorn et al. 2011). Consequently, feeding legume forages increases the rate of dry matter passage, which is expected to reduce rumen methanogenic activity (Haque 2018a ; grange et al. 2021) Abreu's study showed that a 3:1 grass/legume mixed ration increased organic matter (OM) and crude protein (CP) intake and rumen ammonium nitrogen concentration compared to a diet of only grass (Abreu et al. 2004). In addition, having a higher proportion of NSC in legumes compared to grasses may drive rumen fermentation to produce more propionic acid, thereby reducing hydrogen availability to methanogenic bacteria (Wang et al. 2018). Doran 's study demonstrated that whole gut digestibility of crude and digestible protein was significantly higher in alfalfa : oats = 1:1 diets than in diets with oat hay as a source of roughage (Doran et al. 2007). Moreover, the combination of alfalfa (78%) and oats (22%) in the diet resulted in a reduction of energy loss through lower methane emissions, as compared to a diet with only graminoid forages (McCaughey et al. 1999). However, these studies focused on diets where supplementation of legumes was the only factor considered. Few studies have been conducted to explain the effects of different forage combinations on ruminants. Therefore the aim of this study was to determine the effects of adding alfalfa hay and oat hay to lamb diets on productivity, apparent digestibility of nutrients, and methane production.

Methods

Animals, diets, and study design

The experiment was conducted from June to August 2018 at Baiyinxile Ranch, Xilingol League, Inner Mongolia. The experiment involved 24 Uzhumqin crossbred lambs with an initial weight of 23.56 ± 1.54 kg (mean ± standard deviation). The experiment was conducted in a completely randomised block design with the lambs divided into four groups of six each for a period of two months. The lambs were fed natural hay (N), oat hay + natural hay (NO), alfalfa hay + natural hay (NA) and alfalfa hay + oat hay (AO), and the nutrient composition of the diets is shown in Table 1. The lambs were housed in 1m × 2m pens, dewormed from internal and external parasites and vaccinated before the trial, and pre-fed for 10 days. All lambs were given free access to water and feed samples were collected at feeding time. The daily residue was recorded and used to estimate the feed intake per animal.

Table 1 Diet conventional nutrients (air-dried basis) unit : %

Item	AO	NA	NO	N
Dry Matter （DM）	95.88	97.35	96.65	98.12

Acid Detergent Fiber （ADF）	36.90	47.30	50.10	60.49
Neutral Detergent Fiber （NDF）	60.57	54.66	66.40	60.49
Organic Matter (OM)	91.36	92.43	92.97	94.04

Feed intake and chemical composition

Nutrient intake is determined by the difference between the amount of each ingredient contained in the feed provided and the amount contained in the remaining species. The chemical composition of the diets was carried out at the Grass Public Laboratory, China Agricultural University. The compositions of the feed ingredients were determined by the method of AOAC (1998). The neutral detergent fiber (NDF) and acid detergent fiber (ADF) were analyzed based on the method of Van Soest *et al*. (1991) using an ANKOM fiber analyzer.

Greenhouse gas collection

Methane measurements are made using a combination of a sealed respiratory metabolism chamber, a gas collection tube and a greenhouse gas concentration analyser. The metabolic chamber allows the simultaneous measurement of methane production in two sheep. Each respiratory chamber was equipped with a trough and a water trough, and the test sheep were allowed to feed and drink freely during the test period. The animals were placed in 12 batches (2 animals/batch, 2 animals/group) 3 days before the start of the experimental period and acclimatised for 1 h. The methane and carbon dioxide production as well as faecal and urinary nitrous oxide (NOx) emissions were measured for 1 h after feeding. Emissions of methane, carbon dioxide and nitrous oxide were collected through a gas collection tube for 1 h. The gases were stored in a gas collection bag, and the collected gas samples were analysed using a greenhouse gas concentration analyser (G2308; Picarro; Beijing, China).

Statistical analysis

The experimental data were initially collated using Excel 2021. Statistical analyses were performed using SPSS 27 software and one-way analysis of variance (ANOVA) was used to assess the effect of different feeding combinations on feed intake, nutrient digestibility and GHG emissions. Duncan's multiple range test was used to compare significant differences and the significance level was set at $P < 0.05$.

Results

Feed intake and growth performance

Under ad libitum feeding conditions, the dry matter intake of AO and N was significantly higher than that of the other two groups ($P < 0.05$). The protein intake of NO was significantly lower than that of the other three groups

(P < 0.05) (Fig.1). Additionally, the average daily weight gain of lambs in NA was significantly higher than that of NO (P < 0.05) (Fig.2).

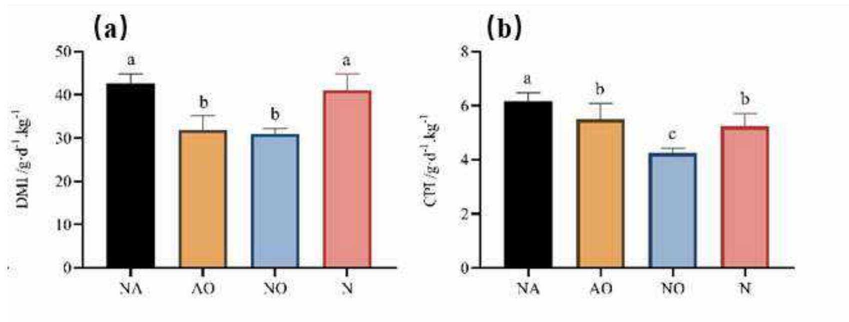

Fig.1 Dry matter and protein intake of different diet groups

Note: NA: alfalfa hay + natural hay; AO: alfalfa hay + natural hay; NO: Oat hay + natural hay; N: Natural hay；a、b、c indicates the difference between dry matter intake and protein intake between diets. Fig.1a shows the dry matter intake of different dietary groups, and Fig.1b shows the protein intake of different dietary groups.

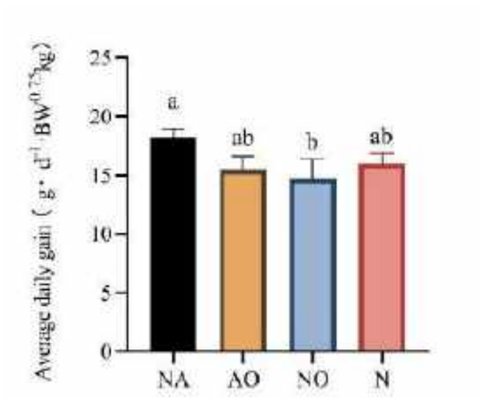

Fig.2 Effect of diet combination on average daily gain of sheep

Note: a、b、c indicates the difference between average daily weight gain of lambs between diets

Apparent digestibility of nutrients

Table 2 shows the effect of different roughage combinations on the apparent digestibility of nutrients in lambs. No significant differences were found between the four roughage combinations in terms of digestibility of dry matter, organic matter and neutral detergent fibre. However, N significantly increased the intake of ADF by lambs (P < 0.05). In addition, ADF digestibility was 26.83% and 19.84% higher with N compared to NA and AO, respectively. In addition, crude protein digestibility was significantly lower (P < 0.01) in N than in the other three treatments.

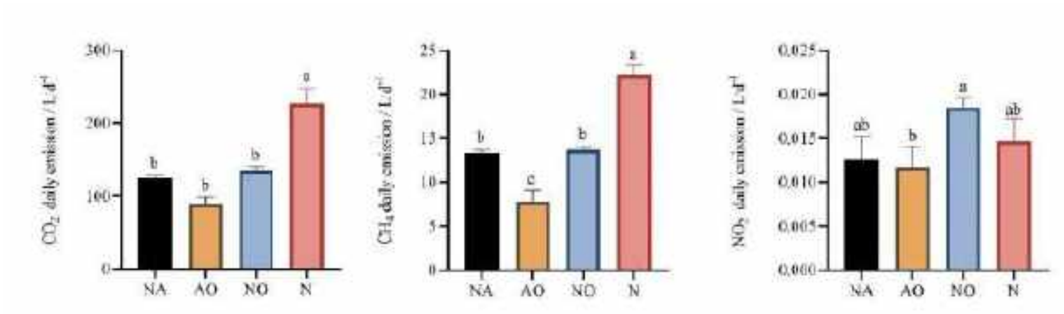

Fig.3 Effects of dietary combination on greenhouse gas emissions of sheep

Greenhouse gas production

The CH_4 emission pattern of lambs was the same as that of CO_2, and N emissions were significantly higher than those of the other three groups. AO emissions were the lowest among the groups. In addition, N_2O emissions were significantly lower for AO than for NO.These results suggest that feeding natural hay significantly increased GHG emissions from lambs ($P < 0.05$) (Fig. 3).

Discussion

Feed type and composition play a crucial role in grazing livestock production systems, significantly influencing nutrient utilization efficiency, animal performance, and greenhouse gas emissions (Schils et al. 2007). Studies have shown that the addition of alfalfa hay significantly improves the nutritional quality of roughage combinations, thereby promoting the daily weight gain of lambs (Wang et al. 2020; Wang et al. 2023). Alfalfa hay, with its high crude protein and low fiber content, provides lambs with sufficient energy and nitrogen to enhance rumen microbial activity and nutrient absorption efficiency (Ishaq et al. 2019). This superior nutritional profile not only improves the nutrient metabolism of lambs but also significantly boosts their growth performance in a shorter time (Ren et al. 2024). In contrast, the oat hay + natural hay group, whilst demonstrating a role in meeting the basic nutritional requirements of lambs, may have limited further improvements in growth performance due to low protein levels (Xiao et al. 2021). In particular, the low nitrogen content of oat hay leads to limited microbial activity in the rumen, which reduces the efficiency of protein catabolism and indirectly affects lamb performance (Kittelmann and Janssen 2011). In addition, although feeding natural hay alone has a higher utilization rate of ADF, its overall protein supply capacity is insufficient. This limitation indicates that relying solely on natural hay as a feed may not meet the growth requirements of lambs, and supplementation with high-protein feeds, such as alfalfa hay, is necessary to compensate for the deficiency (Huang et al. 2021).

The primary greenhouse gases emitted by ruminants include methane (CH_4), carbon dioxide (CO_2), and nitrous oxide (N_2O), and their emission levels are strongly influenced by feed composition (Broucek 2014).This study further highlights significant differences in greenhouse gas emissions among various feed combinations (Haque 2018b). Methane, the primary greenhouse gas produced during rumen fermentation, is influenced by the type of feed and its fiber content. High-fiber feeds typically result in longer fermentation times in the rumen, promoting the growth of methanogenic microbes (Bharanidharan et al. 2021 ; Bhatta et al. 2017). In this study, lambs fed natural hay exhibited significantly higher CH_4 emissions compared to other groups. This is attributed to the higher levels of neutral detergent fiber (NDF) and acid detergent fiber (ADF) in natural hay, which provide ample substrates for rumen microbes, thereby increasing methanogenic activity (Wallace et al. 2015). Conversely, the AO group had the lowest CH_4 emissions due to the feed combination's low fiber and high protein content. High-protein feeds pass through the rumen more quickly, reducing fermentation time for methanogens and effectively lowering CH_4 emissions (Pepeta et al. 2024). The CO_2 emissions of the natural hay group were significantly higher than those of other groups, primarily due to increased energy metabolism driven by the high fiber content. Ruminants expend more energy breaking down fiber, and the fermentation process releases greater amounts of carbon-based volatile compounds, further exacerbating CO_2 emissions (Ungerfeld 2020). N_2O emissions from ruminants primarily result from nitrogen transformations in manure and urine, which are influenced by feed nitrogen content and ammonia volatilization (Zhao et al. 2023). This study found that the AO group exhibited significantly lower N_2O emissions compared to the NO group, likely due to the higher protein content of alfalfa hay. This allows for more efficient nitrogen absorption and utilization by the lambs, reducing the accumulation of residual nitrogen in manure.

These findings provide valuable insights for feed management and low-carbon livestock practices in pastoral areas. By reducing fiber content and supplementing with easily digestible, low-fiber feeds (such as alfalfa hay), methane emissions from rumen fermentation can be reduced. Additionally, increasing protein levels and optimizing the inclusion of high-protein feeds in the diet improves nitrogen digestion and absorption efficiency, reducing ammonia volatilization and N_2O emissions. In areas dominated by natural hay, increasing the use of alfalfa and oat hay can enhance livestock productivity while effectively reducing greenhouse gas emissions. Encouraging scientific feed combinations will bring both economic and environmental benefits.

Commercial-scale implementation of wet season spelling for Mitchell grass recovery

Eastaughffe, J[1]; Pettit, C[1]; Cowley, R[1]; Hearnden, M[1]

[1] Department of Agriculture and Fisheries, Northern Territory.

Key words: wet season spelling, Mitchell grass, grazing management, seasonal variability

Abstract

Mitchell grasses (*Astrebla* spp.) are the dominant component of the alluvial cracking clay grasslands of the Barkly Tablelands region in the Northern Territory, Australia. Mitchell grasses are native palatable, productive and perennial grasses that contribute significantly to cattle diet quality and quantity in the region. Several years of below-average rainfall resulted in a noticeable reduction in Mitchell grass tussocks in 2022. The Barkly Region component of the Rain Ready Rangelands (RRR) project trialled the commercial-scale application of wet season spelling to promote Mitchell grass recovery.

The pastoralist-led demonstration used four paddocks on a demonstration site 440km north east of Tennant Creek, Northern Territory. Three paddocks were used in a wet season spelling rotation, with one paddock continuously stocked as a control. Farmbot™ telemetry units were used to record daily rainfall data remotely. Using the Botanal field sampling methodology (Tothill et al. 1992) data were collected from each paddock before and after the 2023/24 wet season inside and outside of new 100m by 100m cattle exclosures in each trial paddock.

Changes in vegetation throughout the trial period were strongly influenced by successive high rainfall years, biomass increased in all paddocks both inside and outside of the exclosures regardless of management strategy. However, despite the high rainfall and moderate to low pasture utilisation, there was a tendency for a greater increase in total perennial grass basal area inside exclosures than in grazed areas. There was some early evidence from vegetation monitoring that recovery was enhanced inside exclosures and reduced in the poor (C) condition areas where there were very few pre-existing perennial grass plants. There was also a higher pasture growth response at the better land condition site with the same rainfall and grazing impact. This provides evidence of the benefits of promoting land condition recovery. We aim to continue to monitor the impacts of wet season spelling on Mitchell grass health in these paddocks through time.

Introduction

Wet season spelling is a grazing management strategy that can assist in the recovery of palatable perennial pastures by removing selective grazing during the growing phase and enabling palatable, perennial tussocks to establish and rebuild root reserves (Ash et al. 2011, O'Reagain and Scanlan 2013, O'Reagain et al. 2014, Scanlan et al. 2014). Without perennial pastures, annual grasses and forbs can become dominant leading to lower pasture biomass, higher detachment and feed shortages during the dry season. This can have a cumulative impact in years with low rainfall.

Understanding the impacts of grazing management changes can be difficult to measure when combined with highly variable rainfall. Land condition change can be both slow (for most years) and then fast and sudden when rainfall, low grazing pressure and seedbank availability combine to provide the best conditions for establishment of new plants (Watson et al. 1996). Establishing sites that can be monitored long term, with and without grazing across variable years is needed to observe and measure changes.

This demonstration was designed to provide the information that may increase pastoralist confidence in implementing wet season spelling to promote Mitchell grass recovery. The objective of the project was to test the efficacy and practical implementation of wet season spelling to promote the recovery of Mitchell grass at the commercial scale.

Methods

The demonstration site included four paddocks ranging in size from 67 to 125 km^2 on Anthony Lagoon Station in the Barkly Tableland region of the Northern Territory. Three paddocks were part of a wet season spelling rotation (No. 5 East, No. 5 West, No. 6), with one paddock (No. 4) continuously grazed as a control. At the start of the project, the carrying capacity (AE/km^2) (AE = 450kg steer) of each paddock was calculated using regionally calibrated modelled pasture growth and safe utilisation rates for the land type (Pettit, 2011; Rickert et al. 2000; McLennan et al. 2020). Cibo Labs land condition spatial data (provided by the property owner) was used to adjust total modelled pasture growth for each paddock to better reflect potential pasture growth. To calculate the short-term stocking rates in the grazed paddocks carrying capacities were converted to AE/day. Decisions about cattle movements and which paddocks were grazed or spelled were determined by the property manager with advice from the project team. Thus, No. 5 East was wet season spelled with all cattle from No. 5 East and West going into No. 5 West on 18 December 2023.

In each paddock, a 100m by 100m exclosure was erected to exclude grazing for comparison to the surrounding continuously grazed and rotationally spelled paddocks. Site locations were selected between 1 and 2 km from a water point where Mitchell grass was present but in poorer condition. Four transect lines, 87m in length were established inside each exclosure. Four additional transect lines of the same dimensions were established parallel to the exclosure in an area most representative of species' composition and biomass (control treatment). An additional unfenced monitoring site with 4 transect lines was established in an area of good (A-B) land condition in Paddock 5 West where Mitchell grass was dominant. Fifteen $1m^2$ quadrats were assessed for vegetation composition, pasture biomass, ground cover and perennial grass basal area along each transect line in October 2023 and May 2024.

Results

The rainfall in No. 4 and No. 6 Paddocks during the 2023-24 wet season was well above average (in the top 95% of all years) with 1132mm received. The October 2023 baseline pasture assessments highlighted a natural variation in pasture yield between paddocks (Fig. 1). Total standing dry matter (TSDM) inside and outside of the exclosures were similar in each paddock in October 2023. TSDM increased at all sites between October 2023 and May 2024. The average increase in TSDM was consistent in all exclosures (2010 kg/ha ± 112). Outside the exclosures, TSDM varied depending on the grazing treatment and pasture type. The good land condition site in No. 5 West paddock increased TSDM by 1653kg/ha between October 2023 and May 2024, compared to No. 5 West outside exclosure site which increased by 896kg/ha, despite both being in close proximity and the good land condition size having higher grazing scores.

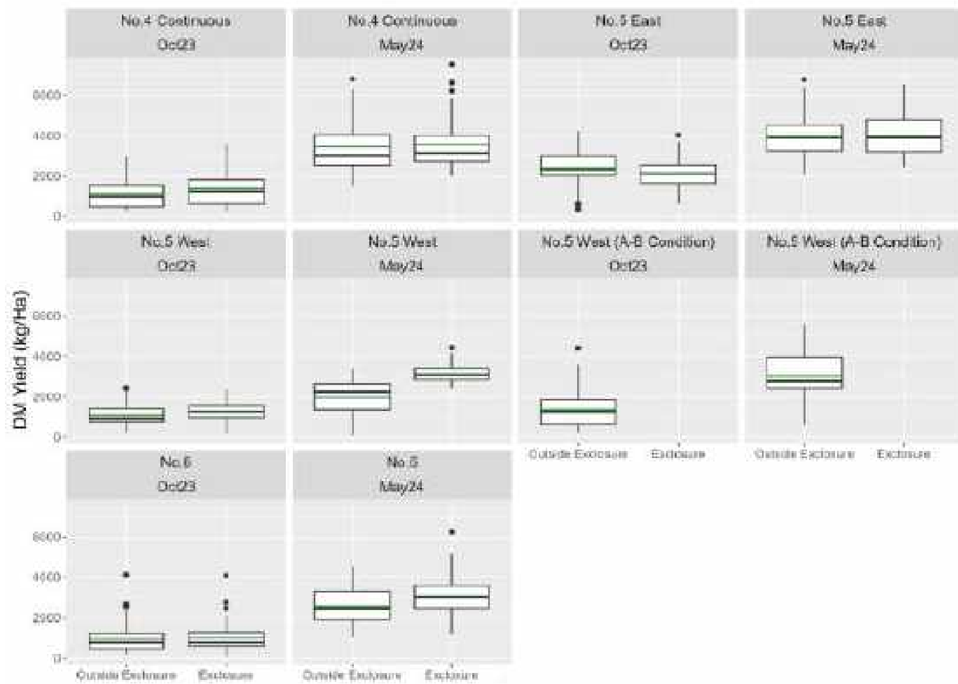

Figure 1: Total yield (kg dry matter/ha) inside and outside of exclosures, October 2023 and May 2024. Mean (green line), median (black line), middle 50% of data (box), min and max (whisker), outliers (dots)

The combined *Astrebla elymoides*, *Astrebla pectinata* and *Astrebla squarrosa* (Mitchell grasses) yield is shown in Fig 2. *Astrebla* species yield increased between October 2023 and May 2024 in all exclosures except No. 5 East. No. 5 West had the lowest yield of *Astrebla* species with no *Astrebla* spp. in the outside exclosure site in October 2023 and a small increase by May 2024 (4kg/ha). The No. 5 West good land condition site had the highest Mitchell grass yield of all sites in May 2024 (1848kg/ha, 61% of TSDM).

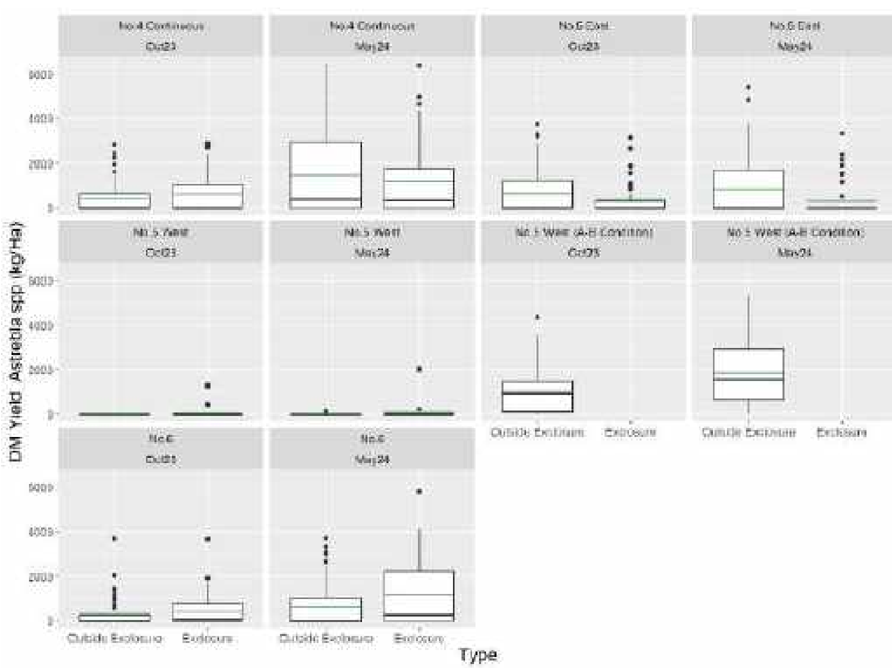

Figure 2: Total yield (kg/ha) contribution of grouped Astrebla spp. inside and outside of exclosures, October 2023 and May 2024. Mean (green line), median (black line), middle 50% of data (box), min and max (whisker), outliers (dots)

There was a high level of variation in grass basal area of *Astrebla* species across all paddocks and treatments (Fig. 3). Grass basal area of *Astrebla* species increased over the wet season at all sites in No. 4 paddock and in the exclosure of No. 6 Paddock.

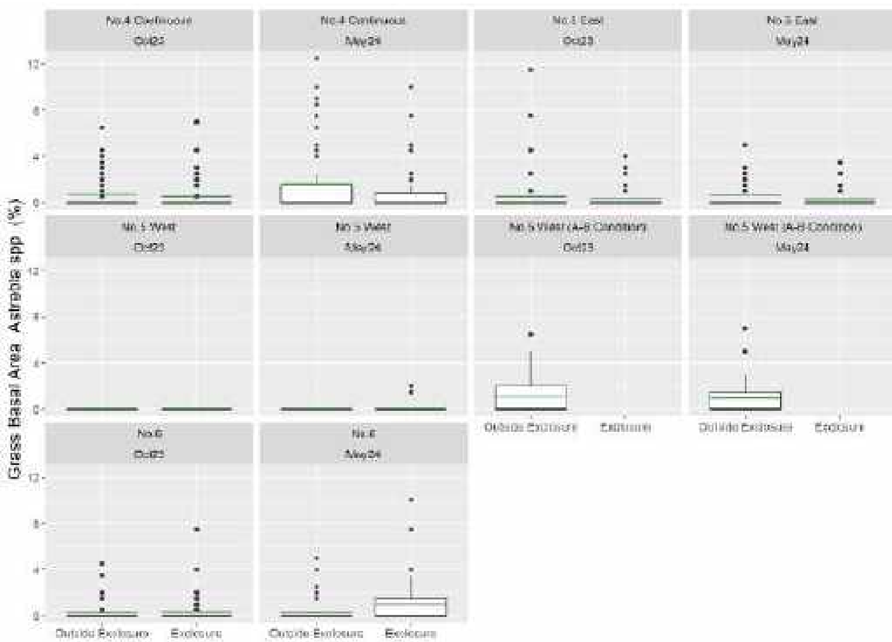

Figure 3: Grass basal area of *Astrebla* spp. in October 2023 and May 2024. Mean (green line), median (black line), middle 50% of data (box), min and max (whisker), outliers (dots)

Grazing scores (defoliation) outside exclosures were low to moderate across all paddocks in May 2024 but were higher in No. 5 West and the good condition site in No. 5 West. This was due to the additional cattle from the spelled No. 5 East paddock on the 18th of December 2023.

Discussion

The initial differences found inside and outside of exclosures and between paddocks in October 2023 (Fig. 1) were due to the underlying variability in soils, vegetation and grazing history, as the exclosures had only been recently established. Results highlighted the natural variance in pasture composition and yield.

Changes in vegetation throughout the trial period were strongly influenced by rainfall. Generally, in high rainfall years yield increased in all paddocks both inside and outside of the exclosures regardless of management strategy. However, yield increase was lower outside No. 5 West exclosure, presumably due to the higher stocking rates in the paddock (supported by the higher observed defoliation). The two outside exclosure sites in No. 5 West had the same grazing treatment and distance from water effects, however they had different pasture growth responses. The total yield increase in the good (A-B) land condition site was close to double the yield increase in the adjacent No.5 West outside exclosure site that began in C condition. While not unexpected, this provides “seeing is believing” evidence of the impact grass basal area has on biomass production and the importance of promoting perennial grass recovery for a climate resilient feedbase.

Astrebla spp (Mitchell grass) biomass increased over the wet season in all paddocks and sites except the No. 5 East exclosure. The low grass basal area of *Astrebla* spp. in No. 5 West C condition site may mean recovery will take longer to occur, with few plants present to provide a local seed source for establishment of new plants.

Changes in land condition and Mitchell grass recovery are unlikely to be observed after just one year in rangelands where land condition change is slow and episodic (Watson et al. 1996). However, after successive high rainfall years, there was some early evidence from vegetation monitoring that recovery was enhanced inside exclosures, and reduced in the C condition areas where there were very few pre-existing perennial grass plants to build upon. There was also a stronger pasture growth response at the better land condition site with the same rainfall and grazing impact, which provides evidence of the benefits of implementing grazing strategies that promote grass basal area recovery and better land condition. Longer term monitoring is required to see if the wet season spelling strategy has advantages over the continuously grazed paddock when both are grazed at recommended stocking rates. The project has established baseline data across the demonstration site to compare future seasonal conditions and impacts of wet season spelling.

Key words: Ecosystem services, shade, shelter, Mitchell Grass Downs

Abstract
The vast open rangelands of Australia's Mitchell Grass Downs Bioregion as depicted in Figure 1 are a significant producer of livestock and the region is dominated by the *Astrebla* grass species. Multipurpose shrub and tree legumes could play an important role in providing many ecosystem services such as drought fodder, shade, shelter, N fixation, carbon sequestration, biodiversity, habitat, and they may also potentially contain novel compounds that could have useful phenolic and or antioxidant, anti-methanogenic properties which could benefit animal production and the environment.

As part of CRC P 58599 project "Legumes for the north" the seeds of a range of native and exotic shrub and tree legumes were sourced from across North Queensland, grown as tube stock and then transplanted at five sites across the region to evaluate their adaptability to the region. The mix of species included fast and slow growing, long lived and short-lived perennials including species of *Acacia, Adenanthera, Albizia, Bauhinia Cajanus, Gliricidia, Peltophorum, Pongama, Sesbania, and Vachellia.* Most of these species were planted at each site on vertosol soils in semi-arid locations with mean annual rainfall from 400mm to 580mm, and irregularly watered by artisan bore water until well established.

After three years of growth, initial observation of the establishment phase and persistence indicates that several species across the sites show agronomic promise including but not limited: *Albizia lebbeck, Gliricidia sepium, Peltophorum pterocarpum.* Several species failed to persist or have had poor growth at least at some sites including *Cajanus cajun*, *Sesbania sesban* and *Adenanthera pavonina*.

It is envisaged that the successful species could be planted as mixed species plantings on the open treeless grasslands radiating out along fence lines from existing bores/farm dams with simple trickle irrigation likely to be essential for at least the establishment phase. Once established the shrubs and trees would provide many of the ecosystem services outlined above.

Introduction

Shrubs and trees have long been considered important for the nutrition of grazing and browsing animals in Australia, particularly in the north where the quantity and quality of pastures is poor for long periods. Over 70% of Australia falls within the arid and semi-arid climatic zones where extensive grazing of livestock is the dominant land use (Lefroy *et al* 1992.) This includes the vast open, mainly treeless (Fig 1) rangelands of the Mitchell Grass Downs Bioregion which are dominated by the *Astrebla* grass species. The climate of the region is severe as is the edaphic environment with vertosol soils. These rangelands are dominated by C4 grasses noted for their resilience but are of poor nutritive value and decline in quality with maturity (Minson 1981). Lowry *et al* (1993) suggest that the introduction of legumes may increase production not only through an increase in total edible dry matter but by acting as a supplement to promote the utilisation of the lower quality diet. To date, the introduction of sown legumes has proved difficult, with few, if any, being successful (Gardiner 2016). However, adapted and resilient shrubs and trees may be an option and could potentially contribute to nutrition and other facets of animal production. During drought, top feed/browse species become of important (Chippendale and Jephcott 1963, Everist 1985). These authors and Newton (1970) and Guttridge and Shelton (1994) list many native and introduced shrub and tree species as having potential in northern grazing systems including *Acacia, Albizia, Bauhinia, Capparis, Desmanthus, Eucalyptus, Gliricidia, Geijera, Leucaena, Owenia, Sesbania* and *Vachellia* among others. Dynes and Schlink (2002) however note that investigations of the potential of native shrubs and trees (particularly *Acacias*) as fodder sources for livestock in Australia have been limited to the more widespread better-known species such as Mulga (*Acacia aneura*).

There are few shade trees in the region and temperatures are high, with mean maximum temperatures exceeding 35ºC for many months per year. For example, Camooweal in Western Queensland has on average 155 days per year with temperatures >35ºC, and 37 days per year >40ºC (BOM 2024, McCosker 2023). The importance of heat stress in limiting potential animal production in NW Australia was noted by Petty (1997, and lack of shade can be detrimental to survival of newborn calves and lambs (Schmidt 1969 cited by Orr and Holmes 1984). Tunkala *et al* (2023) studied the *in vitro* characteristics of several of the aforementioned species and found that *Gliricidia* and *Vachellia* have a slowly degradable protein content while *Bauhinia* emerged as a candidate to assist protein protection in the rumen and reduce methane emissions.

Multipurpose shrub and tree species could play a role in providing many ecosystem services such as drought fodder, shade, shelter, N fixation, Carbon sequestration, biodiversity, habitat, and they may potentially contain novel compounds with useful phenolic, antioxidant and/or anti-methanogenic properties of benefit to animal production and the environment.

This study set out to screen several well adapted shrubs and tree species that may then progress to (if not already) domestication and planting out as multipurpose species (Figure 1). These mixed shrub and tree plantings (including tall, short, fast growing, slow growing, palatable, not palatable species) would radiate out along fence lines from existing bores and farm dams or to nearby shelterbelts or groves with low-cost trickle irrigation to aid establishment.

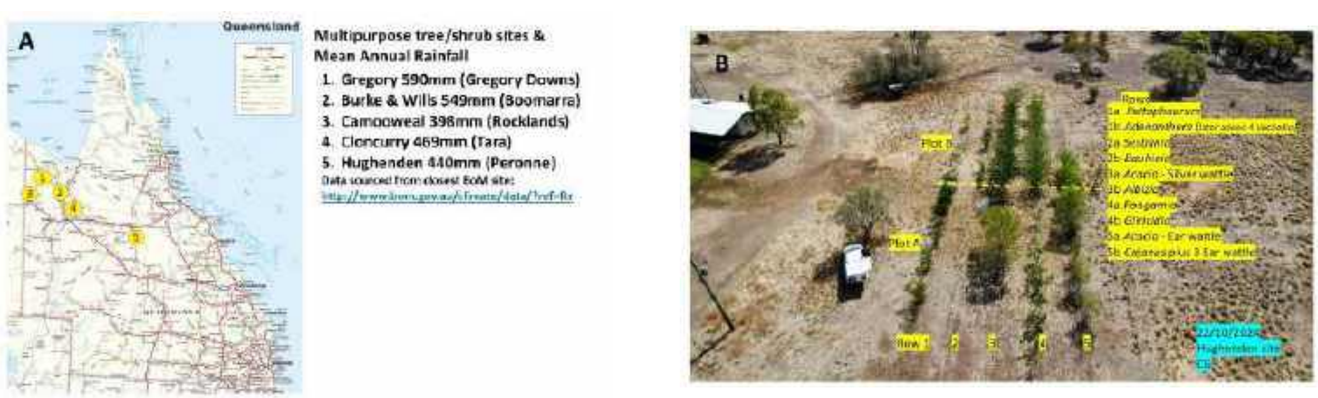

Fig 2. A) The location of the shrub/tree evaluation sites and mean annual rainfall of the sites. B) Aerial view of the layout and surviving species at the Hughenden trial site as of October 2024.

Methods

As part of CRC P 58599 project "Legumes for the north" and during COVID 19 pandemic period,(limiting travel and access to the remote sites) in 2020 seeds of a range of native and exotic shrub and tree legumes were sourced from across North Queensland. They were selected based on availability of seed and desirable traits such as drought tolerance, fodder production, edaphic adaptability, grown as tube stock in a commercial nursery and then transplanted to five sites across the region in mid-2021 (Figure 2). The aim was to evaluate the adaptability of the species to the region. The mix of species included fast and slow growing, long lived and short-lived species *Acacia auriculiformis, A.holosericea, Adenanthera pavonina, Albizia lebbeck, Bauhinia hookeri, Cajanus cajun, Gliricidia sepium, Peltophorum pterocarpum, Pongamia pinnata, Sesbania sesban,* and *Vachellia sutherlandii.* These species were planted at each of the five sites, except for *V. sutherlandii* (due to scarcity of seed) on vertosol soils in semiarid locations with mean annual rainfall ranging from 400mm to 580mm (Fig. 2). Plants where at least initially watered via a trickle irrigation system with water sourced from artesian bores/dams. The frequency of watering and maintenance of the plots varied across the sites. Infrequent watering occurred until the plants were well established. Where available, 13 seedlings of each species were planted 2m apart within rows with 4m between rows. The plots were inspected occasionally, with reports and images from station managers collated. Data presented here are for the Hughenden site only but reflect observed results across the region. At the Hughenden site data were collected on plant survival, height, diameter at breast height (DBH), and the general status of the plants was recorded in October 2024.

Results

After three years growth, initial observation of the shrub and tree establishment phase and persistence indicated that several species showed agronomic promise across the sites including: the *Acacia* species*, Albizia lebbeck, Bauhinia* hookeri*, Gliricidia sepium, Peltophorum pterocarpum* and *Pongamia pinnata.* Survival and growth (some to >4m tall, Table 1) varied across sites, with several short-lived species such as *Cajanus cajun and Sesbania sesban* displaying rapid initial growth and then tended to die at most sites. *Adenanthera pavonina* performed poorly at all sites.

Table 1. Shrub/treegrowth data from Peronne Station (Hughenden, NW Queensland) October 2024

Species	% survival	Mean DBH (cm)	Mean Height (cm)	Notes * = native
Acacia auriculiformis*	69	5.2	317	Dense foliage
A.holosericea*	23	4.4	438	Survivors are robust
Adenanthera pavonina*	15	N/A	100	Poorly adapted
Albizia lebbeck*	100	2.6	335	Leafy, good canopy, well grown
Bauhinia hookeri*	77	2.5	114	Slow growth but good survival
Cajanus cajun	0	0	0	Short lived species, initially good
Gliricidia sepium	100	4.84	302	Leafy, multi branched, thriving
Peltophorum pterocarpum*	100	6.7	177.6	Leafy, thriving
Pongama pinnata*	84	1.46	164	Slow growth but good survival
Sesbania sesban	0	0	0	Initially good, but short-lived
Vachellia sutherlandii*	50	1.6	252.5	Limited seed for planting

A video overview of the concept of multipurpose shrub and trees for the open downs, the Hughenden site and various species is available at: https://www.youtube.com/watch?v=VGvAVjgX7FU

Discussion and conclusions

Albizia, Gliricidia and *Peltophorum* have been particularly successful to date at all sites, with 100% survival and good growth at the Hughenden site. The *A. auriculiformis, Bauhinia, Pongamia,* and *Vachellia* species are promising. The short-lived species such as *Cajanus* and *Sesbania* can potentially provide good quick fodder, habitat, and cover while other species establish, but generally failed to persist, although at other unrelated locations they have been noted to recruit from seed. There are many other species (including non-legumes) that should be investigated, for example Everist (1986), with local native ecotypes most likely to be successful and having some social licence in the community. It is envisaged that the successful species could be planted as mixed species plantings on the open treeless grasslands radiating out along fence lines or in shelterbelts or groves from existing bores/dams with simple trickle irrigation which is likely to be essential for at least the establishment phase. On-going long-term monitoring of these plots is required to evaluate among other attributes their response to lopping/grazing, shade, nutritional value. Further research is also essential to select and evaluate other adapted and appropriate species, develop suitable agronomic and management practices for the establishment, longevity and utilisation of the species, and evaluate the costs and value of both shrubs and trees to livestock production, animal welfare and the environment. Once established these multipurpose shrub and tree species could potentially provide many of the ecosystem services outlined above benefiting the environment, animal welfare and production.

Acknowledgements
The ongoing care of the tree plots by the various station managers and staff is much appreciated as is the contribution of Agrimix staff, JCU, and the CRC P 58599 project for funding. Thanks to Jirapun Kota for assistance with field data collection.

Keywords: Carbon stock; *Lepidium sativum*; *Morus alba*; Organic manures; Jeevamrut

Abstract

Lepidium sativum is a fast growing annual herb belonging to the Brassicaceae family and possesses the galactogogue effect that promote milk synthesis and production. Study was conducted at the experimental farm of Dr. Y. S. Parmar University of Horticulture and Forestry, Nauni, Solan (H.P.) to evaluate the effect of planting condition and different nutrient sources on soil physicochemical properties and carbon stock of Morus based Agroforestry system. The study consisted two structural and functional components *Morus alba* fodder tree as woody perennial and *Lepidium sativum* as intercrop. There were eight treatments *i.e.*T_1: Lepidium + *Morus* +FYM@ 4 tonnes ha^{-1}, T_2: Lepidium + *Morus* +Vermicompost@ 1.12 tonnes ha^{-1}, T_3: Lepidium + *Morus* +Jeevamrut@ 500Litre ha^{-1}, T_4: Lepidium + *Morus* +No Manure, T_5: Lepidium + FYM @ 4tonnes ha^{-1}, T_6: Lepidium + Vermicompost @ 1.12 tonnes ha^{-1}, T_7: Lepidium + Jeevamrut@ 500Litre ha^{-1}, T_8: Control (without *Morus* and no Manure). Jeevamrut liquid organic manure made up of cow dung, cow urine, jaggery, gram flour, soil and water. It acts as an agent to increase the microbial count. The present study revealed that the tree proximity and nutrient sources significantly affected the soil physicochemical properties and carbon stock of the system. The results of the study indicated that the highest soil, bulk density (1.35 g cm^{-3}), available Nitrogen (344.60 kg ha^{-1}), Phosphorus (91.76 kg ha^{-1}) Potassium (539.52kg ha^{-1}), organic carbon (10.50 g kg^{-1}), and soil organic carbon stock (21.31 Mg ha^{-1}) was recorded in treatment T_2*i.e. Lepidium sativum*+ *Morus alba*+ Vermicompost @ 1.12 tonnes ha^{-1} while the lowest was recorded in treatment T_8*i.e.* Control (without *Morus* and no Manure). Maximum seed yield (1613.07 kg ha^{-1}) was observed in treatment T6 while the lowest was recorded in treatment T4. The treatment T_3 (*Morus*+ Lepidium+Jeevamrut) resulted in higher net return (1021.85 USD ha^{-1}) and B:C ratio (2.44) when 500 litres $hectare^{-1}$ Jeevamrut was applied as organic manure.

Introduction

Agroforestry is a sustainable land use a system whereby a deliberate integration is done to manage the agriculture as well as forest resources on the same piece of land in order to harvest the diversified products. It is an intensive farming and forest management shaped by intentional introduction of multiple productive species and management of their complex agroecological interactions to increase marketable yields and provision of ecological services (Gold et al. 2009, Garrett 1997). *Morus alba* (Mulberry) is a multipurpose agroforestry tree species belonging to family Moraceae. It grows in sub-tropical region and up to higher altitudes in the Himalaya-Hindu Kush region (Imran et al. 2010). Mulberry foliage is an excellent source of crude protein (20-24%) and is Morus leaves are feed as a part of mixed ration used to animals in lean period. *Lepidium sativum* (Chandarshoor) belongs to family Brasicacae and is widely cultivated in tropical and subtropical zones of India. The plant has its origin in Egypt and Southwest Asia but is now cultivated throughout the world for its seeds (Manohar et al. 2012). Considerable attention has been given to the use of chemical fertilizers in conjunction to maintain soil health and quality. Improvement of environmental conditions and public health are important reasons for advocating increased use of organic materials (Seifritz 2011). Apart from using conventional farm based products there is an increasing demand for improved materials like Jeevamrut which is liquid organic manure prepared from cow dung, cow urine, unpurified sugar, chickpea flour and soil from underneath the wild trees and water. It acts as an agent to increase the microbial activity and if used consistently, it minimizes the need of chemical fertilizers (Palekar 2006). Jeevamrut is low cost improvised preparation that enriches the soil with indigenous microorganisms required for mineralization of the soil. Application of vermicompost to crop has also been reported to improve early root initiation, increased root biomass, enhanced plant growth and development. It is considered as one of the important indices of sustainable land management, which contributes to improve soil quality and crop productivity. Himachal Pradesh being a north-western region of Himalayas is generally considered as a good site for soil organic carbon sequestration. Emerging evidence indicated that integrated soil fertility management in which both organic and inorganic resources is a feasible approach to overcome the soil fertility constraints. Therefore, to understand the hypothesis, the objectives of the study were to determine the effect of planting condition and different nutrient sources on soil physicochemical properties and carbon stock of *Morus* based Agroforestry system.

Methods

The experimental farm is located at 30° 51' N latitude and 76° 11' E longitude with an elevation of 1200 m above mean sea level and slope of 7-8 % which falls in subtropical sub-humid temperate agro-climatic zone of Himachal Pradesh. The area receives an annual rainfall varying from 1000 to 1600 mm and 75 % falls during monsoon season (July- September). The climate data of the study area shown in fig 1 (Source: Meteorological observatory, Department of environment science, Dr Y S Parmar University of Horticulture and Forestry, Nauni, Solan, HP 173230).

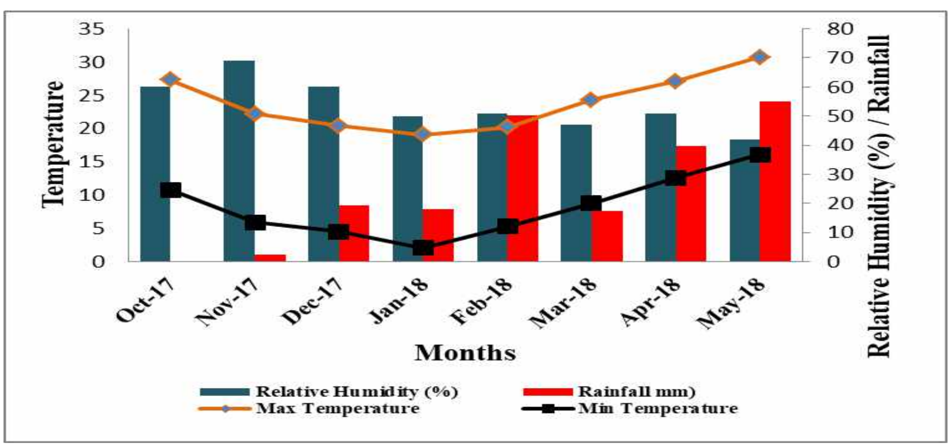

Fig1. Mean monthly temperature (°C), rainfall (mm) and relative humidity (%) during cropping season

Trees rows of *Morus alba* tree consisting of spacing 3×3 m with rows running in East to West direction. The study was conducted in a Randomized Block design factorial with three replications and comprising of four treatments *i.e.* T_1: FYM @ 4 tonnes ha^{-1}, T_2: Vermicopost @ 1.12 tonnes ha^{-1}, T_3: Jeevamrut @ 500Litre ha^{-1} and T_4: No Manure. According to Palekar (2006) Jeevamrut is prepared by mixing cow dung (10.00 kg) with cow urine (10.00 litres), jaggery (1.5 kg), pulse flour (1.5 kg), 1 kg of soil brought from the bunds of the field where cultivation is to be taken up and add 200 litres of water. Bed sizes of 4 × 2m were made and line sowing was done. Before the sowing of seeds N_{20}: P_{40}: K_{10} Kg hectare^{-1} was applied in the form of FYM and Vermicompost in the individual plots. Jeevamrut is applied as soil drench @ 0.4 litre per plot diluted in 7.6 litre water one time before sowing of seeds and 4 times after sowing at an interval of 15 days. The plants were harvested after five months from the date of sowing of seeds in the main field. Soil samples were taken from surface layer (0–15 cm depth) after harvesting to study the soil physical and chemical properties organic carbon and soil carbon stock.

Five random samples were collected per plot and 500 g of composite sample was taken. Collected soil samples were placed in ziplock bags with proper tags and transported to the laboratory for further analysis. The soil samples were air dried and crushed with mortar and pestle to make them pass through a 2 mm sieve. The crushed samples were then stored properly for use in subsequent analysis. The bulk density of the samples (replicated thrice) was estimated using a core sampler by oven drying the samples at 105° C till constant weight. The dried soil sample were prepared for the estimation of SOC by adopting frequently used method of Walkley and Black (1934), available nitrogen by Alkaline potassium permanganate method (Subbiah and Asija, 1956), available phosphorus by (Olsen's et al. 1954), and available potassium by (Merwin and Peach 1951) method. Soil pH were analysed using soil:distilled water (1:2.5) (Jackson, 1973). The selected parameters were analyzed for understanding their variability through analysis of variance (ANOVA), one way design, as specified by Gomez and Gomez using statistical package R Studio Team (2022) for testing the significance of treatments (Į=5%), The packages used were "ggpubr" for line plot using function ~ggline, whereas bar plots were computed using ggplot2 underlying function ~ggbarplot.

Results

The present study revealed that the tree proximity and nutrient sources, significantly affected the soil physicochemical properties and carbon stock of the system (Fig 2). The results of the study indicated that the highest soil, bulk density (1.35 g cm^{-3}) available Nitrogen (344.60 kg ha^{-1}), Phosphorus (91.76 kg ha^{-1}) Potassium (539.52kg ha^{-1}), organic carbon (10.50 g kg^{-1}), and soil organic carbon stock (21.31 Mg ha^{-1}) was recorded in treatment T_2 *i.e.Lepidium sativum*+ *Morus alba*+ Vermicompost @ 1.12 tonnes ha^{-1} followed by T_1: FYM @ 4 tonnes ha^{-1} with the corresponding values (1.33 g cm^{-3}), (330.02 kg ha^{-1}), (85.39 kg ha^{-1}), (529.393 kg ha^{-1}), (9.03 g kg^{-1}) and (18.00 Mg ha^{-1}) while the lowest was recorded in treatment T_8*i.e.* Lepidium+No Manure with the corresponding values (1.22 g cm^{-3}), (305.87 kg ha^{-1}), (60.24 kg ha^{-1}), (504.507 kg ha^{-1}), (5.61 g kg^{-1}) and (10.33 Mg ha^{-1}).

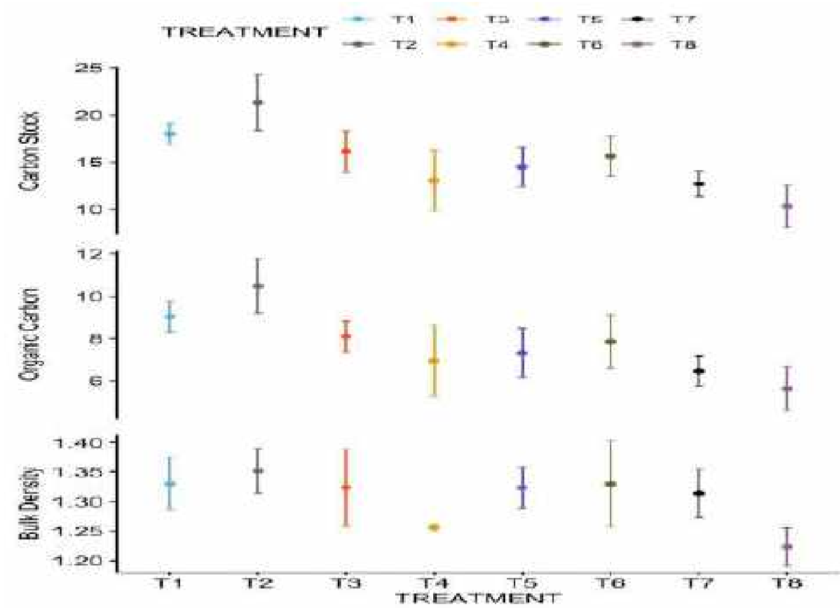

Fig: 2 Effect of planting condition, intercropping patterns and nutrient sources on soil bulk density (g cm^{-3}), organic carbon (g kg^{-1}) and carbon stock (Mg ha^{-1}) under Morus based Agroforestry System.

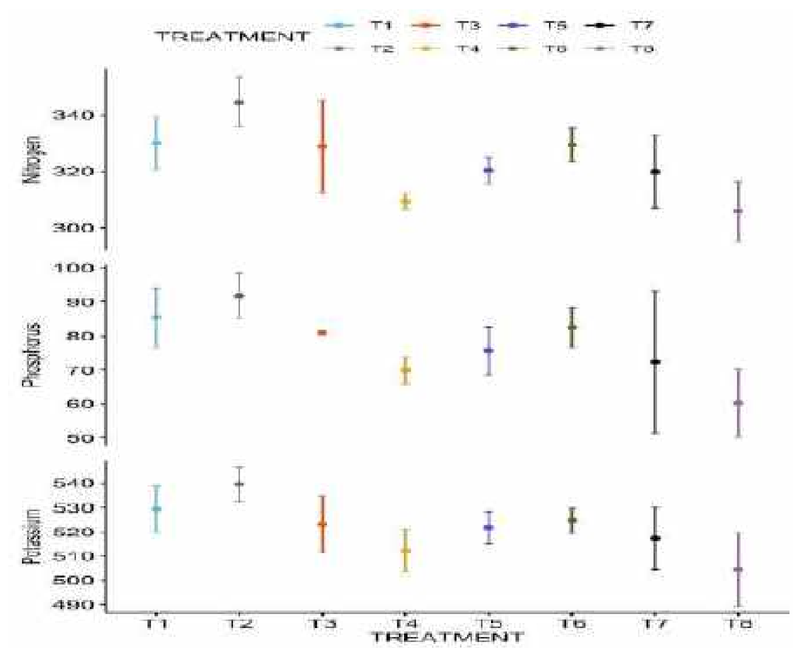

Fig: 3 Effect of planting condition, intercropping patterns and nutrient sources on soil available nitrogen (kg ha^{-1}), phosphorus (kg ha^{-1}) and potassium (kg ha^{-1}) under Morus based Agroforestry System.

Maximum seed yield (1613.07 kg $hectare^{-1}$) was observed in treatment T6 while the lowest was recorded in treatment T4. Under open condition the maximum seed yield kg per hectare (1613.07 kg $hectare^{-1}$) was recorded in treatment T_6 (Lepidium+Vermicompost) which was statistically at par with the T2 (Morus+ Lepidium+

vermicompost). Whereas, minimum seed yield kg per hectare (752.23 kg hectare^{-1}) were observed in treatment T_4 (Morus+Lepidium+No manure). The mean seed yield kg per hectare of *Lepidium sativum* was significantly influenced by different types of organic manures. The maximum seed yield (1460.57 kg hectare^{-1}) was observed in application of vermicompost which was statistically at par with the application of Jeevamrut (1395.26 kg hectare^{-1}) and farm yard manure (1291.66 kg hectare^{-1}) whereas; minimum (834.74 kg hectare^{-1}) was recorded in control where no manure was applied.

Discussion

There have been other reports of increase of N in soil after application of vermicompost (Nethra et al., 1999). Favourable soil conditions as viz. porosity, organic carbon content, biological activities and water holding capacity might have helped in mineralization process of soil nitrogen thereby leading to build-up higher available nitrogen (Kushwala *et al.,* 2017). Findings of the present study are in line with the studies of Nkechi *et al*. (2013) and Singh *et al*. (2017). The continuous inputs of P to the soil were probably from slow release from vermicompost and release of P was due largely to the activity of soil microorganisms (Arancon et al., 2006). Marinari et al. (2000) showed similar increases in soil P after application of organic amendments. The selective feeding of earthworm on organically rich substances which breakdown during passage through the gun, biological grinding, together with enzymatic influence on finer soil particles, were likely responsible for increasing the different forms of K (Rao et al., 1996). The results in the present study are in agreement with the previous studies of (Kumar and Singh, 2017) who observed that the higher seed yield per plant in mustard (*Brassica juncea*) was recorded in combined application of RDF+vermicompost. Theunissen et al. (2010) reported that the vermicompost contains most nutrients in plant available form such as phosphates, exchangeable calcium, soluble potassium and other macronutrients with huge quantity of beneficial microorganisms, vitamins and hormones which influence the growth and yield of plants. This may be due to the fact that application of vermicompost results in improving the physical, chemical, and biological properties of soil and also provide N, P, and K to plants (Baziramakenga and Simard 2001). Based on both analytical data and field observations, it can be concluded that application of Vermicompost @ 1.12 tonnes ha^{-1} under *Morus alba* based agroforestry system had a synergistic effect on improving soil physical as well as chemical properties over control (without any manure under open condition). Application of organic manures in the form of vermicompost resulted into better yield parameters of *Lepidium sativum* as compared to other organic manures. Organic farming and agroforestry can be enhanced to drive greater environmental sustainability, increase crop productivity, and strengthen soil health, thereby creating more resilient agricultural systems capable of addressing global challenges like climate change and soil degradation.

Supporting of cattle grazing in high nature value areas by virtual fencing technology

Golińska, B; Goliński, P

Poznań University of Life Sciences (PULS), Department of Grassland and Natural Landscape Sciences, Dojazd 11, 60-632 Poznań, Poland

Key words: grazing; high nature value areas; suckler cows; virtual fencing

Abstract

Evolution of virtual fencing designed for grazing beef cattle opens up new opportunities for available rangeland and grassland areas. Virtual fencing has the potential to reduce the amount of labour required for fencing, increase the flexibility of fencing to adapt to changing pasture conditions, improve precision and efficiency, and provide more options for grazing management. Taking into account this promising perspective, we have started the project ProEcoFarm which main objective is to produce top-quality culinary beef based on a model of farming suckler cows in a pasture-based feeding system on extensive grasslands located in high nature value areas using an Internet of Things (IoT) system. The experimental pasture is located in the Middle Odra Valley in Western Poland in the complex of semi-natural grasslands under protected area of Natura 2000. The study has been carried out from 2022. The grazed area of 27.5 ha is characterized by high diversification of botanical composition as a consequence of mosaic soil habitats of the pasture. We noticed occurrence of 48 species and 7 grass communities. Based on the monthly monitoring of the pasture during vegetation periods the biomass yield ranged from 0.8 to 2.7 t DM per ha, depending on the grass community. The study area is grazed by Limousine suckler cows by stocking density below 0.5 LU per ha. We conclude that for cattle grazing in high nature value areas the building of conventional fences are often impossible or/and not welcome. The remote control of the cattle herd using collar-mounted devices will make it possible to exclude areas with protected plant or animal species from grazing without building physical barriers. It is worth noting that an essential part of the technological innovation is determining grazing areas according to the cattle's feeding group classification.

Introduction

High quality culinary beef is obtained in pasture feeding conditions (Horn and Isselstein 2022). Young beef cattle are predisposed for this purpose, and above all the technology of suckler cows, from which weanlings are valuable slaughter raw material or can be further fattened to obtain a greater mass (Goliński et al. 2023). The use of pasture sward in the feeding of beef cattle has a very beneficial effect on the quality of meat (Daley et al. 2010; Stanton et al. 2018). Unlike feeding cattle with silage and concentrated feed, meat obtained from animals grazing on pasture has an increased content of unsaturated fatty acids, as well as minerals (O'Callaghan et al. 2016). In many countries in Europe and around the world, consumers are looking for this type of beef as a health-promoting food product ("green beef"). This aspect, as well as animal welfare, speaks in favour of greater use of pastures in animal husbandry, which has become one of the priorities in the agricultural policy of the European Union (Guyomard et al. 2021). Pastures provide natural, valuable feed that is adapted to the digestive physiology of ruminants. Organizing effective feeding of pasture beef cattle is not easy, however it requires knowledge and material inputs. Current trends in the use of pastures consist in the application of innovative decision-support tools, mainly through grazing control using the IoT system (Internet of Things). Its key element is the use of virtual pasture fences (Anderson et al. 2014; Campbell et al. 2019; Goliński et al. 2023). Thanks to GPS technology and wave signal receivers mounted on the necks of animals, it is possible to use innovative technology for pasture feeding of cattle by controlling the herd for better planning and organization of grazing. The objective of the paper is to present the innovative technology of keeping suckler cows using the IoT system based on virtual fencing to control the herd for the purpose of extensive grazing of grasslands located in high nature value areas.

Methods

The study has been carried out from 2022 and is still running. The experimental pasture is located in the Middle Odra Valley (52º04' N, 14º97' E) near to Czarnowo village (Western Poland) in the complex of semi-natural grasslands under protected area of Natura 2000. Its character is of rangeland areas because no fertilization or other agricultural practices have been used there for many years. The grazed area of 27.5 ha is characterized by high diversification of botanical composition as a consequence of mosaic soil habitats of the pasture. The study area is grazed by Limousine suckler cows in the continuous grazing system by stocking density below 0.5 LU per ha (ranging during three year of the study from 0.37 to 0.46 LU per ha). Each year, at the end of the vegetation period, a cleaning cut was carried out to chop up the biomass residues after grazing. In the first stage of the study we assessed the sward yield and its nutritional value using the Crabbe et al. (2019) method. Samples were taken from the designated homogeneous pasture patches, where a 30 m × 30 m plot was randomly selected for in-situ ground measurements. The sward yield was determined using a quadrat frame method collecting biomass each three weeks during vegetation season from May to October. After cutting, the biomass was weighed, dried in the Binder chamber and subjected to laboratory analyses to assess the chemical composition of the sward (ash, crude protein, crude fat, crude fibre, NDF, ADF, β-carotene) using commonly applied methods. Additionally, the botanical composition of the sward using the Klapp method was estimated. Detailed studies of the sward, which constitutes the feed base for suckler cows, were necessary, because the supporting of cattle grazing is carried out on natural meadow complexes in the river valley, the characteristic feature of which is the diversity of plant cover and soil substrate determining the heterogeneous feed potential of the facility. In the next step, based on the collaboration with IT company within the ProEcoFarm project, the concept of supporting of cattle grazing in high nature value areas by virtual fencing technology was elaborated. The idea was to use our own materials and solutions that would make the system more accessible to Polish farmers, mainly from an economic point of view.

Results

Forage potential of the pasture

Studies on the botanical composition of the pasture sward revealed great diversity. In the sward of the analysed pasture, 48 species were recorded, including 11 grasses, 5 other monocotyledonous plants, 5 legumes and 27 other dicotyledonous herbs and weeds. Seven characteristic meadow communities were distinguished: No. 1/ *Poa pratensis-Festuca rubra*, No. 2/ *Alopecurus pratensis-Poa trivialis* with a significant share of legumes and dicotyledonous plants of moist habitats, No. 3/ *Alopecurus pratensis*-*Carex sp.* with a significant share of dicotyledonous plants of moist habitats, No. 4/ *Carex gracilis* community with a significant share of dicotyledonous plants of moist habitats, No. 5/ *Alopecurus pratensis-Agrostis stolonifera* with a significant share of dicotyledonous plants of moist habitats, No. 6/ *Alopecurus pratensis* dominating grass community, No. 7/ *Alopecurus pratensis-Festuca rubra* with a large share of dicotyledonous plants. In the identified communities, the share of grasses in the botanical composition ranged from 2 to 69%, other monocotyledons, including sedges, from 4 to 69%, legumes from 0 to 19% and other dicotyledonous meadow plants from 15 to 32%.

Based on the monitoring of the pasture during vegetation periods within investigation years the biomass yield available for cattle ranged from 0.8 to 2.7 t DM per ha, depending on grass community (Fig. 1).

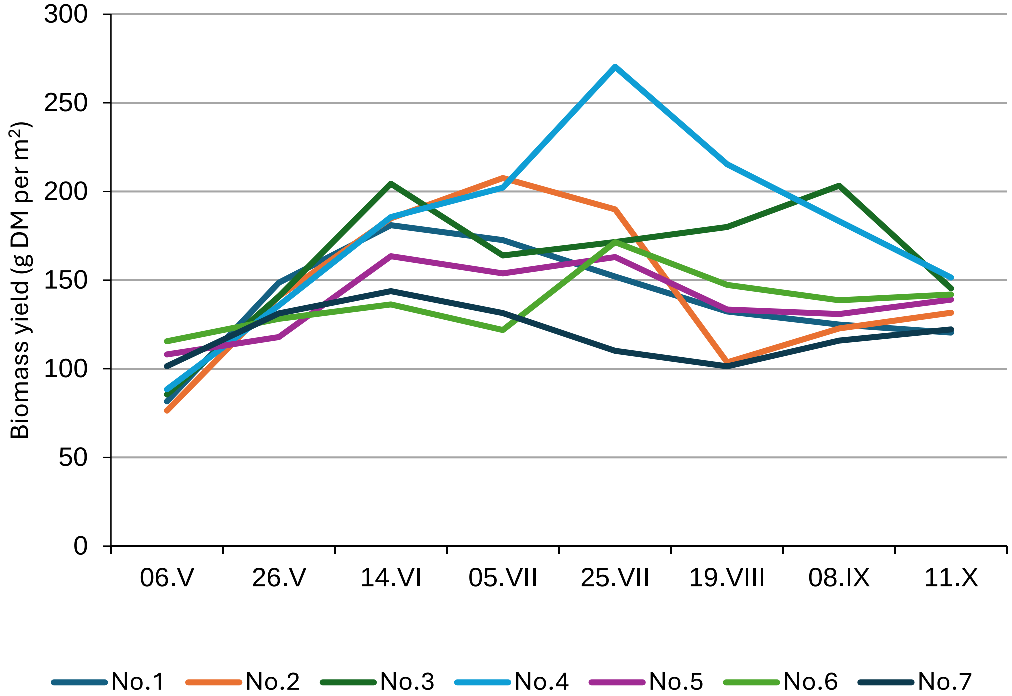

Figure 1. Changes in biomass yield available for grazing of suckler cows during vegetation period (explanation of the No. 1-7 communities given in the main text)

The community of *Carex gracilis* (No. 4) was the least attractive to grazing cows. From the beginning of the vegetation period to the end of July, the sward of this community was grazed very rarely, which caused the biomass yield to increase. In the second part of the vegetation period, suckler cows also grazed the sward available from this community. A similar trend was observed in the *Alopecurus pratensis*-*Carex sp*. Community (No. 3). The lowest yields throughout the vegetation period were found in the *Alopecurus pratensis-Festuca rubra* community (No. 7), because it was the most attractive to grazing animals.

The chemical composition of the pasture sward varied depending on the community (Table 1). The best quality, especially in terms of higher concentration of crude protein, crude fat, β-carotene, and lower ADF, was noted in the *Poa pratensis- Festuca rubra* community (No. 1). Low quality was found in the communities No. 3 and No. 4 with a large share of hygrophilous species, particularly of the genus *Carex*.

Table 1. Chemical composition of the sward communities occurring in the pasture (average values)

Plant community*	Ash g/kg DM	Crude protein g/kg DM	Crude fat g/kg DM	Crude fibre g/kg DM	NDF g/kg DM	ADF g/kg DM	β-carotene mg/kg
1	47.4	122.6	16.5	224.0	548.9	289.0	676.9
2	43.4	114.6	12.4	219.5	526.2	289.5	533.7

*explanation of the 1-7 communities given in the main text

Virtual fencing to support grazing of suckler cows

Recognition of the forage potential of the pasture was the basis for preparation of the map with logical connections into IoT system. In this stage, a virtual pasture in the IoT system on a satellite map was marked up, maintaining its extensive character, as well as developing a grazing schedule, taking into account the parts dedicated to suckler cows and calves, which is the basis for the innovation of the technology. The developed grazing schedule in the river valley complex also included valuable natural and wetland enclaves, to which access of grazing animals will be periodically excluded. The virtual fence was implemented using the same principle as in commercially available systems, where a GPS collar constantly tracks the animal's position and compares it with virtual boundaries set by the farmer and collected from the collar. If the animal approaches the virtual border, the collar will produce an audio signal whose intensity and tone scale increase when the animal comes closer to the border. If the animal does not respond to the audio signal, it will receive an electric pulse. The pulse has about 30 to 50 times less energy compared to a traditional electric fence, but still, it is enough for the animals to be considered unpleasant. The cycle of the audio signal followed by the electric shock is repeated one to two more times if the animal does not respond, the animal is indicated as 'escaped'. The scheme used in our system is presented in the Figure 2. A key element of virtual fencing technology are collars equipped with built-in solar panels that charge the batteries during the day.

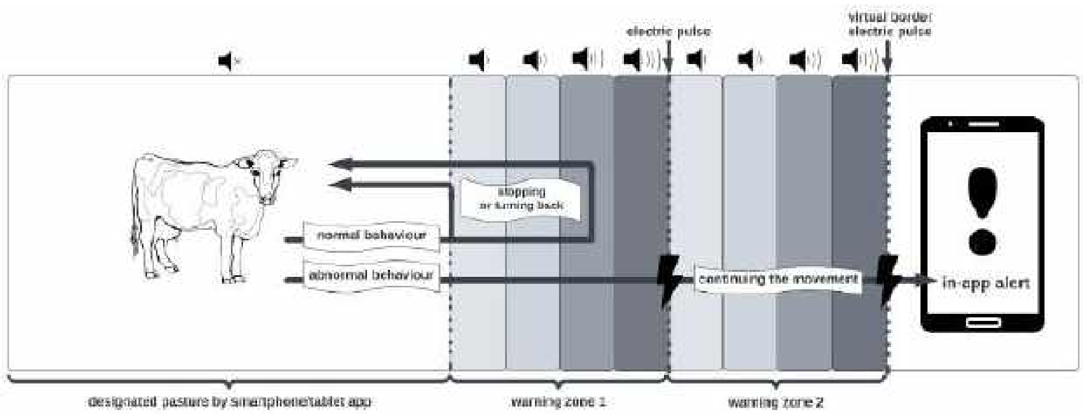

Figure 2. Scheme of possible response of grazing animals to virtual fencing in the IoT system

The next steps for developing of the technology were: field tuning of IoT system components, work on creating a virtual knowledge base, preparation of camera stations, setting camera parameters and including them in the IoT system and programming work. In 2024 the adaptation of grazing animals is in progress and the results are promising. Parallel, the zootechnical studies are conducted, which include physical monitoring of the herd, studies of the nutritional activity of suckler cows and calves in virtual quarters, ethological studies of animals, body temperature tests to detect animal diseases. Every two months from the beginning of grazing the assessment of animal weight gains during the grazing season are conducted. The IoT system supporting the technology of grazing suckler cows in high nature value areas by virtual fencing will be complemented by the analysis of the meat quality of weaned calves after slaughter. Special attention is given in preparation of the physical location and configuration of the energy storage and photovoltaic installation.

Discussion

Grass communities located in the river valleys are of both socio-economic importance (production of animal feed and products, most important elements of the natural landscape), as well as ecological importance, because as habitats for a huge number of plant and animal species, they constitute one of the most important reservoirs of biodiversity in Poland. The results of our study focusing on determination of forage potential of the studied pasture in the Middle Odra Valley confirmed that high nature value areas can be used for cattle grazing. The technology of suckler cows is particularly suited for this purpose. The premise for maintaining the high natural values of those meadow complexes is their utilization. It was confirmed by many authors, e.g. Horn and Isselstein (2022). The using of the IoT system based on virtual fencing support grazing of suckler cows in high nature value areas, where it is often impossible to build conventional fences and constantly monitor the daily activity of animals. Furthermore, remote control of the cattle herd using collar-mounted devices will also make it possible to exclude areas with protected plant or animal species from grazing without building physical barriers. The benefits of directing grazing animals to appropriate landscape niches were also highlighted by Campbell et al. (2020) and Stevens et al. (2021) to virtually exclude from grazing landscape elements of high natural value or habitats of rare and protected species, in particular areas excluded from use in a given year in accordance with the conducted agri-environmental programs. The potential for environmental protection in the aspect of implementing the tested IoT system on similar meadow objects, due to their large area in our country, is therefore very large.

Pastoralism in the Sahel: Perceptions and adaptation strategies of pastoralist youth

Ka, M[1, 3]; Ba, B[2, 3]

[1] Cheikh Anta Diop University of Dakar, Senegal),

[2] Rangelands & Pastoralism, International Livestock Research Institute (Dakar, Senegal)

[3] Youth Working group for IYRP 2026

Key words: Youth pastoralists; Rangeland; Pastoralism; Senegal

Abstract
Our study examines how young people in the Senegalese silvo-pastoral zone perceive and engage in pastoral livestock farming. Nowadays, pastoralism remains a significant cultural element, however traditional practices such as transhumance are perceived as very rigorous. Young people consider livestock farming as a means of saving money but face challenges such as pasture degradation and limited State support. They advocate for reforms to modernize pastoralism and improve their living conditions. While many diversify their income sources, they are reluctant to pass these practices on to their children.

Introduction
Pastoralism is recognized as a sustainable way of utilizing pastoral ecosystems (grazing lands and water points) that promotes the maintenance of biodiversity (Andreas et al. 2017). In pastoral communities, young people (under 40 years) play a crucial role in livestock management and provide reliable support in all pastoral activities, including transhumance, watering, and herd monitoring. Caught between the pull of modernity and traditional pastoral practices, these young people strive to maintain the pastoral culture inherited from their parents while adapting to a modern lifestyle (Korbéogo 2016), made possible by the opening of rural areas to urban influences and the exchange of lifestyles through rural-urban migration, commercial trade, and human interactions facilitated by the improvement of roads (Macia et al. 2023).

In the Sahel, the Senegalese silvopastoral zone provides an excellent setting to study these current social phenomena upon which the future of pastoralism depends (Mauclaire 2019; Mugelé et al. 2023). Young people's perception of pastoral practices deserve analysis to understand how they perceive the future of pastoralism. In Senegal, many young people explore new income opportunities in urban areas. These alternative income sources may eventually lead to visions and ambitions shifts. While such shifts might offer young people socio-economic stability, they could influence or destabilize pastoral activities (Ancey and al. 2020), which, as mentioned, heavily rely on the energy and vitality of youth. This could result in a transformation from traditional pastoralism to modern livestock farming, as well as changes in rangelands, both biophysical and in terms of the way they are used.

This study aims to explore how young people from pastoralist families view traditional livestock practices, particularly in comparison to urban income-generating activities. It will examine the influence of education (both conventional and Quranic) on this shift, and how access to digital technology is reshaping pastoralism and creating new economic opportunities. The focus is on understanding what motivates young people to continue pastoral livestock farming despite the availability of other professional options.

Methods

We developed a concise questionnaire to collect qualitative data on young people's perceptions of pastoral livestock farming. We did not employ a sampling method, as our objective was not to conduct an exhaustive study but rather to explore preliminary insights that could serve as a basis for further investigation. The questionnaire was designed based on our field experience over the past few years of research in pastoral areas. Consequently, we included predominantly open-ended questions to broaden the scope of possible responses. To construct and deploy the questionnaire, we utilized the data collection tool **KoboToolbox**, which allowed us to design the survey and distribute it on platforms like smartphones. This approach enabled us to share the questionnaire via a simple link in unlimited quantities. By leveraging this method, we distributed the link as widely as possible and encouraged recipients to share it further. Through this snowball sampling strategy, we received referrals from participants who had already completed the questionnaire.

We also opted to share the link through social networks, particularly WhatsApp groups and direct contacts. This allowed anyone with basic literacy skills to complete and submit their responses. Additionally, we conducted several interviews via phone calls with herders whose contact information was shared with us but who could not read, write, or use WhatsApp. The collected data was stored on a **KoboToolbox server**, enabling secure storage during the collection process. These data were later downloaded in **XLS** format for processing in Microsoft Excel.

How young people perceive the pastoral livestock farming

Young people perceive pastoral livestock farming as offering limited prospects. Income during the dry season is low, mainly spent on livestock feed, while the rainy season provides slightly higher earnings, though still lower than urban jobs. This makes livestock farming less economically appealing compared to city employment, as highlighted by (Magrin and Raimond 2024) in other Sahelian cities. Incomes during the dry season are under 50,000 FCFA (*local currency*) per month (76 Euros or 83 USD), rising to 100,000 FCFA (152 Euros or 166 USD) in the rainy season. These earnings fluctuate based on season and family needs. Small ruminants are sold weekly, while larger ones are sold occasionally, often to cover feed costs. Thus, livestock income is unpredictable and doesn't provide stable financial security or savings.

For young herders, financial stability depends on herd size, which allows income diversification. Some with large herds or seeking alternatives secure steady income through livestock trading. Experienced herders engage in trading, either as intermediaries or resellers, often reinvesting profits to grow their herds. Trading is seasonal, particularly during the dry season, to cover feed costs. Livestock traders tend to be young people with strong negotiation skills from interactions with urban communities during Quranic studies. As in their early life in quranic schools, these young students spent mornings and evenings begging from passers-by in cities for their Quranic teacher, throughout their entire study period, which could last several years. In this way, they develop great ability to interact and negotiate with urban people. However, rural youth face challenges in urban environments, such as language barriers and unmatched attitudes, from the view of the urban habitants. Only those accustomed to urban life adapt successfully.

Moreover, many pastoral youths have diversified their income through other professions, such as working for international research institutions, accounting, teaching, and consulting, while maintaining their identity as pastoral herders. This diversity of activities encourages further analysis of what keeps young people engaged in livestock farming

Understanding what motivates young people from herding
Understanding the motivations of young people from herding families is crucial for predicting the future of pastoral livestock farming. Our research reveals that young people are drawn to pastoral livestock farming due to its deep connection to their cultural identity. Terms such as "tradition," "culture," and "Fulani" were often mentioned, reflecting the significance of this practice as a cultural heritage. Phrases like "It's about the cultural aspect and honoring our parents" highlight the pride in continuing a family tradition. This cultural identity, shaped by parental involvement in livestock farming, continues to be a source of pride for young people (Luque 2002), ensuring that pastoral practices are maintained across generations.

However, certain pastoral practices, particularly transhumance, face increasing criticism for their economic, physical, and social impacts. Transhumance restricts participation in community activities and prevents children from accessing education and families from receiving medical care. The need to find alternatives to moving entire families with herds has become urgent. Basic services such as schools and healthcare facilities must be accessible to these families.

Most young people interviewed, regardless of education, expressed the intention that their children would not follow in their footsteps due to the harsh realities of pastoral life and lack of access to essential services. This trend suggests that, without reform, pastoral livestock farming in the Senegalese silvo-pastoral zone may decline in the coming generations. However, as Ba (2023) suggests, adaptive changes in livestock farming practices could help sustain this system, despite the numerous challenges posed by agricultural expansion, grazing land shortages, and inadequate state support.

Discussion
The Fulani identity remains closely linked to pastoral livestock farming among young people, serving as a source of pride, as noted by Botte et al. (1999). However, many young people express a desire to transform pastoral practices, particularly transhumance, to improve their quality of life. This includes providing better living conditions for their families, which is difficult in remote, sparsely populated areas where transhumant herders must reside. The traditional "good herder" identity is gradually being replaced by a more modern identity focused on technology, urban networks, and material wealth, as observed by Macina et al. (2023).

State investments in pastoral hydraulics, like the densification of boreholes, have made new areas accessible, but they have also led to overgrazing due to an increase in livestock numbers. Many herders noted that the availability of water in the region has exacerbated the lack of pasture, a trend highlighted by Véron (2014). Degradation of grazing lands, proliferation of invasive species, and overexploitation of communal resources are major concerns. Combined with rising livestock populations and improved veterinary care (Véron 2014), these factors contribute to the environmental challenges facing the Senegalese sylvo-pastoral zone, as noted by Ba (2023).

Results statement: Youth in Senegalese silvo-pastoral zone believe pastoral practices must change to improve the quality of life for families and children, ensuring access to basic services.

Conclusion
Pastoral livestock farming in the Senegalese silvo-pastoral zone is viewed by young people as an activity tied to their "Fulani" identity, yet its restrictive practices hinder participation in community life. While large-scale herders can earn significant incomes, young people see the potential to build "savings herds" with family or hired help, benefiting from rising livestock demand for festivals. With challenges like land degradation and shrinking pastures, young people express reluctance to continue these practices, questioning their long-term viability. However, we advance the need for a larger and quantitative study to gain a clearer understanding view of youth perceptions on the pastoral lifestyle and the pastoralism in the future.

Acknowledgments

We extend our gratitude to all the young people who identify as pastoral herders and who took the time to participate in this study, whether from the heart of the Ferlo region or from major Senegalese cities. This study would not have been possible without their support and consent. This research was conducted using personal resources, with no funding received from any donor. No conflicts of interest were reported among the authors of this article.

Can spatial distribution of cattle manure be controlled? Relationship between cow location and dung pats

Kato, M[1]; Yayota, M[2]; Kawamura, K[3]; Yasuda, T[4]; Kitagawa, M[5]

Abstract

Controlling the spatial distribution of cattle dung pats in a pasture can enhance nutrient utilization and mitigate greenhouse gas emissions resulting from dung in grazing management. Dung pats are distributed in accordance with cattle behavior and location in a pasture, thus frequent monitoring of cattle location and dung distribution is essential for effective dung control. Recently, the detection of dung pat distribution has been achieved using unmanned aerial vehicle (UAV) images. Additionally, a global positioning system (GPS) can provide continuous monitoring of cattle locations. Therefore, in this study, we monitored the effect of cattle location on dung distribution under strip stocking using UAV images and a deep learning approach. Five dairy cows, equipped with GPS collars, grazed for five days under a strip stocking condition. A 3.5 ha pasture was divided into four paddocks, one of which was expanded each day. UAV images were captured before grazing each day. The training data generated were used to estimate dung pat distribution using YOLO (YOLOv8x), an object detection algorithm. The accuracy of the dung distribution was assessed using the confusion matrix. The paddock was further divided into 10 m grids, and a generalized linear model was employed to evaluate the relationship between cow location and dung pat count within each grid. The detection accuracy of dung distribution was 0.793 (precision), 0.222 (recall), 0.210 (accuracy), and 0.347 (*F*-value), indicating the need to improve the accuracy of detecting undetected dung pats. As the pasture area increased, the cows spread out their location, resulting in an expanded dung distribution. However, the cow location did not correlate with the dung location ($R^2 = 0.053$). This is presumably due to the insufficient recall of the dung distribution estimates. Additionally, not only the location, but also the cow's behavior, such as resting and lying, should be assessed.

Introduction

Cattle play a critical role in nutrient cycling within grazing ecosystems by consuming plants and redistributing nutrients back into pastures through excretion (Hirata et al. 2011). However, the spatial distribution of excreta across pasture is often uneven (Hassan-Vásquez et al. 2022). Consequently, nutrient levels within a pasture can vary significantly, with some areas becoming nutrient-rich or even overloaded, while others remain nutrient-deficient. Moreover, in areas with high concentrations of manure, dung patches are formed (Takigawa et al. 1996), which may reduce the efficiency of grassland utilization (Klootwijk et al. 2019). Recently, cattle dung has also been recognized as a source of greenhouse gas emissions, with nitric oxide and nitrogen dioxide being emitted from dung (Osada 2001). Thus, efforts to reduce greenhouse gas emissions, such as the application of nitrification inhibitors, are required (Cahalan et al. 2015). However, the widespread application of nitrification inhibitors across an entire pasture represents a substantial cost and is a labor-intensive endeavor.

Controlling the spatial distribution of cattle dung pats in a pasture would contribute to solving the above problems and is important from the perspective of grassland management and environmental conservation. Since cattle behavior and location are closely linked to dung distribution, frequent monitoring of cattle movements and dung deposition is essential for effective management. In recent years, global positioning systems (GPSs) or global navigation satellite systems (GNSS) have facilitated continuous monitoring of cattle locations (Yoshitoshi et al. 2020). Moreover, the detection of dung pat distribution has been accomplished through unmanned aerial vehicle (UAV) images, employing deep learning approaches that can accurately recognize images and detect objects. In this study, we monitored the effect of cattle location on dung distribution under strip stocking conditions using UAV images and a deep learning approach. Grazing insight into this relationship can inform the development of targeted strategies to manage dung distribution, enhance pasture utilization, and mitigate environmental impacts.

Methods

The grazing trial was conducted for five days from June 26, 2023, in a 3.5 ha grass-legume mixed pasture located in the eastern region of Hokkaido, Japan (N42°33', E143°14'). The pasture had a single gate in its northeastern part and tree sheds along the fence from the east to the northeast in the pasture. The pasture was divided into four paddocks, and strip grazing was implemented. On the initial day, the entire pasture was utilized for grazing, followed by the sequential opening of one paddock per day, starting with the easternmost paddock on the second day.

A total of 53 cows (47 Holsteins and 6 Jerseys cows) were grazed for approximately 8 hours from 7:30 am. to 3:30 pm. The cows were milked twice a day, once before and once after grazing, and were provided supplementary feed in the barn. Five cows (three Holsteins and two Jerseys), selected based on age (3.6 ± 2.9 years) and breed, were fitted with GPS collars to track their movements during the grazing.

Aerial photography was conducted on four of the five grazing days, excluding June 28 due to rain. An UAV (Parrot, Anafi, France) equipped with a camera (4K HDR) was used for aerial photography. Four Ground Control Points (GCP) were set up to perform geometric corrections prior to aerial photography. The UAV was operated using the Pix4D capture flight management application. The flight altitude was 35 m, the camera angle was 80°, the overlap setting of 80% for forward movement and 60% for lateral movement, and the image resolution was 1.3-1.5 (cm/pixel).

To validate the dung distribution data, three 10 m × 10 m plots were established in the pasture. The dung distribution estimated via aerial imagery was compared to data obtained through direct observation using a Real-Time Kinematic GNSS (RTK-GNSS). Aerial images were geometrically corrected and orthorectified using Agisoft Metashape (Agisoft LLC, Russia).

For the creation of training data, annotations were performed using the Makesense tool (https://www.makesense.ai/). Training was conducted using YOLOv8x (https://github.com/ultralytics/yolov8), a real-time object detection algorithm YOLO (You Only Look Once). The dataset included 3,284 annotations, combining data from the present study and our previous study (Kawamura et al. 2024) conducted at a different location.

Statistical analyses were performed using R version 4.3.2 (R Core Team, 2023), except for estimating cow dung distribution. The accuracy of dung distribution detections was assessed through a confusion matrix. The logarithm of GPS point counts was used to evaluate cow movement patterns. A Poisson regression model (GLM) was used to examine the relationship between cow location and dung distribution. The number of GPS points within each grid of the pasture served as the explanatory variable, while the number of dung detections represented the response variable. The predictive accuracy of dung counts, estimated from the regression equations, was assessed using R^2 (coefficient of determination), RMSE (root mean square error), and AIC (Akaike Information Criterion).

Results

The average vegetation coverage was 62.0%, with meadow fescue (*Festuca pratensis* L.), white clover (*Trifolium repens* L.), and orchard grass (*Dactylis glomerata* L.) as the dominant grass species. The detection accuracy of dung distribution was 0.793 (precision), 0.222 (recall), 0.210 (accuracy), and 0.347 (*F*-value). GPS data were obtained from all five cows on one day, four cows on three days, and three cows on the remaining day.

Figure 1 illustrates the daily counts of GPS points and the cumulative total of detected cow dung. The spatial distribution of cow increased as the grazing paddock expanded, leading to a wider spread of manure distribution. However, despite the paddock expansion, cow tended to concentrate their activities near the tree shades in the southeastern part of the pasture.

The relationship between the time spent by cows in each area and the number of dung was analysed using Poisson regression (GLM), as shown in Figure 2. The regression equation is as follows:

Number of dung = exp (0.37+0.19×log [GPS points]): R^2=0.053, RMSE=2.403, AIC=1600.186

The low R^2 value indicates that cow locations accounted for less than 5% of the variation in the dung distribution.

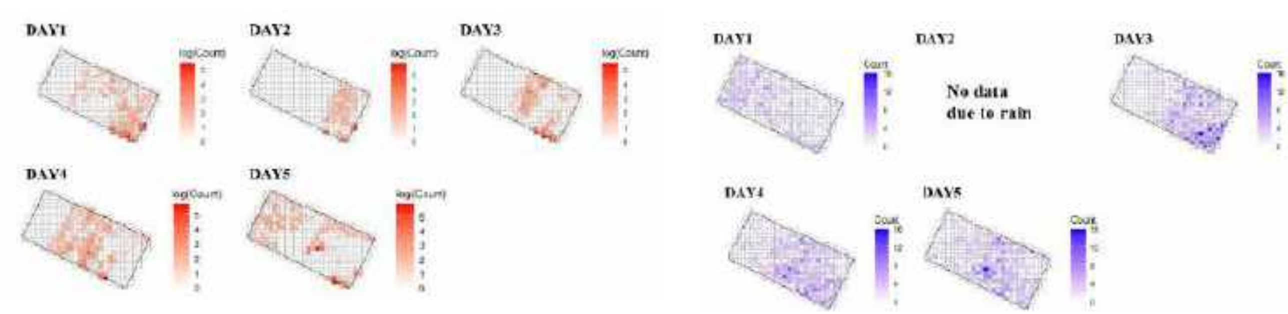

Fig. 1 Cattle location (left) and estimated dung distribution (right) in the strip stocking pasture

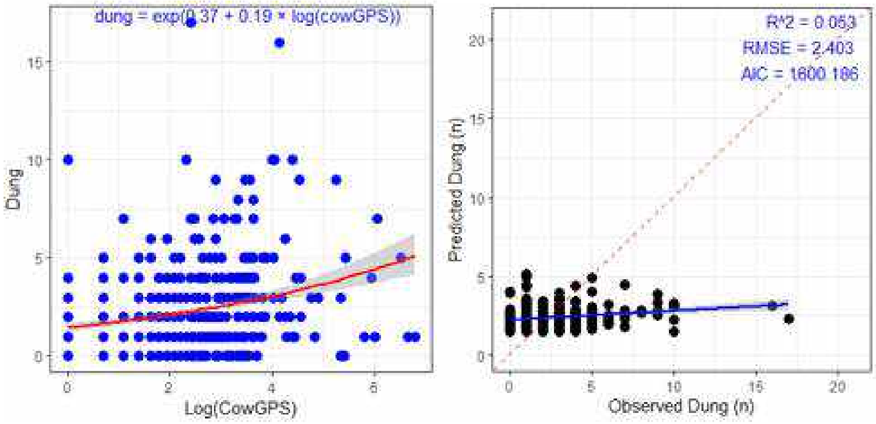

Fig. 2 The regression equation and graph obtained through Poisson regression, based on the number of GPS counts within the grid and the detected number of cow dung (left). The accuracy of the regression equation is evaluated by comparing the number of cow dung estimated from the equation with the actual number of dung detected (right).

Discussion

Strip grazing influenced cattle behavior significantly. As the pasture area increased, cows spread out their location, resulting in an expanded dung distribution. However, the cow location did not correlate with the dung location (R^2 = 0.053). This low correlation may be attributed to the low detection rate of cow dung in aerial images (recall: 0.222), which highlights the need for improvement. The resolution of the aerial images, approximately 1.3–1.5 cm/pixel, was coarser than that used in a previous study by the authors (0.9–1.0 cm/pixel), potentially causing smaller dung patches to go undetected. Kawamura et al. (2023) recommend a drone flight altitude of 40 m (resolution: 2 cm) or lower for efficient surveying in large fields. However, achieving higher-resolution images at lower altitudes may be essential for accurate detection in a pasture.

Machine learning models demonstrate enhanced accuracy with larger and more diverse training datasets, thus augmenting their practical applicability (Oki et al. 2019). Therefore, in addition to optimizing aerial photography conditions, it is crucial to enhance detection model accuracy by expanding the variety of supervised data for cow dung images, particularly given the challenges in distinguishing them from their surroundings.

Regardless of the expanded grazing paddocks, cow activity was concentrated in specific areas. This behavior likely reflects cows exploring and grazing in newly opened paddocks but returning to shaded areas for rest and ruminating. Research has indicated that cows defecate less frequently when lying down or foraging and more frequently after standing up and feeding (Suzuki et al., 1983). To enhance the predictability of cow dung distribution, it is essential to analyze not only the duration of stays but also grazing, ruminating, and resting behaviors at each location.

Keywords: Conventional tillage, Fertilizer, HCN**,** Rotavator, Subsoiling, Sugar yield

Introduction

In India, sorghum occupies 4.09 million ha area with production and productivity of grain about 3.48 million tons 849 kg grain/ha, respectively (Agricultural Statistics at a Glance, 2020). Presently sweet sorghum (*Sorghum bicolar* (L.) Moench.) is gaining popularity among farming communities mainly because of its fast growing habit, wide adaptability, tolerance to abiotic stress, higher grain productivity, good quality of green fodder and moreover the potential source of energy. Its stalk contains 15-17% fermentable sugars, 47% juice with 7.24% sugar content (Hugar, 2010). Besides, single cut sweet sorghum produced 35-50 t ha^{-1} stalk, 1.5-2.5 t ha^{-1} grain and 2760 lakh ha^{-1} ethanol (Ratnavathi *et al*., 2004). Sweet sorghum is a promising source of biofuel like ethanol, jaggery and syrup that can produce nearly 2000-2800 lha^{-1} and grains can also be used for making potable ethanol with a recovery rate of 400 lt^{-1} of grain (Singh, 2010). In general, sorghum plant attains height up to 3.50m, leaves are broad ~12 cm and long ~125cm and the stalk contributes 70-80% to biomass.

Tillage and balanced fertilization are two basic indices for sustainable crop production. The heavy tillage with regular use of disc harrow has now been obsolete in view of conservation tillage mainly because traditional tillage pulverizes top 15 to 20 cm soil leading to formation of hard pan (Kumar, 2003) resulting into reduced percolation. Hence water stagnation creates a reduced rhizosphere which is unfavorable for nutrient absorption and root growth. Subsoiling and differential rate of deep tillage along with fertilizer application have proved the suitability for not only breaking the hard pan but also making nutrients available at different depths for higher crop productivity (Manoj *et al*., 2022). Chen and Haung (1972) reported that differential rate of subsoiling at a depth of 25-30 and 60-90 cm improved the yield of autumn planted cane.

Fertilizer broadcasting results in low fertilizer use efficiency due to various losses (Rababi, 2006) as surface applied nitrogenous fertilizers are more prone to volatilization. That is, 40 to 50% of applied nitrogen and only 22 to 30% of applied phosphorus and potassium fertilizers are effectively used by the crop and the remaining get either washed away, volatilized, leached to ground water or get fixed with soil (Rowse and Stone, 1980).

Broadcasting is a common method of fertilizer application just before last tillage or seeding. These fertilizers are localized in the upper layer of soil, so the soil's larger, deeper portion is less available to plant roots. Therefore, it is essential to place P and K fertilizers in root zone for higher availability and its use efficiencies. Thakur and Mandal (2010) reported greater nutrient uptake and higher sugarcane yield under sub-soiling, with deep and differential rate placement of fertilizers in the root zone of the crop. Besides demonstrating such great importance of deep and differential place of fertilizers, very little research work has been conducted so far on commercial crops including sweet sorghum. Considering the above facts, the present study was carried out to study the effect of subsoiling tillage and nitrogen levels on fodder productivity and ethanol production of sorghum *(Sorghum bicolar* L.) in the Northern Himalayas.

Methods

The field experiment was conducted during the *Kharif* crop season (June to October)-2011 and 2012 at the Instructional Dairy Farm, Nagla, G.B. Pant University of Agriculture and Technology, Pantnagar, U. S. Nagar (Uttarakhand), India. The climate of the experimental site was humid sub-tropical with hot summers and cold winter. The mean annual rainfall is 1554.1mm of which 80 to 90 per cent is received from June to October. The total rainfall received during the crop period in 2011 and 2012 was 2007.8mm and 752.8mm, respectively. The soil of the experimental field was well drained with a slight silty clay loam texture and pH 7.21. The available organic carbon was 0.72% and available nitrogen and phosphorus and potash were 272.3, 29.0 and 236.1kg/ha, respectively. The experiment consisted of four tillage levels in main plot i.e. conventional tillage (CT), subsoiling (20cm) followed by (fb) rotavator x1(SS fb R), subsoiling-cum-deep placement (40cm) fb rotavator x1(DP fb R) and subsoiling-cum-differential rate fertilizer placement (25 & 50 cm) fb rotavator x1(DRF fb R) and four N levels in sub plot i.e. control (zero nitrogen), 40, 80 and 120 kg N/ha, was laid out in split plot design with four replications. The recommended dose of phosphorus (60 kg/ha) and potash (40 kg/ha) was deep placed as per the subsoiling treatments, while in conventional tillage it was applied at last tillage. The nitrogen was applied manually as per treatments in two equal splits i.e. 50 % basal and 50% at 30 days after sowing in all treatments. Sweet sorghum variety SPSSV-6 was planted on 27 May 2011 and 4 May 2012. The crop was harvest at pre heading stage and green, dry fodder yield were recorded. The ethanol yield was estimated with the help of sugar yield (Spencer and Meade, 1955) as given below;

Sugar yield (t/ha) = Available sugar (%) x Juice yield (kl/ha) /100

Ethanol yield (l/ha) = Sugar yield (t/ha) x 3.78 x1000 x 0.8

Results and Discussion

a. Effect of tillage options

Tillage options had significant impact on the green and dry fodder yields (Table.1). The pooled values of two years of field experimentation indicated that DRF *fb* R produced significantly highest green fodder yield (Fig.1). The DRF *fb* R had 6.3, 13.5 and 23.8% greater green fodder yield than DP *fb* R, SS *fb* R and CT respectively. Similarly DP *fb* R gave 6.6, while SS *fb* R gave 9.1% more green fodder yield than SS *fb* R and CT, respectively. The dry fodder yield was also recorded significantly higher under DRF *fb* R, while DP *fb* R produced 6.7% higher dry fodder yield than SS *fb* R which also had 1.9% higher dry fodder yield than CT. DP fb R and DRF *fb* R also had 8.6% and 19.3% higher dry fodder yield than CT, respectively. Further, it was also noted that DP *fb* R and DRF *fb* R also produced 6.7% and 17.1% more dry fodder yield than SS fb R, respectively (Fig.3). The higher values of green and dry fodder yield under differential rate fertilizer placement favoured better utilization of nutrient and moisture resulting into higher growth attributes. Kumar *et al.* (2022) also reported significantly higher green and dry fodder yields than CT and SS fb R.

The ethanol yield varied significantly among tillage options during both the years (Table.1. Significantly highest ethanol yield was obtained under DRF *fb* R followed by DP *fb* R, SS *fb* R and the lowest under CT, during both the years. Based on pooled values, the DRF *fb* R yielded 23.2, 41.7 and 45.1% higher ethanol than DP *fb* R, SS *fb* R and CT, respectively (Fig.5). The higher ethanol yield was ascribed to higher stalk juice yield. Singh (2008) supported these findings.

b. Effect of nitrogen levels

The green and dry fodder yield increased with increasing nitrogen levels with highest values at 120 kg nitrogen/ha (Table.1). The pooled values showed that application of 120 kg N/ha produced 6.9 and 14.7% higher green fodder yield than 80 and 40 kg N/ha, respectively, while it was 8.2% higher at 80 kg than 40 kg N/ha. Similarly at 40 kg nitrogen, the green fodder yield was 4.7% higher than the control (Fig.2). A similar trend was also observed in dry fodder yield which was 7.1% higher at 120 kg than 80 kg N/ha (Fig.4). The higher values of fodder yields were attributed to taller plants, higher leaf area index and dry matter accumulation. The results of Moghimi and Emam (2015) and Kumar *et al.* (2022) support these findings, however they had different field ecologies and crop varieties. The ethanol yield was increased with increasing level of nitrogen and the highest values were recorded at 120 kg N/ha during both the years (Table.1). The pooled values showed 29.3, 57.8 and 62.8% higher ethanol yield at 120 kg N/ha, respectively (Fig.6). The higher ethanol yield was the result of higher green stalk yield and juice percentage. Shehab and Guo (2020) also recorded similar results.

An interaction was found between subsoiling and nitrogen levels (Table.2). The ethanol yield was increased with increasing level of nitrogen with significant highest values at 120 kg N/ha except under DP fb R, SS fb R and CT that had non-significant values between 0 to 40 and 40 to 80 kg N/ha. The conventional tillage gave the lowest ethanol yield at all the nitrogen levels and the values were non- significant between 0 and 40 as well as 40 and 80 kg N/ha and a similar trend was observed an SS *fb R* and DP *fb R* produced higher yield at 40 kg N than CT, Similarly the ethanol yield was noted significantly highest under DRF *fb R* at all the nitrogen levels but DP *fb R* and DRF *fb R* were non-significant at 80 kg N/ha. In general the ethanol yield was recorded as non-significant under CT, SS *fb R* and DP *fb R* at both control and 40 kg N/ha, whereas DP *fb R* gave significantly higher ethanol yield at both 80 and 120 kg N/ha.

Interaction	NS	NS	NS	NS	S	S

Table 2. Interaction between tillage and nitrogen level on Ethanol yield at harvest based on pooled data

Tillage	Ethanol yield (kilo litre/ha)			
	Nitrogen levels (kg/ha)			
	0	40	80	120
CT	1.3	1.6	1.9	2.4
SS fb R	1.4	1.7	2.0	2.7
DP fb R	1.8	1.9	2.4	2.8
DRF fb R	2.1	2.6	2.8	3.8
			S Em±	CD at 5%
For Comparing tillage at constant N level			0.13	0.40
For comparing N level at constant tillage			0.11	0.40

Conclusion and Implications

Based on pooled values of 2011 and 2012 field experimentation, it may be concluded that sweet sorghum may be grown under differential rate placements of P and K at 25 and 50 cm depth with application of a recommended 120 kg N/ha for higher fodder yield and ethanol production in Northern Himalayan regions of India. This may be able to be replicated in similar ecologies of the world.

Drylands research in KALRO: addressing feed availability, livestock performance, climate smartness and business orientation challenges

Kuria, SG

Kenya Agricultural & Livestock Research Organization (KALRO), Arid & Range Lands Research Institute (ARLRI), P. O. Box 12-90138 Makindu Kenya; Simon.Kuria@kalro.org, kuriasg@gmail.com, +254 722 289 697, +254 737 530 905 (Corresponding Author)

Key words: Certified Range Grass Seeds, Quality Low Methane Feed, Beef Finishing, Business Models

Introduction

The drylands in Kenya represents about 84% of land mass, hosts a ¼ of human population and >70% of livestock herd. Drylands experience below optimal livestock productivity, constrained by unavailability of quantity and quality feeds. Low availability of feeds is attributed to poor management of grazing resources in the natural systems leading to degradation and, limited adoption of improved pasture and fodder technologies leading to limited restoration and establishment of new pasture fields. Livestock in the drylands produce methane from enteric fermentation of low quality feed in the rumen. Manure also produce methane but to a lesser extent (Gerber *et al*. 2013). Enteric methane emission also represents a 2-10% loss of the dietary energy (Moraes *et al*. 2014). In the last couple of years, KALRO has been undertaking research aimed at enhancing feed availability, livestock performance, climate smartness of the production systems and profitability.

Methodology

To address the feed availability challenge, KALRO adopted the innovative approach of developing and commercializing forage varieties, working closely with Kenya Plant Health Inspectorate Service (KEPHIS). Variety development entails germplasm collection, molecular and phenotypic characterization, selection and on station evaluation of promising candidates, the National Performance Trials (NPTs) in different agro-ecological settings and Distinctness, Uniformity and Stability (DUS). The trials culminate in registration and release of varieties by KEPHIS. To realize commercialization of the varieties, the certification process was done. Certification is about building the quantity of seeds available to marketable volumes. The process starts with planting of the nucleus seed to produce breeder seed, later planted to produce pre-basic while pre-basic is planted to produce basic and so on to the certified seed generation 2. The pre-basic and basic classes are commercially produced by registered seed merchants. The basic, certified seed generation 1 and 2 goes to farmers for feed production.

To enhance livestock performance, existing forage technologies (crops) were transferred to farmers and the latter's capacity to use the technologies innovatively build using the Training of Trainers (ToT) – Demo plots methodology. About 20 forage technologies (crops) were transferred where trainer of trainees drawn from county governments of Taita Taveta, Kajiado, Narok and producer organizations were recruited and trained by KALRO research team. The trained trainers (TTs) were each assigned a demo plot or 2 where they worked with farmers to establish the forage crops which included grasses and legumes. The TTs used a training curriculum to train 30 to 50 farmers at each demo plot on forage establishment, weeding, harvesting, conservation and utilization including feed ration formulation. The farmers did own evaluation of the different forages including biomass yield, tolerance to low moisture, attack by diseases and pests, palatability and acceptability by livestock using the Secret Ballot method and, effect on the milk yield of livestock. Chemical composition of the forages was determined and the results shared back with farmers. The training enabled farmers to select forage crops to adopt and grow on scale for their livestock. Feed rations were innovatively formulated using different combinations of grasses and legumes exposed to farmers through the demo plots in order to attain the energy-protein balance required for good livestock performance.The feed rations were also tested for capacity to finish beef. Sheep were used in the trials where 6 different rations were tested against control (pure grass diets) for 90 days where the trial animals were individually stall fed. During the trials, growth performance, nutritive value and cost data were collected.

To enhance climate smartness, KALRO introduced inclusion of legume in livestock feed. During the feeding trials, data on proximate composition of the feed rations (wet chemistry) and growth performance was collected and used to estimate enteric methane emission per kg of meat produced following Intergovernmental Panel on Climate Change (IPCC), 2019 equation shown below.

(1)

$$DMP\ (g\ /\ d) = \frac{(GE\ (MJ) \times Y_m(\%)/100)}{0.05565}$$

Where;
DMP is daily methane production; Ym is the methane emission factor of 6.7 %
GE is the gross energy of the rations, computed from the equation below;
(2)

$$GE = 0.0226CP + 0.0407EE + 0.0192CF + 0.0177NFE$$

Where; CP =Crude protein; EE= Ether extract; CF= Crude fibre; NFE = Nitrogen free extract

Cost data also collected during the feeding trials was used to determine average variable cost and profitability of each ration. Business cases were formulated based on the feed rations and promoted.

Results and Discussion

The varieties: Cenchrus ciliaris (CECI) Var. MGD KBK, Cenchrus ciliaris (CECI) Var.TVT3 KBK, Enteropogon macrostachyus (ENMA) KBK, Chloris roxburghiana (CHROX) KBK4, Brachiaria KS1 and Brachiaria BS1were registered and released in December 2021. The species including Megathysus maximus MK1, Megathysus maximus MK6 and Eragrostis superba are currently undergoing the NPTs with a view of having them registered and released by KEPHIS as well. On commercialization, about 3.2 tons of pre-basic class seed have so far been bulked and are in the process of being distributed to investors for commercial multiplication.

Forage technologies transferred to farmers are: Cenchrus ciliaris (African fox tail), Enteropogon macrostachyus (Bush rye), Chloris roxburghiana (Horse tail), Sugar graze, Nutrifeed, Brachiaria cayman, Brachiaria cobra, Brachiaria camello, Panicum maximum, cowpea M66, Dolichos lab lab, Lucerne, Desmodium, Mucuna, Purple vetch, among others. A 40% adoption of the forages was registered with the farmers. In the low rainfall areas, the grasses Sugar graze, Brachiaria camello and Masaai love grass were the most adopted while the same was true for Boma Rhodes in the high rainfall areas. The legumes, Dolichos lablab, Cowpea M66 and Sweet Potato vines, Greenleaf desmodium (Desmodium intortum). Adoption of the forage technologies by farmers was informed by; biomass yield, drought tolerance, acceptability and palatability by livestock and animal performance.

For the beef finishing trials, table 1 shows CP, Metabolizable Energy (ME) of the feed rations, initial live weight, Average Daily Gain (ADG), Final Weight, Net Weight, Dry Matter Intake per day (DMI/day) and DMI as a % of Live Weight (LWT).

Table 1: CP, ME, Average Initial Weight, Final Weight and Weight Gain for Goats Fed with Different Diets

Diet	CP (%)	ME (MJ/Kg DM)	Initial Weight (Kg)	ADG (g)	Final Weight (Kg)	Net Weight Gain (Kg)	DMI g/day	DMI as a % of LWT
Maiza grain+Lucerne hay+Wheat bran+Commercial ingredients	14	11	21.3	357[a]	48.8[a]	27.5	-	-
Brachiaria sp var cayman+Desmodium	8.7	8.6	15.5[a]	317.5[b]	44.1	28.6	593.2	3.29[a]
Brachiaria spp var cayman +Lucerne	10.8	9.4	16.7[a]	277.8[b]	41.7	25.0	583.3	3.0[a]
Megathysus maximus+Lucerne	7.5	7.9	16.7[a]	238.1[b]	38.1	21.4	643.1	3.3[a]
Megathysus maximus +Desmodium	7.1	8.6	17.0[a]	297.6[b]	43.8	26.8	562.6	2.8[a]
Megathysus maximus	3.1	6.6	17.0a	119.0a	27.7	10.7	686.3	
SEM	14	11	0.69	28.1	0.99	0.59		

Inclusion of legume in the diets enhanced nutritive quality, feed intake and the average daily weight gain of sheep. This was attributed to enhanced crude protein, digestibility and low fibre content in agreement with Krause *et al*. (2002).

Table 2 shows methane yield from other trialed feed rations.

Table 2: Methane Yield from Forage Based Feed Rations by Sheep over 91 Days in a Feedlot System

Parameter	C. ciliaris	C. ciliaris + Lucerne	C.ciliaris+ Desmodium	E.macrostachyus+Lucerne	E.macrostachyus+Desmodium	E.macro stachyus	SEM	P value
CP (%)	4.4[ab]	12.1[b]	7.1[a]	8.1[bc]	11.8[c]	5.5[ac]	-	-
*ME (MJ/Kg DM)	8.2[a]	8.5[b]	8.2[a]	7.8[c]	9.1[ab]	7.1[c]	-	-
DMI kg/day	0.87[c]	0.84[c]	0.68[a]	0.71[b]	0.81[bc]	0.92[c]	0.04	**
Daily Methane production (DMP g/day)	18.4[c]	17.7[c]	14.0[a]	15.15[ab]	16.94[b]	19.36[c]	0.81	**
CH_4 yield (g CH_4/kg DMI)	21.2[c]	21.2[bc]	20.8[a]	21.2[bc]	20.8[ab]	21.0[abc]	0.13	**
Methane intensity (g CH_4/kg LW	690.2[a]	470.9[b]	350.1[b]	599.6[a]	286.7[b]	645.6[a]	146.9	NS

*[a,b,c] Mean values within a row with different superscript letter differ significantly at p<0.05; C – Cenchrus; E – Enteropogon; SEM – Standard Error of the Mean; NS – Not Significant; *The asterisk indicates values obtained through computation. Column mean with different letter superscript are significantly different at p< 0.05*

A significant difference (p<0,05) was recorded on daily methane production from sheep fed on the six diets with inclusion of Desmodium in the *Megathysus maximus* diet reducing the DMP by 25%. This is tied to the fact that increased non fiber sugar content in ruminant feeds lead to a more propionate-based fermentation pattern which in turn decreased the amount of hydrogen produced (Archimède *et al*.2014) and consequently led to lower methane emissions. Methane yields obtained in the present study ranged from 20.8 -21.2 g/kg DMI which was within the range found by other studies in tropical environment with tropical low quality forages (Archimede *et al*.2018, Gera *et al.* 2022).

Table 3: Profitability Case for 100 units

Diet	**TVC**	**Revenue**	**GM**	**BCR (>1)**	**ROI**	**Viability (V) & Ranking**
Brachiaria+Desmodium	39,976.1	201,000.0	161,023.9	5.0	4.0	V-1
Brachiaria+Lucerne	55,249.8	174,000.0	118,750.2	3.1	2.1	V-3
Megathysus maximus	39,430.6	75,000.0	35,569.4	1.9	0.9	V-5
Megathysus maximus +Desmodium	39,976.1	189,000.0	149,023.9	4.7	3.7	V-2
Megathysus maximus +Lucerne	55,249.8	150,000.0	94,750.2	2.7	1.7	V-4

TVC – Total Variable Cost; GM – Gross Margin; BCR – Benefit Cost Ratio; ROI – Return on Investment

Brachiaria+Desmodium and *Megathysus maximus* +Desmodium returned the highest BCRs of 5.0 and 4.7 and ROI of 4.0 and 3.7, respectively. *Megathysus maximus* basal diet showed the least returns. The legume addition to grass-based diets returned high BCR, GM, low Break Even Quantity (BEQ) and high ROI confirming the importance of the protein rich ingredients in livestock feeds.

Conclusion and Recommendations

KALRO is on course in terms of making available, certified range grass seed varieties for restoration of degraded rangelands and establishment of new pasture fields. This will contribute to the government effort to close the 56% livestock feed supply deficit experienced at the moment. Seed companies, farmer groups or individual farmers are encouraged to engage in commercial seed multiplication using the basic seed now available in KALRO. In so doing, the companies will help the country produce and meet the demand for certified grass seed. With a 40% adoption of forage technologies by farmers, the country is on course to significantly increase feed availability and by so doing increase livestock productivity. The KALRO team recommends that counties encourage farmers to continue adopting the improved forage crops in order to make more livestock feed available. Inclusion of the legume in the diets enhanced nutritive quality, feed intake and the average daily weight gain of sheep on the feed rations. It is therefore beneficial for sheep farmers to adopt growing of grasses and legumes for use in forage-based feed ration formulation to finish the sheep. The alternative is to ensure supplementation of the free grazing goats with cultivated protein rich feed material for the livestock finishing activities to make economic sense. Finishing of the sheep should start at between 4 to 6 months old to take advantage of the naturally fast growth at this stage and in a feedlot system. Legume addition to low quality roughage reduced daily methane emission and methane yield per unit of beef produced implying, the system is a good option for achieving the emission reduction goals for sustainable sheep production. The legume addition to grass-based diets returned high BCR, GM, low BEQ and high ROI confirming the importance of the protein rich ingredients in livestock feeds. The on-farm feed production was more cost proficient than buying from the market and thus more farmer profit maximizing.

Effect of drought on performance in continuous grazing with breaks with and without inclusion of a rotational grazing module systems.

Lombardo, S[1]; Pereira Machín, M[1]

[1]Instituto Plan Agropecuario (www.planagropecuario.org.uy)

Keywords: grasslands; grazing systems; good practices; drought; Uruguay.

Abstract

Rangelands are the mainstay of cattle and sheep systems in Uruguay. The current demand for global results from different grazing systems puts pressure on the generation of new knowledge. In this context, spring droughts in Uruguay are one of the most relevant challenges for livestock farmers. The objective of the following work is to evaluate the impact of drought on a continuous grazing with breaks with and without inclusion of a rotational grazing module system. The study was conducted during the 2021/2022 and 2022/2023 seasons, with the former encompassing a spring drought and the latter a severe spring and summer drought, examined two grazing systems: continuous grazing with breaks (CG) and continuous grazing with breaks plus rotational grazing module (CGR). The results showed that Aboveground Net Primary Productivity (ANPP) decreased by about 12% in both groups. The Meal Plate Index (MPI), an index that relates available grazing to the grazing required for optimal animal performance, decreased by 13% in CG and 7% in CGR. Grass Availability (GA) also decreased by 15% and 4% for CG and CGR respectively. The proportion of pasture greater than 5 cm (PRG5) decreased from 19% to 12% for CG and increased from 26 to 33% for CGR for both seasons. The main differences are that CGR maintains Meat Production (MP) (105-107 Kg per hectare) and Efficiency per Stock Unit (MPES) (133-132 kg). On the other hand, CG was not able to maintain its MPES (144-128 kg), which decreased by 12%. For CG, 9 out of 12 were negatively affected, resulting in a 22% decrease of MP. Within CG, the least affected had values of PRG5=16 and MPI=0.72, while the most affected had values of PRG5=7 and MPI=0.6. The severe drought had a differential impact on systems, CGR group showed improved levels of grass indicators and reduction in the negative impact on MP and MPES.

Introduction

Rangelands are the mainstay of cattle and sheep systems in Uruguay. The current demand for information on the overall results obtained from the different grazing systems is putting pressure on the generation of new knowledge, FPTA 356 proyect (e.g. Singh, pers. comment.). In this context, spring droughts in Uruguay are one of the most relevant challenges for livestock farmers. The objective of the following work is to evaluate the impact of drought on a continuous grazing with breaks with and without inclusion of a rotational grazing module system.

Methods

The study was conducted during the 2021/2022 and 2022/2023 seasons, with the former encompassing a spring drought and the latter a severe spring and summer drought, examined two grazing systems: continuous grazing with breaks (CG) and continuous grazing with breaks plus rotational grazing module (CGR). We work with 19 cattle and sheep ranches (average 1300 hectares) that were part of the FPTA Nº 356 (Pereira Machin, 2020) pasture management project implemented by the Instituto Plan Agropecuario (IPA). The six outputs or index that were analyzed were: 1 - Aboveground net primary productivity (ANPP) expressed in kg DM. The 'Paddock Monitoring' module allow updating the status of the paddocks, as well as displaying the following outputs or global forage performance indicators of the establishment; 2 - Grass Availability (average stock in kg DM per hectare that the establishments have at a given time). 3 - Meal Plate Index (MPI), an index elaborated in the FPTA-INIA Project No. 345 (Duarte, 2020), this index is the result of comparing the forage or grass available in the establishment, with the one that should be available for an optimal performance of the livestock. The result is expressed in decimals, MPI value 1 means that the available grazing area is equal to that needed, while lower or higher values show shortages or surpluses. 4 - Proportion of area available for grazing at different height ranges (*i.e.* generated from the proportion of area at three height ranges), this variable is represented by the following three indicators: Proportion of area with forage height; 'less than 2.5 cm' (PGR-2.5), 'between 2.5 and 5 cm' (PGR2.5To5) and 'greater than 5 cm' (PGR5). In order to assess the performance of pasture management, it was necessary to develop an indicator to describe pasture management (Lombardo, 2023). 5 - Meat Production (MP) in Kg per hectare / year, and 6 - Efficiency per Stock Unit (MPES) expressed in kg of meat produced per kg of live weight maintained in the system.

Results

The results showed that Aboveground Net Primary Productivity (ANPP) decreased by about 12% in both groups. The Meal Plate Index (MPI), an index that relates available grazing to the grazing required for optimal animal performance, decreased by 13% in CG and 7% in CGR. Grass Availability (GA) also decreased by 15% and 4% for CG and CGR respectively. The proportion of pasture greater than 5 cm (PRG5) decreased from 19% to 12% for CG and increased from 26 to 33% for CGR for both seasons. The biggest differences are in this indicator, CG decreased by 7 percentage points (37 % overall) while CGR increased by 27 % overall, which shows the capacity to provide pasture in both systems. The results show that in the 2021-2022 season, the majority (14/19) of the ranches maintained PGR5 with values above 15%. In 2022-2023, only 9 of the 19 were able to maintain this condition. In the same direction, the main differences are that CGR maintains Meat Production (MP) and Efficiency per Stock Unit (MPES). For this analysis we can look at that CGR systems have the best values for grass use efficiency (MPES), linked to improved values of GA, MPI, PRG5, MP.

Table 1. Results outputs of CG and CGR in two seasons

	CG		Difference	CGR		Difference
	2021-2022	2022-2023	in %	2021-2022	2022-2023	in %
ANPP (KgMS/ha/year)	4980	4400	-12%	4690	4150	-12%
MPI [0 To 1.2]	0,77	0,67	-13%	0,74	0,69	-7%
GA (KgDM/ha)	871	736	-15%	997	959	-4%
PGR5 (%)	19	12	-37%	26	33	27%
MP (Kg/ha/year)	99	87	-12%	106	107	1%
MPES (Kg/Stock Unit)	145	128	-12%	134	133	-1%

Figure 1. Proportion of area with forage height; 'less than 2.5 cm' (PGR-2.5) in red, 'between 2.5 and 5 cm' (PGR2.5To5) in yellow, and 'greater than 5 cm' (PGR5) in green by CG in 2021/2022.

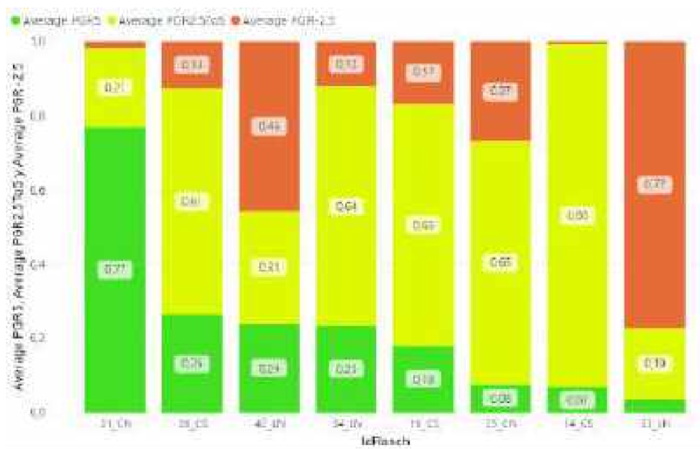

Figure 2. Proportion of area with forage height; 'less than 2.5 cm' (PGR-2.5) in red, 'between 2.5 and 5 cm' (PGR2.5To5) in yellow, and 'greater than 5 cm' (PGR5) in green by CGR in 2021/2022.

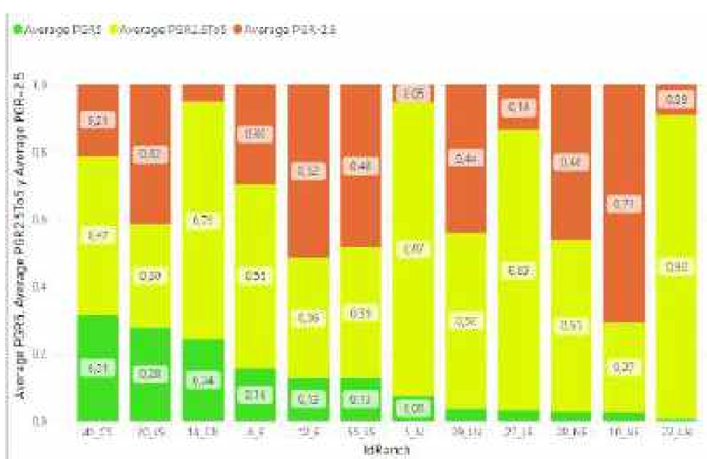

Figure 3. Proportion of area with forage height; 'less than 2.5 cm'(PGR-2.5) in red, 'between 2.5 and 5 cm'(PGR2.5To5) in yellow, and 'greater than 5 cm'(PGR5) in green by CG in 2022/2023.

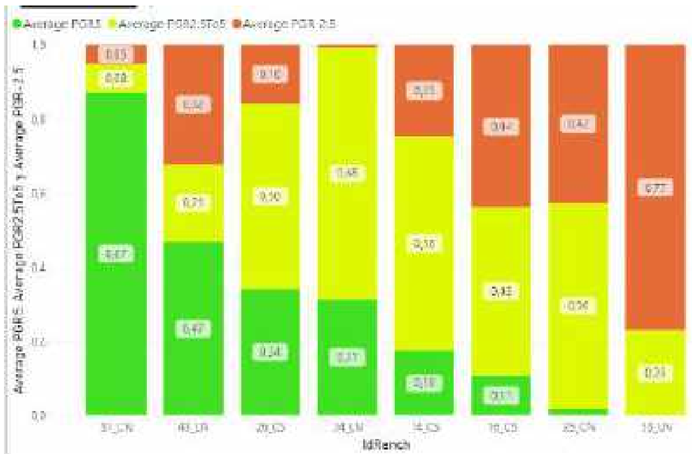

Figure 4. Proportion of area with forage height; 'less than 2.5 cm'(PGR-2.5) in red, 'between 2.5 and 5 cm'(PGR2.5To5) in yellow, and 'greater than 5 cm'(PGR5) in green by CGR in 2022/2023.

Discussion

CG was not able to maintain its MPES (144 -128 kg), which decreased by 12%. For CG, 9 out of 12 rancheswere negatively affected, resulting in a 22% decrease MP. Within CG, the least affected had values of PRG5=16 and MPI=0.72, while the most affected had values of PRG5=7 and MPI=0.6. The severe drought had a differential impact on systems, CGR group showed improved levels of grass indicators and reduction in the negative impact on MP and MPES. CGR systems had higher grazing efficiency and productive performance, they also provided higher quantities of forage. The originality of the indicators used (PRG´s) does not yet allow for comparison with local research carried out.

Navigating fragmented landscapes: pastoralism and dependence on open natural ecosystems in western India

Majgaonkar, I[1,2]; Young, J[3]; Krishnan, S[1]; Vanak, AT[1]

[1] Ashoka Trust for Research in Ecology and the Environment, Bengaluru, India; [2] Manipal Academy of Higher Education, Manipal, Karnataka, India [3] French National Institute for Agriculture, Food and Environment, Paris, France.

Key words: land use, movement, pastoralism, deccan peninsula

Abstract
Open Natural Ecosystems (ONEs) cover about 10% of India's geographical area and are extremely fragmented. Sustainable use of ONEs for low-input livelihoods like extensive pastoralism requires an understanding of the nature of the dependence of pastoralists on these native habitats. This is especially crucial in India where such socio-ecological systems lack recognition and are classified as 'wastelands' in policy and legislation. We tracked livestock movement in different land uses of western India's ONEs for 109 days between 2022-2023. We used non-participant observations and interviews with pastoralist men and women to understand movement-related decision making. Based on simple linear models and availability vs use frameworks, we infer pastoralism's fine-scale use of the landscape. Livestock movement patterns show that pastoralist dependence on ONEs at higher elevations is highest in the monsoon (use is >2.5 times the availability of ONEs), and the availability of irrigation, household labor, and social networks determines this movement. Pastoralism in this region is heavily influenced by the availability of agricultural residues and farmer decisions contrary to the popular understanding, some households appear to benefit from irrigated agriculture. Despite rapid land transformations, however, pastoralism remains a low-input and economically lucrative livelihood that allows seasonal use of savanna ecosystems. Our findings contribute to understanding of how these ONE-based livelihoods navigate land use change and offer insights into the potential of community-led ecosystem management.

Introduction

Globally, India does not figure as a country with extensive rangelands and 'grazing-only' systems because of the wide presence of socially complex small-scale farming systems (Godde et al. 2020; Herrero et al. 2017) and hence is a data-deficient region in global analyses on rangeland management (Godde et al. 2020). However, 10% of India's geographical area is covered by Open Natural Ecosystems (ONEs) which are naturally occurring grass-dominated landscapes in semi-arid and arid regions of India (Ratnam et al. 2016). These consist of ecosystems like deserts grassy to mesic savannas, ravines, and rocky outcrops (Madhusudan & Vanak 2022). Like many other regions of the world, India has a significant population of extensive pastoralists who practice large and small livestock rearing by relying on ONEs for some parts of the year. Extensive pastoralism is a specialized method of rearing livestock in semi-arid regions that relies on movement between geographies to benefit from the fluctuation of water and biomass availability (FAO 2021). Although the contribution of this system to India's food security and economy is being formally investigated, some estimates suggest that 53% of India's milk production and 74% of India's meat production comes from extensive pastoralist systems (Kishore & Kohler-Röllefson 2020).

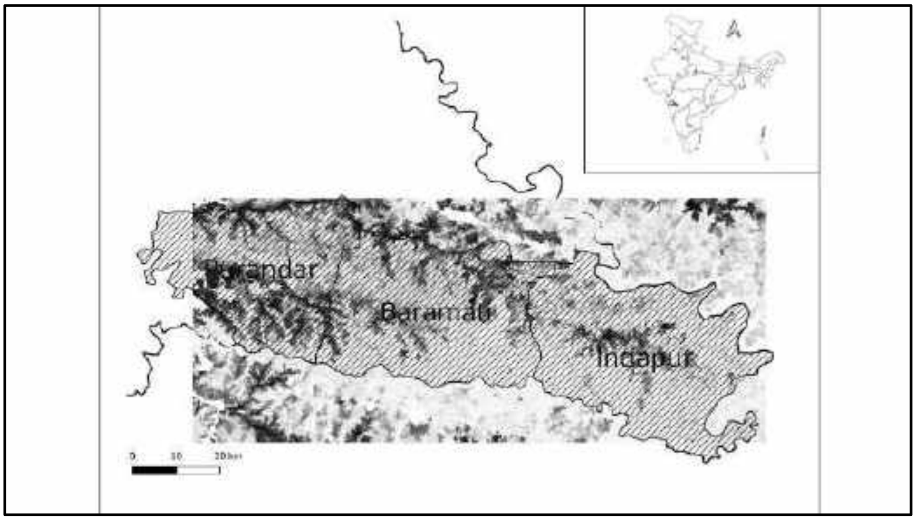
Land use diversion in ONEs, especially towards year-round agrarian production, is a well-known phenomenon. About 14.8 million ha of grasslands and shrublands have been converted to croplands in the 20th century and this conversion was especially faster post-1960s (Tian et al. 2014). Currently, ONEs are extremely fragmented, so much so that 94% of ONE patches are now only between 1-100 hectares (Madhusudan & Vanak 2022). With these high levels of fragmentation in ONEs, livestock management systems and associated institutions regulating access have further gone to the margins. Additionally, since India is not a typical extensive rangeland system (i.e. with low human population densities, dry climate & low ease of farming), livestock production systems are viewed as only supplementing agrarian livelihoods. However, at least 13 million pastoralists practice specialized forms of livestock keeping dependent on some level of mobility (Kishore & Kohler-Röllefson 2020). Hence, it becomes imperative to understand the nature of dependence and seasonal use of lands for pastoralism from the perspective of pastoralists' response to the fragmentation of ONEs.

Research on land use and pastoralist mobility from other parts of the world has shown that fragmentation causes disenfranchisement. Burnsilver et al. in Galvin et al. 2008 record how the Maasai in the Amboseli landscape, due to land fragmentation were pushed to opt for intensification of husbandry practices in smaller areas that included rearing poorly adapted hybrid cattle in arid regions. Groups of pastoralists like the Samburu, Turkana, Fulani, and Sahelian pastoralists have all been affected by some form of fragmentation (Galvin et al. 2008) bringing about changes in the way they move in the landscape and their socio-economic conditions. Butt 2014 describes a case of functional fragmentation where the creation of parks for wildlife conservation has affected how the Maasai move. He shows how new land tenure arrangements because of conservation parks has 'co-produced' the phenomenon of 'cattle incursions'. Another important form of functional fragmentation, albeit not from an arid or semi-arid savanna is the case of the Gaddi pastoralists in Himachal Pradesh. Ramprasad et al. 2020 note how afforestation activities, along with changing plant species composition, has threatened pastoral livelihoods by reducing fodder availability and forcing a change in migratory routes. However, contrary to the literature on disenfranchisement, there is also growing evidence from Africa which shows that commonages which were fragmented are also being brought back under management for pastoralism through both top-down and bottom-up tenurial arrangements (Bollig & Lesorogol 2016). However, India remains a blindspot in understanding responses of pastoralists to fragmentation.

Methods

Study site

We chose to work in the Pune district of western Maharashtra because of the presence of a considerable pastoralist population and fragmented ONEs. We specifically focused on pastoralist villages in four talukas - Purandar, Daund, Baramati & Indapur (Map 1; QGIS 3.34.13). The land cover in these 4 tehsils is a mix of ONEs (grasslands, rocky habitats, inselbergs, and scrub vegetation), irrigated and dry-land agriculture, industrial/urban areas, and rural settlements. Concerning land tenure, the ONEs in the study area are largely uncultivated private lands, followed by those managed by the Forest Department and as village commons. The region receives an annual rainfall of between 800-1200 mm.



Map 1: The above map shows the location of the study area in India. Darker the color, higher the possibility of that pixel being an ONE.

Data collection

We tracked livestock movement in different land uses of the study area for 69 days in the monsoon of 2022 and 40 days in the summer of 2023 (a total of 109 days) to understand seasonal movement patterns. We used handheld GPS devices and low-cost custom-made GPS trackers to map livestock movement where we recorded time spent in each land use by the herd (Butt et al. 2010, Wade et al. 2024). In these walk-along movement tracking surveys, we used non-participant observations of pre-herding, post-herding, and herding activities of 74 pastoralist households (both women and men) to understand movement-related decision making. We used semi-structured interviews to collect data on household socio-economic characteristics to understand dependence on pastoralism and test for relationships with movement patterns (Salamula et al. 2017; Jones et al. 2022).

Analysis

For the movement data, we used the spatial points downloaded from the GPS devices, to perform a use vs. availability analysis on land cover. Land cover information was extracted from the Dynamic World V1 10 m resolution raster available on Google Earth Engine (Brown et al. 2022). From this, we inferred whether pastoralists selected for specific land covers seasonally based on what was available for them. Since pastoralists could move, we considered the 'available' land cover as those in all 3 administrative units of our study area. We then used simple linear regressions to test for relationships between household socio-economic characteristics and movement patterns (Rstudio 2023.06.2). Lastly, using axial and open coding (Corbin & Strauss 1990), we analysed notes from our field observations on decision-making around movement and living experiences of herding livestock in ONEs and agricultural landscapes.

Results

We collected data of 75 households from 26 pastoralist settlements, out of which 70 households belonged to the Dhangar group of pastoralists and 5 were from other groups. Because we focused on herding activities, there was a gender and age bias within our pool of respondents since this demographic tended to herd livestock more often than others. Out of 75 households we interviewed or observed activities of, 64 were that of pastoralist men, 46% of whom were within 21-40 years of age. For the rest of the 10 households, 5 were women herders and 6 were pairs of men & women from the same household who were herding together.

Neither daily distance traveled seasonally nor annual migration patterns were dependent on herd sizes kept by a household (Adjusted R^2=0.006, effect size =-0.008(SE=0.006); Adjusted R^2=0.094, effect size

=0.004(SE=0.001)). However, herd sizes were strongly predicted by the number of people in the household who were engaged full-time in pastoralism and agricultural activities (Adjusted R^2=0.443; Figure 1). More specifically, with every additional member in pastoralism, 32 additional livestock heads could be reared on an average while with every additional member in farming, the herd size was reduced by 14 heads on an average.

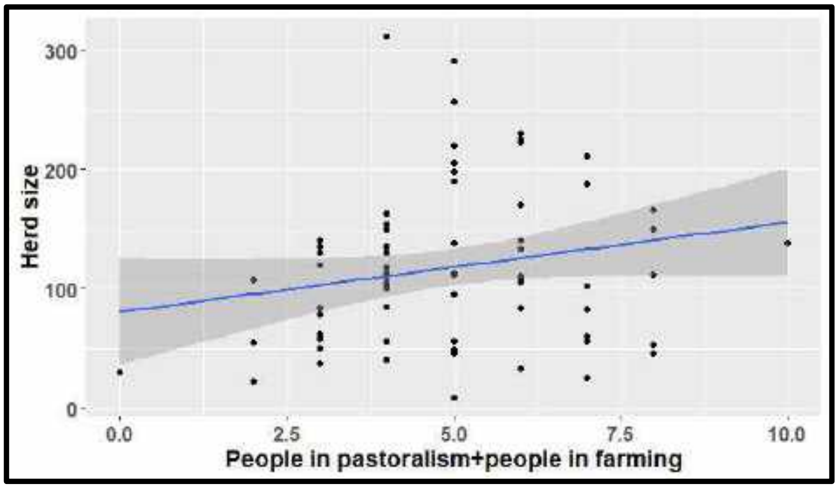


Figure 1: A linear model showing the relationship between the number of people in the household who were engaged full time in pastoralism and farming and the herd size kept by the household.

Fine-scale livestock movement patterns, when looked at from a use vs. availability analysis, show that pastoralist dependence on land covers like grass & scrub (which form ONEs) is highest in the monsoon (the frequency of their use is 2.5 times higher than their availability; Figure 2). Additionally, pastoralist households travel less in the monsoon compared to dry seasons (~ 7 km lesser on an average).

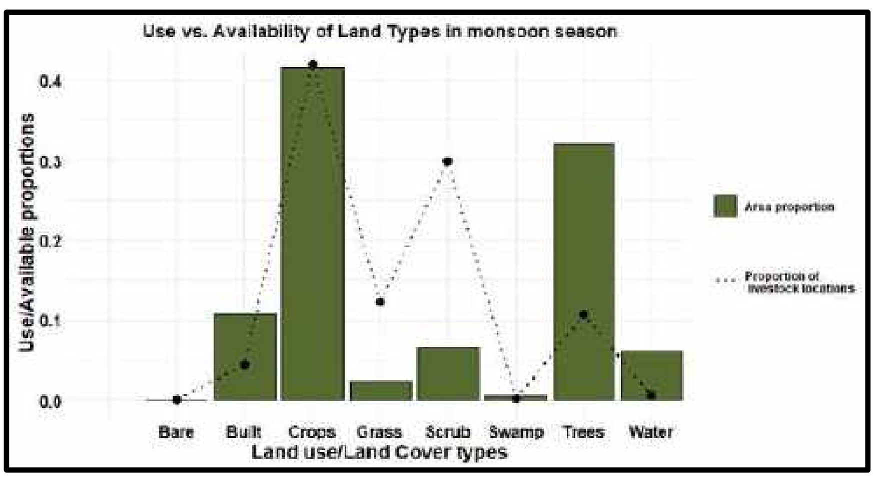

Figure 2: The bars in the above graph indicate the proportion of available land covers while the dotted lines indicate the proportion of spatial points that fell in that land cover in the monsoon season.

More than 80% of the households accessed only private fallow lands during both seasons (Figure 3).

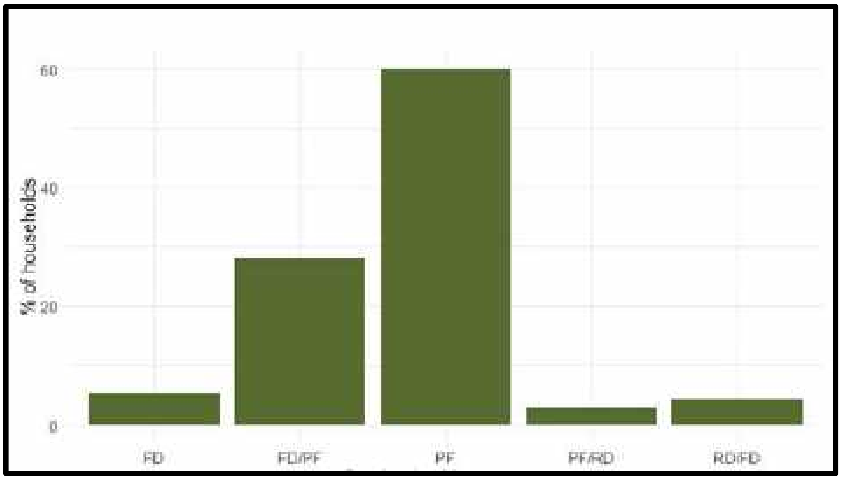

Figure 3: The bars in the above graph indicate the proportion of daily tracks in different land tenures. (FD=reserve forests, PF=private fallows, RD=Revenue department lands)

The presence of irrigation and farmer decisions determined the accessibility of lands for pastoralists. Households accessed fodder in both seasons based on interpersonal relations and social networks with farmers. Access to reserve forests was also based on informal understanding with the lower rungs of the forest bureaucracy, which often also resulted in conflicts. Because of the fragmented nature of village common lands, they were rarely sufficient for multiple pastoralist herds and thus, very few households relied on them consistently throughout a single season.

Discussion

Seasonal differences in daily distance traveled by pastoralists was expected because biomass needs are met more easily in the monsoon due to the proximity of ONEs. However, contrary to our understanding, we found poor evidence for the relationship between herd sizes and daily travel patterns as well as long distance migration patterns. Additionally, private fallow lands seemed overwhelmingly important for pastoralism in this landscape. We conclude that availability of household members and increasing social networks with farmers enabled pastoralists to navigate changing land use. This finding offers a different perspective from the more common understanding of pastoralist-farmer relations centered on conflict (Usman and Nichol, 2022; McGuirk & Nunn, 2024). We argue hence, that pastoralism needs to be viewed as a livelihood embedded in an agrarian landscape in this region of India. This is because dispersed household decisions in the landscape around the cultivation of land is determining land availability for pastoralists.

We also find that ONEs are extremely important for pastoralists in the monsoon. However, the process of 'commoning' or creation and strengthening of institutions managing commons is not adequate for livelihood security of pastoralists in this region (Bollig and Lesorogol, 2016). Instead, securing the agriculture-pastoralism nexus through institutions appears to be more beneficial for pastoralism.

Lastly, we provide evidence that ONEs in this region of India are supporting livestock production seasonally. However, land diversions in ONEs are assumed to have minimal impact on people and ecosystems. That is the reason that these lands are termed 'waste' (DoLR 2019) and demarcated for diversion. For eg. almost 60% of ONEs in Maharashtra are demarcated for potential afforestation (Madhusudan and Vanak 2022). Our findings help to develop a nuanced understanding of the nature of dependence of livestock- based livelihoods on ONEs in a rapidly modifying landscape.

Keywords: Fermentation quality; Identification; Isolates; lactic acid bacteria, sweet sorghum.

Abstract

The purpose of this study was to identify lactic acid bacteria (LAB) from elephant grass silage throughout the fermentation process and investigate their effect on improving quality of sweet sorghum silage. The isolates were identified based on morphological, physiological, and biochemical features, as well as 16S rRNA profiling. A total of 120 lactic acid bacteria were isolates from elephant silage seven strains were purified and idntified three strains (*Pediococcus acidilactici* (AZZ1), *Lactobacillus plantarum subsp. plantarum* (AZZ4), *L. plantarum subsp. argentoratensis* (AZZ7) and one commercial bacteria *L. plantarum, ecosyl* MTD/1(CB)) were chosen as additives at 6 log colony forming units per gram of fresh sweet sorghum grass in laboratory silos (1000 g). Silos for each treatment were opened after 30, 60, and 90 days. All isolates were Gram-positive, catalase-negative, and grew properly in 65% sodium chloride. The strains AZZ1, AZZ2, and AZZ5 were classified as the *Pediococcus genus*, while AZZ3, AZZ4, AZZ6, and AZZ7 were *Lactobacillus genus*. Compared to the control, all the isolates enhanced the silage quality of sweet sorghum silage, evidenced by significantly ($P < 005$) decreasing pH, ammonia-nitrogen contents, undesirable microbe counts, and greater lactic acid (LA) contents. During ensiling, AZZ4 performed better among all inoculants, indicated by significantly ($P < 005$) lowered pH and ammonia-N contents and increased LA contents. In conclusion, strain AZZ4 is recommended as starter culture for tropical and subtropical grasses.

Introduction

In recent years, the demand for dairy products has increased in many developing countries as well as the tropical and subtropical regions of Asia and Africa. However, the production of silage for dairy farming has been hindered in these regions because of ensiling process that is highly dependent on local environmental conditions (Sifeeldein et al., 2019). To produce high-quality silage consistently in these regions, acid-tolerant, thermophilic lactic acid bacteria (LAB) or homolactic acid fermented LAB must be identified and used as starter strains. (Sifeeldein et al., 2019). Because of the limitations of available technology, screening, selecting, and constructing starting cultures for silage production remains difficult, as is the classification of isolated strains. Closely related species, such as *Lactobacillus plantarum, Lactobacillus casei, Lactobacillus rhamnosus,* and *Lactobacillus pentosus*, which are the primary dominating strains in silage, are difficult or impossible to differentiate based on their phenotypes and genotypes (Duar et al., 2017).

In contrast, sorghum is one of the most suited plants for silage production and is becoming an increasingly significant feed crop in many regions of the world (Xie & Xu, 2019). Due to its high water soluble carbohydrates contents (WSC) and low buffer capacity, it is easy to ensile (Klevenhusen & Zebeli, 2021). It may also be an acceptable choice for silage production in marginal locations due to its high fodder output and drought tolerance. Inoculants have been proven to increase silage quality, as evidenced by lower pH and a greater number of lactic acid bacteria (LAB) (Guo et al., 2023).

Material and Methods

Sweet sorghum (*Sorghum bicolor)* grown at experimental field of Nanjing Agricultural University, Jiangsu, China. The grass was harvested at the mature stage.

Silage preparation

The chopped grasses were inoculated with three strains of LAB, *Pediococcus acidilactici* (AZZ1), *Lactobacillus plantarum subsp. plantarum* AZZ4, *L. plantarum subsp. argentoratensis* (AZZ7) and a commercial LAB *Lactobacillus Plantarum*, Ecosyl MTD/1 (CB) Ecosyl Product Inc. USA. LAB applied as additives at 6 colony forming units (cfu)/g calculated based on the fresh material weigh; Triplicate jars for each treatment were opened on days 30, 60, and 90 of ensiling.

Chemical analyses

The ammonia- N (NH_3-N) was determined according to the method of phenol-hypochlorite reaction. The pH of fresh grasses and silage were measured using a pH meter .Organic acids, including the lactic acid (LA), acetic acid (AA), propionic acid (PA) and butyric acid (BA) were analyzed by high-performance liquid chromatography according to the methods described by Mala et al.

Microbial population

A sub-sample (10 g) of wet silage from each sample was mixed with 90 mL of sterile saline solution (8.50g L^{-1}). Enumeration of LAB, aerobic bacteria, and yeast was performed using de Man, Rogosa, and Sharpe agar, nutritional agar, and potato dextrose agar, respectively. Finally, the total microbiological data were converted to log10 and presented on a fresh weight basis.

Results and Discussion

All isolates were identified as Gram-positive, catalase negative, rod-shaped bacteria. Compared to the control, all the isolates improved the silage quality of sweet sorghum silage, indicated by significantly (P < 005) lower pH and ammonia-nitrogen contents and undesirable microorganism counts, and higher lactic acid (LA) contents. During ensiling, AZZ4 performed better among all the inoculants, indicated by a significantly (P < 005) decreased pH and ammonia-N contents and a higher increase in LA contents.

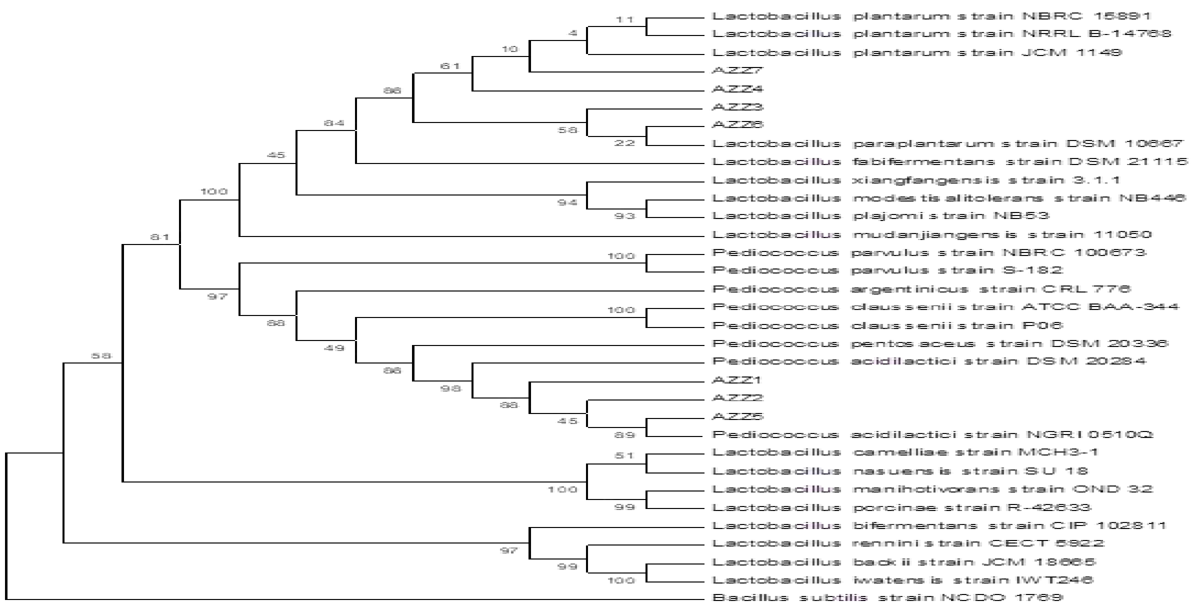

Figure 1 Phylogenetic tree of partial 16S rDNA sequences of isolated strains AZZ1, AZZ2, AZZ3, AZZ4, AZZ5, AZZ6 and AZZ7 isolate from elephant grass silage and sequences of identified bacteria in the nucleotide database of GenBank.

Effect of LAB on organic acids, pH and ammonia nitrogen of sweet sorghum silage

Effect of LAB on organic acids and ammonia nitrogen of sweet sorghum silage is shown in Fig 2. The addition of lactic acid bacteria isolates caused a higher level of LA, resulting in more decrease in pH and ammonia content than the control. The contents of acetic acid (AA) of all silages increased from 30 d to 60 days of ensiling, whereas the AA in the inoculated silages were lower (P<0.05) than the control. Propionic acid and butyric acid contents increased during ensiling and inoculated silage had lower PA and BA content than the control.

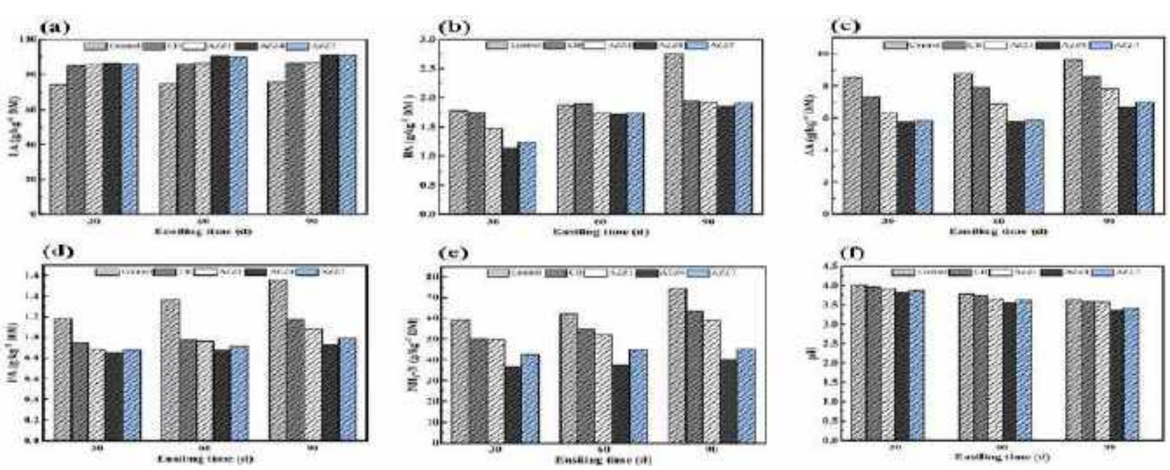

Figure 2. Effect of LAB on organic acids and ammonia nitrogen of sweet sorghum during fermentation period (a) LA: lactic acid, (b) AA: acetic acid, (c) PA: propionic acid, (d) BA: butyric acid. (e)NH_3-N: Ammonia nitrogen CB: Commercial bacteria.

Effect of lactic acid bacteria on microbiological compositions of sweet sorghum silage during ensiling

The effect of isolated strains on the microbiological compositions of the sweet sorghum silage after 30, 60 and 90d of ensiling shown in Figure 3. The population of microbial affected significantly ($P < 0.05$) by LAB addition

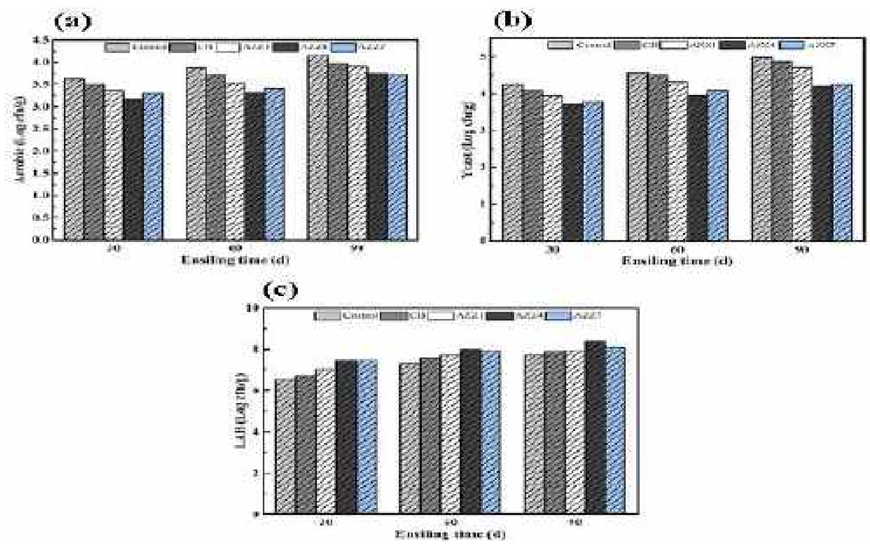

Figure 3. Effect of LAB on microbial composition of sweet sorghum silage during fermentation period, (a) LAB counts, (b) Aerobic bacteria counts, (c) Yeast counts of sweet sorghum silage. CB: Commercial bacteria, AZZ5: *Pediococcus acidilactici*, AZZ4: *Lactobacillus plantarum subsp. Plantarum*

Conclusions

In this experiment, the addition of AZZ1, AZZ4 and AZZ7 as inoculants significantly ($P < 005$) reduced the pH of the sweet sorghum silages and improved silage quality. Inoculants were efficient in improving fermentation quality, reducing NH_3-N as well as dry matter losses of sweet sorghum silage.

Camel herder perceptions towards rangeland utilization at semi-arid areas in the Sudan

Mansoor, A[1]; Fadalla, B[2]; Abdelkreim, M[2]

[1] University of Zalingei, College of Forestry Science, Department of Range Science, Zalingei - Sudan

[2]Sudan University of Science and Technology, College of Forestry and Range Science, Department of Range Science, Khartoum – Sudan

Keywords: Camel Herders, Livestock Production System, Rangeland Utilization.

Abstract

A study was conducted in a semi-arid area in North Darfur State, Sudan, to investigate camel herders' perceptions on rangeland utilization and the main factors affecting pastoralists and pasture. Fifty individuals were interviewed using a structured questionnaire. Herders, who were either nomadic, transhumant, or sedentary, were selected randomly for interviews at home or at markets. Those who declined to cooperate were replaced. Data were analyzed using SPSS, with a T-test estimating differences between means. The results indicated that 86% of respondents were males aged 21-60 years, with 80% not attending secondary school. The study revealed that 46% of interviewees were transhumant, 46% nomads, and 8% sedentary. Sources of income were livestock (84%), agriculture (14%), and trade (2%). Animals raised were camels, sheep, cattle, and goats, using rangeland primarily during the rainy season. Camels were offered sodium chloride in the wet season at 0.45 kg three times a week and sodium bicarbonate in the dry season at 0.23 kg once a week. Sheep received 0.11 kg of sodium chloride twice a week and 0.11 kg of sodium bicarbonate once a week. Cattle were given 0.23 kg of sodium chloride three times a week and 0.23 kg of sodium bicarbonate once a week. Goats were offered 0.11 kg of sodium chloride daily. Some 92% of respondents recognized threats to rangelands namely decreased rainfall (44%), overgrazing (34%) and desert creep, and soil erosion (14%) while 8% perceived no problem. About 90% of respondents blamed nomads for damaging grazing through seasonal fires and early grazing. Shifting cultivation and climate change were also reported. Some 75% of respondents market animals when 1-3 years old increasing pressure on the range. Appropriate management of the range requires reseeding, organizing seasonal movements of pastoralist groups, and enforcing laws.

Introduction

Sudan camel herd is estimated at about 4.9 million. and play an important role in the livelihoods of pastoralists in arid and semi-arid areas of Sudan (Ali et al., 2017). Camels in the Darfur region are commonly raised under nomadic conditions. The annual migrations of nomads vary from year to year to exploit the seasonally abundant forage depending on the amount of rainfall (Abu Sin 1990). Pastoralists have invaluable Indigenous knowledge regarding the environmental changes and vegetation characteristics reflected in how they manage rangeland (Abdalla and Samat 2012). Camel pastoralists in Sudan rely on camels for food, transportation, earning cash, entertainment, and tent manufacturing. Water scarcity in these areas adversely impact camel rearing forcing them to travel for long distances to feed on the sparse desert shrubs. Long-distance walking leads to emaciation, skinniness, and reduced meat and milk production. Camels are classified as browser-grazer species. Arid and semi-arid zones are characterized by limited amounts and scant distribution of trees and shrubs which are shared with other browser animals in the range such as goats and deer (Mansoor et al. 2016). This study investigates the perceptions of pastoralists on rangeland utilization and the main factors affecting pastoralists and pastures in the study area.

Materials and methods

Data collection: A structured questionnaire which contained closed and open-ended questions was developed to enlist the responses of camel herders on their perceptions on range management and vegetation characteristics. fifty questionnaires were distributed to multiple subjects of the study sample in different localities. Because the nomads were mostly lower education level and illiterate, they were directly interviewed and all questionnaires were filled perfectly (recovery rate of 100%). The data were analyzed using (SPSS.20). A t-test was used to estimate the significance of differences between means**.**

Results and discussion

1. Personal characteristics: All herder respondents in this study were males because the management of camels needed protection and care and that entails roaming to far places, so it is a task assumed by male members of a household. The results in Table 1 indicated that 86% of the respondents were in the age range of 21-40 and 41-60 years. Differences in age groups involved in camel rearing are highly significant (P<0.000). Thus, camel rearing absorbs the most active individuals in the community since it is a tedious job. Therefore, men less than 20 or more than 60 years of age are rarely associated with camel rearing. Highly significant differences (P<0.000) in the education level of pastoralists were also found (Table 2). About 60% of interviewees had education at the Khalwa (Religious school) and primary school level, 30% had intermediate and secondary school education, 4% had a university education and 6% were illiterate. with this result in mind, perhaps it is difficult to apply pastoral extension systems because the Awareness level is an important factor concerning extension activities required to promote technologies that can contribute to improving the livelihoods of camel producers.

Table (1) Distribution of respondents according to age groups (Years)

Age group	Number	Percent
Less than 20	5	10
21– 40	23	46
41 – 60	20	40
More than 60	2	4
Total	50	100
DF	---	2.3

Primary	13	26
Intermediate	7	14
Secondary	8	16
University	2	4
Total	50	100
DF	---	3
Sig	---	***

***Significant at 0.000 level

2. Pattern of utilization of pasture

The results indicated that 92% of the respondents belong to transhumant and nomadic systems while only 8% are sedentary. This agrees with (Abu sin, 1990) whose findings show that camels are commonly rose under a nomadic system in the study area (Darfur region). According to interviewees, the range in previous years was better than nowadays due to the better quality of plant species (42%) and an abundance of plant species (34%). In addition to the limited agricultural areas, small numbers of livestock, and insignificant harmful activities such as tree felling were reported by 12%, 8%, and 4% respectively as reasons for poorer range nowadays. Since camel herders almost completely depend on grazing as their main source of livelihood, rangeland quality is an important factor to consider. Tilahun et al. (2016) found that the traditional pastoral systems are environment-friendly compared to interventions to improve rangeland which, in turn, puts the range under severe pressure.

3. Main types of animals raised by pastoralists

A large number of pastoralists keep sheep and camels and only a few also raise goats and cattle as shown in Figure 1. Moreover, all respondents sold some of their animals to obtain money. Animals sold were mostly males between the age of 1-2 years as reported by 54% of respondents. Moreover, only 14% of respondents stated that they sell animals before they are one year old, while 20% sell at the age of 2-3 years and 12% at more than 3 years of age. This is an area for extension to convince pastoralists to sell animals at an earlier age as this reduces pressure on the range and avails markets with more tender meat.

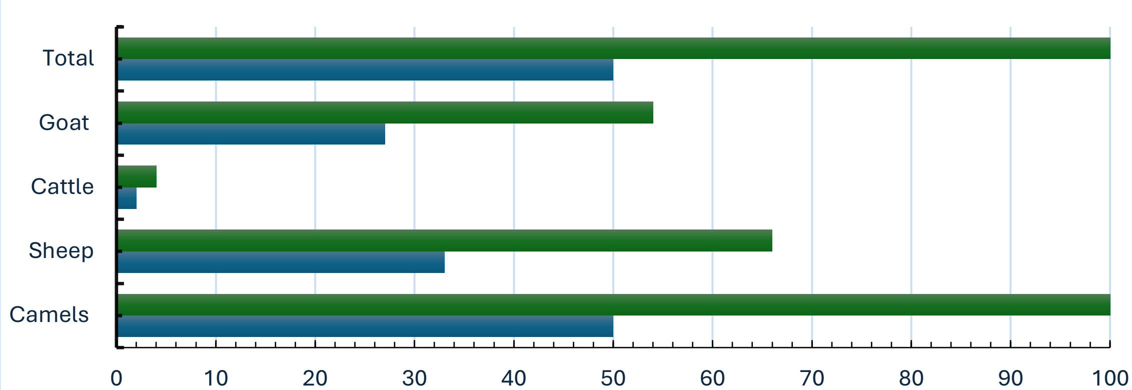

Fig 1.The Main Type of Animal Raising by Respondent in Study area

4. Common problems related to the use of pasture.

According to 92% of the respondents, there was deterioration in the pasture due to various reasons mainly a decrease in rainfall (44%), overgrazing 34% and desert creep and soil erosion (14%). Only 8% of respondents reported that there was no deterioration in the range. These results are in line with several studies that determined the factors causing rangeland deterioration. Amole et al. (2022) reported that the limited availability of forage in terms of quality and quantity in sub-Saharan Africa represented the main factor affecting livestock productivity, often rangeland deterioration is caused by the causes mentioned previously, in a study conducted by (Fenetahun & Yong-dong, 2018) which reported that absence of grazing management, extensive removing the plants for fuel wood, and unclear ownership authority of the rangeland, affect plant abundance, biomass productivity.

Conclusion

Camel herders possess considerable indigenous knowledge of their pastoral systems and they are good range managers. Besides its contribution in rangeland degradation, there are some advantages to the nomadic system such as providing higher quality forage through the seasonal movement and allowing rest periods for the plants to complete their growth cycle. However, the nomadic lifestyle has undesirable effects on pastoralists' education as seen in their education levels.

The Paddock Challenge: comparing business as usual with recommended stocking rates

Materne, C[1]; Taber, L[1]; Kain, A[1]; Anderson, G[1]; Cowley, R[2]; Wirf, B[2], d'Abbadie, C[3]

[1] Northern Territory Department of Agriculture and Fisheries, Alice Springs; [2] Northern Territory Department of Agriculture and Fisheries, Darwin; [3] Western Australia Department of Primary Industries and Regional Development

Key words: stocking rate; carrying capacity; rangeland management; research adoption

Abstract

Cattle producers love a challenge. Will getting their stocking rates right provide production stability and allow for land condition improvement on a commercial property in Central Australia? The Paddock Challenge is a component of the Rain Ready Rangelands Project funded by the Australian Government Future Drought Fund, with the philosophy that learning through doing is the key to adoption. It aims to work with commercial producers to adopt, demonstrate and test the learnings from the Quality Graze project under their unique circumstances, and to use data to drive stocking rate and development decisions. Two pastoral stations, 400km southwest and 300km northwest of Alice Springs, Australia (Fig. 1), are collaborating with the Northern Territory Department of Agriculture and Fisheries to test the Quality Graze recommendations and compare their grazing management to a 'Challenge' paddock where a strategy adapted from Quality Graze is being applied. Comparisons and benchmarking are at the whole paddock or water-point scale, depending on station infrastructure. The first year of the challenge involved working with producers to explore their current management, collecting baseline data on pastures, animal performance, landscape use, nutrition, and health. Station data were used to inform bioeconomic modelling of the economic impacts of different stocking and management strategies. The project collaborated with producers to develop strategies aimed at enhancing the rain responsiveness of their landscapes, thereby reducing the impact of climate variability on land condition and animal production and build the climate resilience of their businesses.

Introduction

The north Australian beef cattle industry has historically been slow to adopt new research and tools (Bell and Sangster 2023). With a "learning-by-doing" and "seeing-is-believing" philosophies mind set, and with producers and researchers learning together and from each other, the Paddock Challenge project was developed as a platform for the commercial adoption of the stocking rate management recommendations from the Quality Graze project at Old Man Plains Research Station (OMP) located near Alice Springs, Australia. The Quality Graze project, a long-term grazing trial on OMP, has shown that applying stocking rates based on the long-term carrying capacity (LTCC) led to land condition improvement while producing consistently high animal performance and production stability (Materne *et al.* 2021). Furthermore, improvements in land condition increased the carrying capacity of the station.

Paddock Challenge aimed to help the participating producers develop and adopt alternatives to their existing grazing strategies that would maintain or enhance land condition while improving herd performance and business profitability. It involved exploring factors linking stocking rate, pasture utilisation, individual animal performance, total production, and profitability.

The stations' motivation for involvement was to build business resilience and stability, with the challenges of the recent dry period between 2018 and 2020 still fresh in their minds. While they can't prevent such events, the properties involved aimed to be better equipped to manage them and strengthen their operations.

Methods

The Paddock Challenge involved two properties (Mulga Park and Mt Denison) each providing two paddocks for comparing baseline pasture condition, and production and herd performance against an alternative grazing strategy developed during the project. The "**Business-as-usual**" paddock was unmodified and represented standard station practices; while the "**Challenge**" paddock was stocked based on a recommended strategy using LTCC, informed by GRASP modelling (McKeon et al. 1990), forage budgeting, and seasonal analysis, and adjusted collaboratively by producers and researchers.

Figure 1. Location of the Paddock Challenge stations and Old Man Plains Research Station (OMP)

Pasture and herd performance were monitored using a BACI design (before, after, control, impact) with spatial gradient analyses (distance-to-water as a proxy for stocking intensity). Representative pasture monitoring sites were strategically located along a transect with distance (500m, 1km, 2km, 4km and 6km) from a watering point in each paddock. Quantitative (quadrat based-BOTANAL (Tothill et al. 1992) and drone footage) and subjective (visual point-based assessment/photo point) data was gathered from each site on pasture yield and species composition, ground cover, grass basal area, defoliation, cattle activity and biocrust samples. Paddock pasture growth and utilisation were modelled following Cowley and Walsh (2023). Animal equivalents (AE) were calculated from paddock stock records and animal performance where possible (McLean and Blakeley 2014, McLennan et al. 2020). Watered area was determined using site infrastructure data, including natural and semi-permanent sources.

Pasture utilisation was modelled assuming cattle spent all their time within a 4 km radius of waters to identify potential stocking rate effects on herd performance and grazing distribution. Diet quality was assessed monthly via NIRS analysis of dung samples. Animal health monitoring focused on five common production diseases to identify discrepancies in performance. Cattle landscape use was tracked with Global Navigation Satellite System (GNSS) collars.

Baseline pasture data informed the pasture modelling for LTCC estimates while baseline individual animal performance data identified non-performing animals to inform the culling program to improve herd efficiency and match stock numbers to the LTCC.

Economic analysis, following the methodology of Holmes et al. (2017), assessed each property production system. Baseline data and animal performance were reviewed, and tailored scenarios were explored with station owners. Comparisons included results from the Quality Graze trials at OMP. Economic modelling and the stations' baseline data were used to model the financial impact of adopting change, and to provide options to navigate the transition to the new grazing system. The central modelling question was: Can we get more (land condition improvement, animal performance, kilograms of beef, profit) from less (fewer cattle)?

Results

Both stations have highlighted the value of data collection and benchmarking of their herds and business performance. Data collection enabled a snapshot of where their business currently stands and the gaps in which they can invest their efforts for the greatest return. The importance of robust, high-quality data cannot be overstated. Reliable data are the foundation for building accurate models, generating meaningful insights, and delivering outcomes that truly reflect the complexities of the systems we study.

Mulga Park plans to collect and collate additional past and present data, making it easily accessible through farm management software, to support management decisions. These include planning and matching stocking rates to LTCC to prepare for inevitable dry periods, implementing a structured weaner and heifer management program, developing targeted work plans to create a more efficient herd, and investigating strategies for managing water points with high fluoride levels.

Mt Denison is interested in adapting their stock numbers to improve herd performance and develop resilience to climate variability. They anticipate building a more efficient herd through genetics allowed by infrastructure developments, identifying indicator grass species for land condition, and continuing with some components of the project data collection such as weights and pregnancy testing.

Discussion

The Paddock Challenge project aimed to collect a variety of on-station data to identify the effect of stocking rate on land condition and herd performance, and ultimately better understand the logistic and economic complexity of adopting science based grazing land management recommendations.

Economic modelling provided the producers with a pathway to adopt new management and the benefits forward and highlighted the long-term production and financial benefits of matching stocking rates to LTCC.

Figure 2. "Paddock Walk" with producer group

Figure 3. Development of a 10-year plan

Establishing trust through long-term engagement is crucial when working with pastoralists. By presenting them with ideas and tangible results they can observe and relate to, we fostered an environment where new concepts were more readily understood and adopted. Two-way communication facilitated knowledge transfer between producers and researchers and was critical in the development of the strategy trialled in the Challenge paddock and developing plans for the next decade (Fig. 3). This subsequently encourages the uptake of recommended changes.

Continual re-enforcement of animal nutritional needs and its relation to pasture utilisation and the safe LTCC through the participants attending various courses and events helped them to gain an understanding of the science behind the 'Paddock Challenge'. This knowledge along with the baseline data collection highlighted the importance of good land condition and how the utilisation rate of these pastures through stocking rate management can improve herd performance and business stability and profitability in an extremely variable climate.

Results were extended to the wider industry through "Paddock Walks" (Fig. 2) that provide a group learning platform that was made up of personally invited neighbouring producers. Although one-on-one extension activities are resource-demanding, the findings from the Paddock Challenge are transferable to the wider industry. The benefits to the industry include an improved understanding of LTCC and safe utilisation rates of various land types, potential animal performance and landscape use, as well as enhanced and tested carrying capacity methodology. There is also a better understanding of the link between utilisation and animal performance. Additionally, the findings provide insights into other factors that affect individual animal performance, such as water quality, production diseases, and seasonal dietary needs that require supplementation.

Conclusion

Sustainable stocking rate is not necessarily about reducing total production, but about reducing the number of animals to get the same or more production from fewer animals. Economic modelling reinforced this concept and helped allay pastoralists' concerns that reducing animal numbers would reduce profit. Establishing trust through long-term engagement is crucial when working with pastoralists. By presenting them with ideas and tangible results they can observe and relate to, we foster an environment where new concepts are more readily understood and adopted.

Change is not easy, nor the ability to implement infrastructure change, particularly with the perceived business risks and worries about reduced herd production from reduced stock numbers. The difficulty in implementing and adopting science-based recommendations on a commercial property proved challenging and faced significant unforeseen challenges such as extensive wildfires that required flexibility. However, the Paddock Challenge project highlighted the advantages of 'learning-by-doing', which will ultimately lead to adoption. Change in station management and the adoption of a new grazing strategy requires a holistic approach that encompasses the entire station's LTCC, infrastructure, production system and business circumstances.

Acknowledgements

This work was funded as part of the Rain Ready Rangelands project by the Future Drought Fund Resilient Soils and Landscapes. Thanks to the producers on stations for their support.

Cattle performance does not differ between patch and broadcast burning

Moffet, CA[1]; Gunter, SA[2]

[1] USDA-ARS, Oklahoma and Central Plains Agricultural Research Center, Woodward, Oklahoma, USA; [2] USDA-ARS, Oklahoma and Central Plains Agricultural Research Center, El Reno, Oklahoma, USA

Key words: Prescribed fire; grazing; animal performance; long-term study

Abstract

Over the past few decades, patch burning has become a recommended practice in the Southern Plains of the USA rather than burning an entire pasture at one time. Patch burn plans follow a burn sequence where several patches with different times-since-last-burn occur within the pastures, whereas for the broadcast burn plans entire pastures are burned at one time every several years so that each year the time-since-last burned is uniform across the pastures. The objective of our study was to determine whether animal performance, per hectare or per head, differed between the two treatments. In our long-term experiment, in three replicate blocks, the blocks were divided into two pastures that were randomly assigned the patch-burn treatment, where ¼ of the pasture was burned in a 4-yr rotation, or the broadcast burn treatment, where the entire pasture was burned every 4 years. The pastures were grazed each year with weaned growing cattle (BW = 242±16 kg) to harvest a targeted 25% of the expected annual forage production over an approximately 180 d period (45% of the use was in the dormant, DS, and 55% of the use was in the growing season, GS). Cattle received a range cube protein supplement during the dormant season. The annual gains per hectare were 60.0 kg/ha for both the broadcast and patch burn treatments. The effect of grazing season on gain per hectare and average daily gain was significant with GS gain of 49.4 kg/ha and DS gain of 10.6 kg/ha. Average daily gains were more than three times greater in the GS (0.78 kg/d) than in the DS (0.21 kg/d). These data show that whatever benefits exist for patch burning over broadcast burning, animal performance cannot be counted among them, nor can animal performance be used to justify one over the other.

Introduction

Fire is an important part of the disturbance regime in the Great Plains of North America that helped to maintain the grassland and to suppress woody plant encroachment (Anderson et al. 1970; Limb et al. 2011; Wright and Bailey 1982). Patch burning has been proposed as conservation-based management that gets fire back on the landscape (Limb et al. 2011). One feature of patch burning is that the most recently burned patch is more highly selected than other patches with longer times-since-last-burn and utilization rates are greater in the newest burn patch than others (Scasta et al. 2015). When the pasture is moderately stocked, but the most recently burned patch can only supply a fraction of the grazing animals forage demand, then utilization of the recently burned patch is uniformly heavy and use is light in other areas. In years when production is limited, the use can increase in otherwise lightly used patches and these patches serve as a forage buffer. In subsequent years, standing dead material accumulates within the pasture and forage quality declines. If patch burning is stopped for a period of years, grazing may need to be adjusted to allow the most recently burned patch to recover from heavy use within the growing season as occurs when a new patch is burned. The continual rotation of burned patches within a pasture increases the uniformity of use on the cycle time scale, but increases heterogeneity on the annual time scale. In broadcast burn pastures that are moderately stocked, the forage is all high quality, but grazing use is only moderate and soon plants that don't get grazed early in the grazing period will become less desirable and animals may begin repeat grazing some plants and avoiding other plants or even grazing sites. The uniformity of grazing use in these broadcast burn pastures, on time scales from grazing season to fire return interval, is less than for the recently burned patches. The annual provisioning of high-quality forage that occurs in the patch burn pastures each year could contribute to better animal performance. The objective of this study was to determine whether animal performance, in terms of average daily gain or gain per hectare, differs between patch and broadcast burn treatments.

Methods

The site of this long-term burning and grazing study was the Southern Plains Range Research Station in Woodward, Oklahoma, USA. The site is located near the boundary between the Cfa Koppen-Geiger climatic zone (temperate, without a dry season, and hot summers) and Bsk zone (arid, steppe, and cold; Peel et al., 2007). The experiment was set up as a randomized complete block design with 3 blocks of two pastures. The pastures ranged in size from 6.1 to 16.1 ha. Within each block, pastures were randomly assigned to one of the two burn treatments, broadcast burning or patch burning. The broadcast burn treatment involved burning the entire pasture every 4th year and the patch burn treatment involved dividing the pasture into 4 patches and burning 1 patch each year in a 4-yr rotation. For both treatments, the prescribed burns were conducted in late winter or early spring. The pastures were grazed with growing steers for a period of 83 to 97 d in the growing season (mid April to mid July) and another 83 to 91 d in the dormant season (late November to late February). Cattle were received 45 to 35 d prior to the beginning each grazing period and weighed. The cattle were stratified by receiving weight and each strata was proportionately represented in each experimental unit. The target initial weight for the growing season steers was 227 kg and for the dormant season steers it was 249 kg. Stocking rates were adjusted based on the expected annual forage production and pasture size to achieve a target forage harvest for the year of 25% with 55% of the target harvested in the growing season and the remaining 45% harvested in the dormant season. Cattle received a protein supplement during the dormant season grazing 3 days each week to meet their protein requirement.

Forage production each year was estimated by clipping quadrats in the fall from inside exclosures that had been established the winter before. In each patch of the patch-burn pastures and quarter of the broadcast-burn pastures, 8 exclosures (~ 1m in diameter) were established and the standing dead material was removed by cutting with a string trimmer to approximately 3-cm stubble height unless the patch or pasture was burned. In the fall when the plants were mostly senesced a quadrat (0.5 m^2 square) was centred in the exclosure, clipped to a 3-cm stubble height, the standing crop was placed in labelled paper bags, and taken to the laboratory to be dried in an oven and weighed.

Results

The effect of grazing season on average daily gain (ADG) interacted with forage year ($p < 0.001$). The advantage in ADG cattle had during the growing season ranged between 0.379 kg/d more (2018) and 0.831 kg/d more (2023). Averaging across forage years, the ADG for steers was more than three times greater during the growing season (0.78 kg/d, SE = 0.020 kg/d) than during the dormant season (0.21 kg/d, SE = 0.020 kg/d, $p < 0.001$). Burn treatment had no significant effect on ADG ($p = 0.5325$) irrespective of the grazing season, forage year, or both (p = 0.7679, 0.6222, or 0.5684, respectively, Fig. 1).

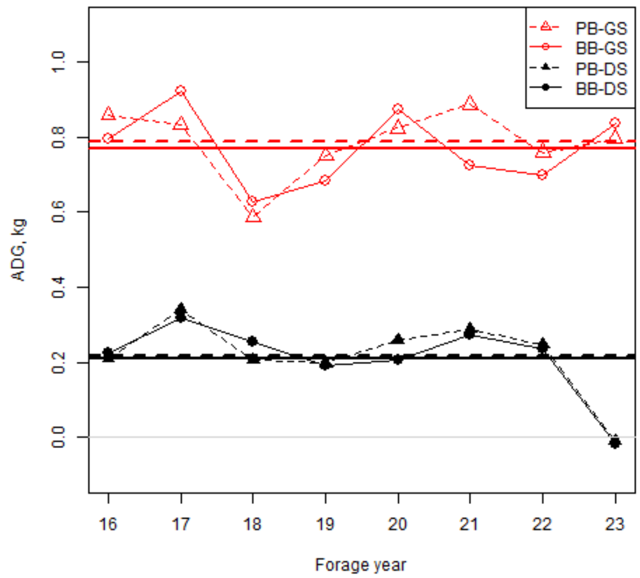

Fig. 1. Average daily gain of steers in each forage year, grazing season, and burn treatment.

Converting individual animal performance to performance per unit area for each grazing season and treatment, the significant grazing season effect on ADG translated to a significant grazing season effect on gain ($p < 0.001$) with an average growing season gain of 49.4 kg/ha (SE = 1.69 kg/ha) and dormant season gains of 10.6 kg/ha (SE = 1.69 kg/ha), irrespective of burn treatment (the p value for the season by treatment interaction was 0.8511). There was also no significant main effect of burn treatment on gain ($p = 0.9872$). Combining the two grazing season gains in each forage year and treating forage year as a fixed effect, the effect of forage year on annual gains was significant ($p < 0.001$, Fig. 2), but annual gains were not different between burn treatments ($p = 0.9853$) and burn treatment didn't interact with the effect of forage year ($p = 0.8646$). Annual gains in forage years 2017 and 2020 were each greater than in forage years 2018 and 2023 and no other forage year differences were significant. Treating forage year as a random effect, annual gains were not significantly different between the broadcast and patch burn treatments ($p = 0.9802$) and both averaged 60.0 kg/ha (SE = 2.74 kg/ha).

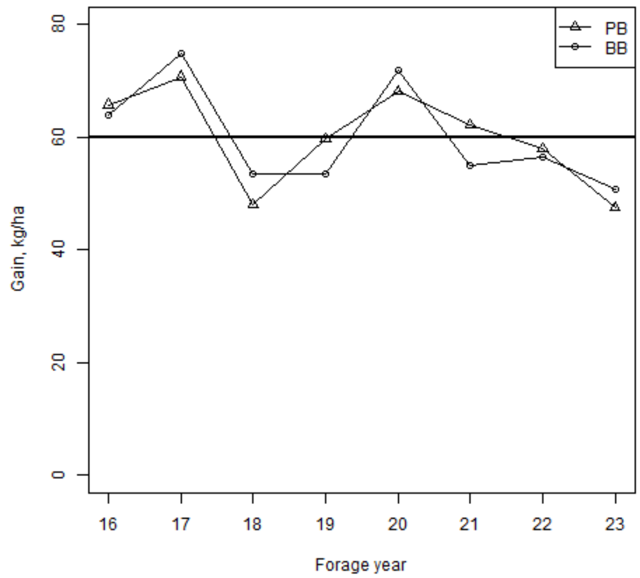

Fig. 2. Animal body weight gain (kg per hectare) for steers grazing each forage year in patch burn and broadcast burn treatments.

Conclusions

These data show that whatever benefits exist for patch burning over broadcast burning, animal performance cannot be counted among them, nor can animal performance be used to justify one over the other. Animal performance in this study varied by forage year and the season when grazing occurred, but the burn treatment was never significant and it never interacted with the other effects.

Acknowledgements

The use of animals in this experiment was reviewed by the Oklahoma and Central Plains Agricultural Research Center's Animal Care and Use Committee at Woodward and approved (AUP-002, AUP-016, and AUP-025).

Addressing the feed deficit of the semi-arid Taita Taveta County of Kenya

Mureithi, JG.; Mwabili, HN[2]

[1] Director, African Conservation Tillage Network, P.O Box 10375 - 00100, Nairobi, Kenya, mureithijg@gmail.com.

[2] Director of Livestock Production and Fisheries, Taita Taveta County, Kenya, P.O Box 1066 – 80304, Wundanyi, hmnyambu@gmail.com.

Key words: Animal source food; feed strategy; feed value chains

Abstract

Livestock production is a key economic sector in Taita Taveta County, and accounts for over 40% of agricultural earnings. The demand for animal source foods is on the rise due to increasing human population and the expanding middle class. The main livestock types kept include cattle, goats, sheep, camels, donkeys and poultry. The main feeds include roughages but climate change has adversely affected pasture and fodder production in cultivated and natural vegetation systems. According to a national feed inventory and feed balance assessment conducted in 2019, the County had a feed deficit of 23% based on livestock dry matter (DM) requirements. The deficit was further exacerbated to about 60% by a prolonged drought experienced in 2022. To promote growth of the county feed industry, a 10-year Animal Feed Strategy was developed. The strategy aimed at bridging the feed gap, and enhancing livestock numbers and livestock products by addressing challenges in the feed industry. The strategy also sought to ensure rangeland resources were managed sustainably as well as guided decisions in land use planning and investments. To meet the feed requirements by the tenth year of the strategy, USD $282.2 million was to be spent to produce 5.74 billion metric tonnes of DM feeds. The industry was to realize an annual net income of USD $133 million and create 6,000 jobs.

Introduction

The potential for livestock production in Taita Taveta County was high due to expansive rangelands covering 24% or approximately 4,100 km^2. Ranching was a major production system for beef cattle rearing. Red meat production was mainly from ruminant livestock reared under an extensive farming system while dairy cattle were reared in the hilly areas under small-holder farming systems. The estimated livestock population for 2022 and projected growth up to 2032 is shown in Table 1.

Table 1: County Livestock Statistics 2022 and Projected Growth up to 2032

Livestock		Year		
		2022	2027	2032
Dairy		32,587	34,761	37,080
Beef		149,905	191,321	244,179
Sheep		63,994	112,779	198,756

Source; Taita Taveta County Animal Feed Strategy, 2022 – 2032 (2023)

A County animal feed inventory and feed balance analysis in 2019 indicated an overall dry matter feed deficit of 23% and crude protein and metabolisable energy deficits of 42.9% and 50.6%, respectively. To address this deficit, the County developed a 10-year animal feed strategy (AFS) for the period 2022 to 2032.

Strategy development methodology
A County Livestock Technical Working Group (TWG) was formed mainly comprising of animal production and animal health technical personnel. The group was trained through a series of facilitated workshops by a team from Kenya's State Department of Livestock (SDL) in the process of developing the strategy, including data collection and writing. The SDL had formulated a standard framework for developing animal feed strategies. The data included, human population trends, per capita consumption of animal source foods, livestock types, feed requirements, potential feed resources, cost-benefit analysis of producing feeds and potential feed business cases / investment plans in the county.

Estimating demand for animal source foods based on County per capita consumption
The county's human population in 2022 was 360,000 and its projected growth for the strategy period was 385,800 by 2027 and 407,280 by 2032 (Kenya National Bureau of Statistics census, 2019). This growth was expected to increase demand for animal source foods based on the county annual per capita consumption (Table 2). The per capita consumption were based on the following estimates of annual consumption: milk 220L, beef 9 kg, mutton 2.4 kg, chevon 2 kg, chicken 12 kg, pork 0.8 kg and 180 eggs.

Table 2: Total estimated demand and supply of animal source foods in the County

Year	Milk (Million Litres)		Meat (Million Kg)		Eggs (Millions)	
	Estimated demand	Estimated supply	Estimated demand	Estimated supply	Estimated demand	Estimated supply
2022	79.2	21.5	9.4	0.99	64.8	61.3
2027	84.8	43.1	10.1	14.5	69.4	115.7
2032	89.6	86.4	10.6	16.5	73.3	122.2

To supply the required animal source foods (Table 2), the county livestock was to be fed with sufficient feed resources to meet their nutrients requirements. These feeds were to be grown in the county by entrepreneurs developing agribusinesses. The County government was to provide an enabling policy environment.

Animal Feed Resources
Priority feed resources/value chains for the county were identified in addition to the natural pastures that supplied the bulk of livestock feed (Table 3). They were selected based on their adaptability to the local conditions and potential to increase their yield.

Table 3: Production Estimates of Animal Feed Resources in 2020 and Projected Demand by 2032

Feed Resources	2020	2027	2032
	Metric tonnes	Metric tonnes	Metric tonnes
Energy Sources			
Hay	66,285	301,385	459,916.1
Fodder grasses	19,885	52,479	80,641
Maize grain	16,609	113,434	203,671
Sorghum	567.6	1,723.5	3,449.3
Protein sources			
Sunflower seed cake*	15,427.9	36,669.9	55,919.8
Legume fodder	9,279.90	10,495.8	14,233.6
Sweet potato vines	2,651.4	7,871.8	13,720.3
Groundnuts	456.0	1,332.4	2,629.4
Animal protein Sources			
Black Soldier Fly Larvae	190.7	516.2	804.4
Natural grazing			
Field-based feed resources**	1,915,839	2,841,696	4,622,221
Total	2,047,191.5	3,367,603.6	5,457,205.9

* 95% of the sunflower seed cake was imported from outside the county.

**Acreage for field-based feed was to remain constant over the period but productivity per unit was expected to increase as a result of improved management.

Source: Taita Taveta County Animal Feed Strategy, 2022 – 2032, 2023.

Investments Plans
These plans were based on the cost-benefit analysis of developing the feed value chains to meet county demands as shown in Table 4.

Implementation of the Strategy
Implementation of the strategy was to cost approximately US$282.44 million over a period of 10 years. A detailed implementation framework with clear stakeholder roles and responsibilities and a monitoring and evaluation framework, at all levels of implementation, was developed. The County Department of Agriculture, Livestock, Fisheries, and Irrigation was to lead the implementation in collaboration with other relevant agencies and stakeholders. Upon the full implementation of the strategy, the feed value chains were expected to generate a net income of US$133 million and create 6,165 salaried jobs.

Table 4: Feed Commodity Cost-Benefit Analysis and Value Proposition to Investors

Value chains	Input Analysis		Output Analysis		Job creation[1]
	Hectares	Metric Tonnes	Total cost (Million US$)	Annual Net Income (Million US$)	
Energy Sources					
Hay	137,836.7	459,916.1	85.38	17.08	793

Abstract
Grasslands offer a sustainable and cost-effective resource for livestock feed while supporting carbon sequestration, thereby mitigating climate change. However, current remote sensing methods for grassland monitoring have not adequately addressed adaptive grazing management at the fine scales required for intensive grazing systems. Grazing trials conducted under La Niña conditions, with recovery periods of 3, 6, 9, 12, and 15 months, aimed to advance regenerative grazing techniques in small plots (<1 hectare). Sentinel-2 imagery combined with random forest outperformed XGBoost in estimating biomass, achieving better regression statistics ($R^2 = 0.56$, RMSE = 1,532 kg DM/ha vs. $R^2 = 0.48$, RMSE = 1,726 kg DM/ha). The model effectively captured carbon stock variability across recovery periods, with the 3-month recovery exceeding 2,000 kg C/ha. This proof-of-concept study underscores the potential of high-resolution remote sensing to enhance precision agricultural management and promote climate-resilient farming practices

Introduction
Pasture biomass, a major natural carbon sink, plays a critical role in global carbon sequestration and mitigating greenhouse gas emissions (GHG) to meet Paris Agreement targets (Harrison et al., 2016). While remote sensing and machine learning have advanced sustainable grazing management, most studies focus on regional scales, limiting their applicability at field scales (Ali et al., 2016; Ogungbuyi et al., 2023a). Regenerative grazing practices, such as short, intensive grazing periods and multi-paddock systems, promote soil health by enhancing microbial activity and organic matter incorporation (Ogungbuyi et al., 2023b). However, field biomass measurement and soil organic carbon (SOC) assessment remain capital-intensive and labourious (Mondal et al., 2017).

This study is proposing Sentinel-2 imagery, with its high spatiotemporal resolution, and machine learning to estimate carbon stocks at the field scale. Destructive sampling, combined with carbon conversion factors and root-to-shoot ratios recommended by the IPCC, provides a direct means to quantify carbon stocks (Cienciala et al., 2006; Penman et al., 2003). Previous studies show that machine learning models, such as random forest and XGBoost, effectively handle smaller datasets and manage model complexity, enabling accurate biomass estimates (Morais et al., 2021). The main objective of study is to assess pasture biomass and carbon stock variability across paddock treatments under regenerative grazing systems.

Methods
The study was conducted in Triabunna, southeastern Tasmania (S 42° 30, E 147° 59), with annual rainfall of 648 mm and temperatures ranging from 7°C to 17°C. Fertile soils and a mix of sown and native pastures support intensive rotational grazing, aided by reliable winter rainfall.

Six 0.25-ha plots—Vault 1 (V1), Vault 2 (V2), Vault 3 (V3), Vault 4 (V4), Vault 5 (V5)—and a 10-ha Vault Control (VC) plot were stocked at a rate of 2000 DSE/ha for one day. This corresponds to a stocking density of 8000 DSE/ha for the 0.25-ha plots (see Ogungbuyi et al., 2024 for details). The treatment plots were subjected to high stocking density with varying spelling and recovery periods, except for the Vault Control, which had no specific recovery period. The recovery periods were as follows: 12 months (V1), 9 months (V2), 6 months (V3), 3 months (V4), and 15 months (V5).

Aboveground biomass was destructively sampled from December 2021 to November 2022 using a battery-operated shearing handpiece in 50 x 50 m quadrats, with the average of five readings computed per paddock to minimise sampling error. Cloud-free Sentinel-2 Level 2 surface reflectance images (n=56) were downloaded from Digital Earth Australia for dates matching the biomass sampling period. Ten spectral bands (b2–b8A, b11, b12) were used to extract reflectance values after removing cloudy pixels with a detection algorithm.

A random forest model was trained using the ten spectral bands and 56 biomass samples, split into 75% training and 25% test sets. To prevent overfitting, model parameters included 50 trees, limited tree depth, and default maximum features per split. Training accuracy was assessed using out-of-bag (OOB) error estimates, and performance was evaluated with R^2, RMSE, and MAE. Similarly, an XGBoost model was trained with the same dataset and features. Hyperparameters included a learning rate of 0.05, maximum tree depth of 4, and subsample/column sampling rates of 0.8, with boosting rounds optimized using early stopping. Model performance was evaluated with R^2, RMSE, and MAE.

Aboveground carbon (AGC) and belowground carbon (BGC) were derived from field biomass and Sentinel-2 random forest (S2-RF) estimates using Equations (1) and (2):

$$Carbon = Biomass \times Carbon\ conversion\ factor \quad (1)$$

$$BGB = AGB \times root - to - shoot\ ratio \quad (2)$$

We used a carbon conversion factor of 0.47 and a root-to-shoot ratio of 0.3. Total carbon stock was calculated using Equation (3)

$$Carbon\ stock = AGC + BGC \quad (3)$$

Seasonal carbon stock variability for treatment plots was analysed using standard error of the mean. Due to the lack of SOC field data for validation, we examined NDMI, derived from Sentinel-2 as Equation (4)

$$NDMI = \frac{NIR - SWIR}{NIR + SWIR} \quad (4)$$

Results
Modelling pasture biomass with XGBoost and random forest
The random forest model outperformed the XGBoost model with better regression statistics (R^2 = 0.56, RMSE = 1,532 kg DM/ha, and MAE = 2,021 kg DM/ha) compared to XGBoost (R^2 = 0.48, RMSE = 1,726 kg DM/ha, and MAE = 2,188 kg DM/ha), demonstrating its suitability for handling complex environmental datasets, such as high biomass volumes resulting from seasonal accumulation (Figure 1).

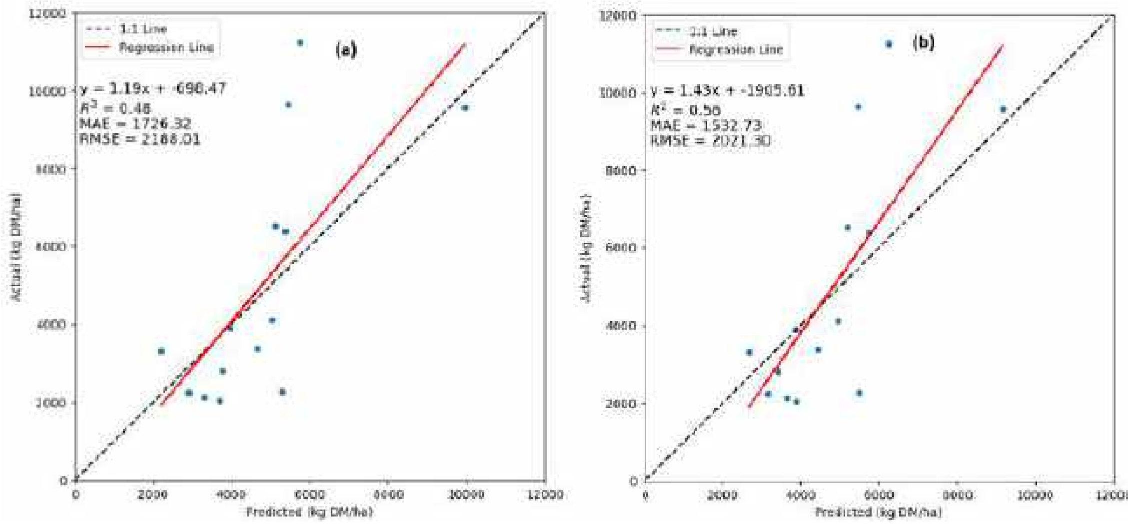

Figure 1. Comparison of Sentinel-2 estimated biomass using (a) the XGBoost model and (b) the random forest model against the actual biomass.

Carbon stock variability in the Vault Plots

The Vault plots exhibited seasonal variability in carbon stock, with Vault 4 (the three-month spelling plot) showing strong alignment between field-measured and Sentinel-2-derived carbon estimates, particularly exceeding 2,000 kg C/ha in seasonal trends (Figure 2). Additionally, the Vault 4 plot recorded the highest soil moisture index (Figure 3).

Discussion

This study highlights the capability of Sentinel-2 imagery combined with a random forest model to accurately estimate pasture biomass at the field scale, even with a limited dataset. Unlike earlier studies, this approach effectively handles high biomass volumes accumulated seasonally without saturation (Ali et al., 2016; Ogungbuyi et al., 2023a), leveraging ten spectral bands to account for environmental conditions. The random forest model outperformed XGBoost, demonstrating superior adaptability to complex data.

Vault 4, with its three-month spelling and recovery period, exhibited the highest carbon stock, benefiting from La Niña-induced rainfall and improved productivity. This aligns with prior research (Ogungbuyi et al., 2024), which found that short-term spelling under intense grazing enhances litter formation and carbon sequestration through trampling effects. Additionally, the Sentinel-2-derived soil moisture index validated this result, showing Vault 4's highest soil moisture concentration (Figure 3).

The use of a carbon conversion factor consistent with Tasmanian soil properties (50% SOC as noted by (Brady et al., 2008; Cotching, 2018) strengthens the study's methodology. This innovative approach provides a proof of concept for deriving carbon stock in the absence of direct soil sampling, offering a valuable tool for future research.

Herder-cattle-rangeland interactions: shaping grazing behaviour in the mountainous rangelands of Kunene, Namibia

Nuule, W[1]; Scheiterle, L[1]; Kaufmann, B[1]

[1]German Institute for Tropical and Subtropical Agriculture

Key words: Dry season pasture, drought periods, Himba, human-animal-environment interactions, pastoral livestock production

Abstract

Livestock grazing behaviours play an important role on the health of animals and the rangelands, significantly impacting livestock production and human livelihoods. Grazing success relies on the intricate interactions between people, animals, and their rangelands. This relationship is particularly vital for pastoral communities, which often face challenges in developing environmental infrastructure. On the mountainous rangelands of Kunene in Namibia, dry seasons and drought reserves pasture areas are difficult to access. Small pockets of resources can provide essential fodder, and the ability to navigate mountainous terrain becomes vital, as pasture is often found at higher elevations. Up to now, our knowledge of the human-animal-environment relationships that shape such grazing practices is still limited. To address this gap, this study aims to investigating factors that influence cattle behaviour associated with mountain grazing. Data on cattle keeping and grazing practices were gathered with Himba pastoralists through semi-structured and narrative interviews. The findings indicate that Himba pastoralists are well aware of features of their cattle that are essential for mountain grazing. They do not only select specific traits in their cattle but also teach them new behaviours, such as foraging behaviour or navigation skills. The climbing performance of the individual animal is shaped by factors like breed, body condition, familiarity with the area, and mountain climbing experiences. Herders employ different techniques to train and assist cattle to climb, including establishing paths by removing rocks that may have caused fear due to past injuries or placing cattle dung along a track to guide the animals uphill. Himba pastoralists skilfully utilize the individual variability among their livestock, enabling cattle to learn from one another while actively shaping their grazing patterns through the instruction of new behaviours. The results specify the interrelationships between humans, animals, and environments and explain in detail how they contribute to an effective utilization of rangeland resources. The skills and knowledge of the herders, along with the skills of their cattle, enable the use of hardly accessible pasture resources, essential for the sustainability of pastoral systems in the mountainous regions of northern Kunene.

Introduction

The northern part of Kunene region is predominantly inhabited by Himba pastoralists who utilize common rangeland resources. During the critical periods, forage vegetation can still be found on rocky mountainous areas, distant from water sources (Bollig 1997). To ensure that cattle access these pastures herders adopt different practices. This human-animal-environment interaction is critical for rangelands characterized by high spatial and temporal variability in rainfall leading to high variability in the distribution of water and fodder resources (African

Union 2010). To optimize livestock grazing, herders utilize their empirical knowledge to develop grazing strategies that stimulate animals' appetite and subsequently promote increased food intake (Meuret and Provenza 2015). Understanding the behavioural patterns of individual animals facilitate livestock keepers in shaping the animals' grazing behaviours, thereby enhancing efficiency and productivity (Dimitri and Longland 2018). Due to the challenging conditions in Kunene north, accessing pastures during the dry season and drought periods depends on the relationships between herders, their herds, and their rangeland. Both the herders' practical knowledge and the cattle's adaptability are critical factors for the successful utilization of these pasture areas (Kaufmann et al. 2016). In the study region, cattle calve once a year, contributing to the sustenance of the Himba people's livelihoods for centuries. This is made possible through these interactions, which highlights the collective importance of human expertise and animal adaptability in pastoral ecosystems. However, comprehensive knowledge on how this interaction influences herding and grazing practices within these pastoral systems remains limited. The aim of this study is to understand cattle-rangeland interactions from the perspective of Himba pastoralists and to explore the factors influencing cattle behaviour associated with mountain grazing in Kunene North.

Methods

This study was conducted in the northern part of the Kunene region, which is characterized by low and erratic precipitation, with annual rainfall ranging from 50 to 400 mm over a maximum of four months. Kunene region is described as a rocky mountainous landscape (NPC, 2015).

Between March 2023 and June 2024, a total of 45 semi-structured interviews and 15 narrative interviews were conducted with Himba pastoralists in three study areas: Omuhonga, Etanga, and Etoto. Semi-structured interviews typically lasted 1 to 1.5 hours, while narrative interviews ranged from 1.5 to 2 hours. The initial participants were selected through purposive sampling, and thereafter respondents were identified through snowball method. The interviews were conducted with herders actively engaged in daily cattle management to capture first-hand experiences, knowledge, and practices. Participant observation, combined with informal discussions and prolonged engagement over 9 months, contributed to the robustness and validity of the collected data. To ensure accuracy all interviews were recorded and transcribed by a native speaker of the local language. Data analysis followed a multi-stage approach. The recorded interviews and data were organized, transcribed, and coded. Recurring themes and patterns were then identified. Respondents were grouped, and their answers to the research questions were examined. Content analysis was conducted to develop codes and categories (Creswell, 2007). Data analysis was performed with the help of MAXQDA.

Results

Cattle breeds and their characteristics

Three common cattle breeds and their respective characteristics in the study area were identified through interviews. (i) The Nguni, which is an indigenous breed (sometimes referred to as Nguni/Sanga or Sanga sub-type/eco-type), has a small body frame and low milk production (<3L/day). However, this breed is well-adapted to the region and demonstrates competence in walking long distance as well as mountainous terrain and rocky areas. Consequently, this attribute contributes to its ability to reach pastures across the seasons, enabling it to meet its nutritional needs, which in turn supports reproductive performance, by maintaining good body condition and hence go on heat few months after calving and uphold an annual calving pattern. A high calving rate not only enhances herd growth but also ensures a steady supply of milk. Although the quantity may be limited, it is often sufficient during critical periods, particularly for younger children. (ii) The Brahman which was introduced to the area from commercial farms, primarily through exchanges; it is not well-adapted to the region but can cope with extended dry season and the rocky mountainous areas to some extent. It has a big body frame that provides favourable prices when sold. (iii) The Herero (locally referred to as a breed originating from Hereroland, also referred to as composite of Brahman, Simmental, Nguni and possibly Bonsmara), demonstrates limited ability to survive drought conditions, but it is larger and produces more milk (5-7L/day) than the other two. Despite their susceptibility to drought events, about 80% of the herders maintain them, as deadly droughts occur approximately once every six to ten years. Thus, the benefits of increased milk production and meat yield, or potential financial gains from sales, are perceived to be worth the risk of losing these animals during drought periods. In terms of calving rate, both Brahman and Herero breeds are reported by the herders to likely skip one or two years of calving. Herders maintain a diverse combination of breeds and crossbreeds in their herds, as each breed offers distinct advantages.

Herders' perceptions on cattle breeds grazing behaviours

Kunene North pastoralists prefer cattle that are capable of performing grazing activities independently, such as walking to water sources, to the pasture and returning home to their calves (particularly lactating cows). This preference stems from the dominant free-ranging practices, where cattle are guided to grazing zones and left to forage on their own. This cattle-free-ranging practices is driven by labour constrains and low presence of cattle predators unlike for small ruminants that need to be herded due to the presence of jackal and leopards in the area. During the dry season, navigating mountainous and rocky terrain is crucial for the livestock to meet their nutritional requirements. Additionally, in these periods watering animals becomes one of the main activities, hand-dug wells need to be re-excavated reducing herders active herding time. Animals unable to carry out grazing activities on their own are considered by the Himba to be lazy, weak, or incapable, requiring herder's intervention. Himba pastoralists specify several cattle characteristics that resonate with their preferences.

Breed-dependent factors: The mountainous terrain poses varying levels of challenges for different cattle breeds. Nguni cattle are capable of independently ascending to mountain pastures. In contrast, Brahman cattle typically ascend partially and require herder intervention to reach grazing areas at higher elevations. Herero cattle, however, depend entirely on herders for any uphill movement.

Breed-independent factors: Individual cattle experience with mountainous environments plays a crucial role in their ability to navigate such terrain. Animals originating from non-mountainous areas lack the experience and depend on herder's support. Additionally, body condition is a critical factor; weak animals lack the strength for independent uphill ascending and thus require herders' intervention.

Herders' supportive strategies towards accessing mountain pasture

Due to the availability of pastures solely in the rocky mountainous areas during critical periods, and the inability of some cattle to access these pasture areas, it is crucial for herders to intervene to ensure continuous provision of feed resources for the animals. Herders' intervention involves different approaches, based on the individual animal's specific limitations. When livestock are unfamiliar with the area and unaware of pasture locations, the herder may employ the following strategies: *Dung application method* - herders strategically apply fresh dung along an imaginary trail. When cattle detect the scent, they assume the route is commonly used to access pasture, motivating them to ascend. *Training the lead cow* - the lead cow, typically possessing good memory and learning capabilities, is guided for about a week. Once trained, it takes the lead, and the rest of the herd follows. When animals are in poor body condition, alternative strategies are employed such as: *Creating pathways* - herders remove large, sharp rocks to facilitate cattle movement. Navigating slopes and rocky terrain can be exhausting, especially for weak animals. *Evening ascension* - to avoid daytime temperatures that can reach 35–40°C, herders move livestock during the cooler evening hours. Slow, deliberate movement also reduces exhaustion and minimizes the risk of slips, falls, and injuries. *Choosing flatter routes -* whenever possible, herders select flatter paths, as these are easier to climb, and some animals are fearful of steep slopes. *Dividing the herd* - The herd is separated into strong and weak groups and grazed on different mountains based on distance and slope gradient. Strong animals capable of efficient walking and climbing are assigned to more challenging routes, while weaker animals, including lactating cows, thin, ill, or old individuals, are grazed on less demanding terrain.

Discussion

Adaptive herding strategies: cattle breeds, environmental knowledge, and pastoral expertise

Accessing mountain pastures: Each cattle breed exhibits distinct characteristics and behaviour patterns that reflect its adaptability to the region's conditions and its value to livestock keepers. While exotic breeds perform well under optimal conditions, such as during the wet season, producing substantial amount of milk and larger framed offspring, they face challenges due to the prolonged dry seasons, drought, and the difficulty of navigating mountainous and rocky terrain. This limitation reduces their ability to access the scattered and difficult to reach pockets of fodder available on mountain pastures during the dry season/drought periods and ultimately hampers their survival under the region's peculiar conditions. In contrast, the indigenous Nguni cattle, are well-adapted to the pedo-climatic conditions. Similarly, pastoralists highlighted the strengths of local breeds, noting their resistance to drought, ability to travel long distances without water, and capacity to adapt to new or changing environments (e.g., Marshall et al. 2019; Ayantunde 2007; Tamou et al. 2018).

Herding skills: The training that herders perform to teach their animals to access to mountain pasture and to encourage them to walk on rocky paths allow continuous fodder intake of their cattle for sustenance and production. Experienced herders are known to create meal sequences for their livestock to optimise feed intake, hence improving the nutrition, health, and production of animals and landscapes (Meuret and Provenza 2015).

Calving rate: The ability of Nguni cattle to access mountain pastures enable them to meet their nutritional needs, maintaining good body condition and also enhancing annual calving rate. Adequate nutrition helps cows return to oestrus faster after calving and maintain optimal reproductive efficiency (Diskin and Kenny 2014); cows have a 70% probability of conception if they are gaining weight, compared to only 17% if they are losing weight (Pradhan & Nakagoshi, 2008). Research conducted on a Namibian research station on comparing the calving rate of different breeds over a period of 10 years under equal conditions found that, Nguni cattle have a calving rate of 89,6%, compared to the 77,4% average of four other breeds (Afrikaner, Simmental, Hereford and Santa Gertrudis) (Schoeman 1989).

Herd composition: The majority of herders, where the topographic conditions permit, prefer maintaining a mix of cattle breeds. This strategy enables them to capitalize on higher yields during favourable years while benefiting from the resilience of Nguni cattle, which ensure a consistent supply of milk and offspring with minimal input requirements. Similarly, Rendille camel herders in Kenya do not prioritize a single breed but instead maintain a diverse herd composition, recognizing that different breeds serve various roles in terms of production and self-sustenance within the herd (Kaufmann, 2007). This underscores the importance of herders' strategic herd composition, which is determined by a variety of factors beyond the simple "production" aspect often emphasized.

Conclusions

The strategic importance of herd composition enables herders to mitigate risks associated with climate variability, and ensure that immediate household requirements and long-term production objectives are met. The strategies utilized by Himba herders reflect their profound knowledge of animal behaviour and rangeland conditions, demonstrating a sophisticated understanding of the potential of the interplay between the two. The human-animal-environment interactions play significant role in utilising the hardly accessible rangeland resources, which enables livestock production, thus sustaining livelihoods of Himba pastoralists.

Zn and Fe bio-fortification and its effect on fodder maize and sorghum for sustainable livestock production in Himalayan foothills of India

Pal, MS

College of Agriculture, G B Pant University of Agriculture & Technology, Pantnagar (India)

Key words: Bio-fortification; crude protein; Fe; Leaf:Stem ratio; Zn

Abstract

A field experiment was conducted at G B Pant University of Agriculture & Technology, Pantnagar, India) in kharif (crop-growing season from June to October) 2019 and 2020 to study the effect of Zn and Fe biofortification on fodder quality of maize and sorghum in Himalayan foothills of India. The experimental site was clay loam with organic matter 0.74% and available N, P and K was 280.2, 25.2, 215 kg ha^{-1}, respectively. The initial soil Fe and Zn content was 3.582 and 0.461 ppm, respectively. The growth, yield, quality and economics of fodder crops differed significantly with higher plant height, number of plants m^{-1} row length, flowering, fodder yield, crude protein yield and economics in sorghum. Fodder sorghum produced 27.2, 18.8 and 82.5% % higher green fodder yield, dry fodder yield and net return, respectively, than maize. The green and dry fodder yields, crude protein yield and economics were significantly higher at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$, while Zn and Fe contents in soil and plants were significantly greater at $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$. Therefore, it may be concluded that both maize and sorghum, preferably sorghum, could be biofortified with application of 10 kg $ZnS0_4$ ha^{-1}+10 kg $FeS0_4$ ha^{-1} (basal)+1% $ZnS0_4$+1% $FeS0_4$ (foliar 45 DAS) for higher biofortified fodder yield and net profit for sustainable livestock production in Himalayan foothills of India and these results may be replicated in similar ecologies.

Introduction

Presently India is short of 36% green fodder, 21.9% dry fodder and 44% concentrates. Fodder maize (*Zea mays* L.) and sorghum (*Sorghum bicolor* L.) are the major crops cultivated globally for green fodder, silage and hay but cereal-based diets are deficient in essential amino acids, i.e. lysine and tryptophan, vitamin A, zinc (Zn) and iron (Fe). Recently wide range deficiency of Fe and Zn in soil, food and feed has drawn attention due to nutritional health problems. Fe is the third most limiting nutrient for plant growth and its deficiency causes chlorosis, low yield and a loss in nutritional quality in many agricultural plants. Zn is also an essential micronutrient and acts as co-factor of many enzymes and regulates auxin synthesis and antioxidant production, but its deficiency decreases photosynthetic rate and induces chlorosis, sterility and fungal infection. Normally sorghum is deficient in Ca, Zn and Fe causes health problems in livestock. Most sorghum varieties contain 30 ppm Fe and 20 ppm Zn, while balanced nutrition requires 60 and 32 ppm, respectively. Agronomic manipulation is an effective tool of biofortification of micronutrients like Fe and Zn in forage crops. Mousavi et al. (2012) reported positive effect of Zn and Fe on biomass components and composition of plants. Zinc improves kernel number and weight in maize (Liu et al., 2020). Deficiency of Fe and Zn in sorghum can be altered through biofortification, which is a sustainable solution to their deficiencies (Kumar et al. 2015). Recent studies showed that foliar application of a minute concentration of nutrients, especially Ca, Zn and Fe significantly increased nutrient contents and yield in both sorghum and maize. However, research work on biofortification of Fe and Zn in forage maize and sorghum is very limited. Therefore, the present study was planned to study the effects of bio-fortification of Zn and Fe on yield and quality of maize and sorghum fodder for sustainable livestock production in Himalayan foothills of India.

Methods

Field experiment was conducted at Fodder Block, G B Pant University of Agriculture & Technology, Pantnagar, India, during *kharif (*crop season from June to October) 2019 and 2020 to study the effect of Zn and Fe biofortification on fodder maize and sorghum for sustainable livestock production in Himalayan foothills of India. The soil at the site was clay loam with pH 7.2, 0.74% organic carbon, available nitrogen 280.2, phosphorus 25.16 and potassium 215.0 kg/ha, 0.461 ppm Zn and 3.582 ppm Fe. The experiment consisted of two crops, i.e. maize and sorghum, in main plot and 07 treatments in subplot was planted in split plot design and replicated thrice.
The maize var. African Tall and sorghum var. PC-6 were planted at 30 cm x 10 cm plant geometry on 21st June in 2019 and 28th June 2020. The recommended dose of fertilizers for both crops was 100 kg N ha^{-1}, 60 kg P_2O_5 ha^{-1} and 40 kg K_2O ha^{-1}. Pendimethalin 30EC @ 1.0 kg ai ha^{-1} was sprayed as a pre-emergent herbicide to control weeds. The crop did not require irrigation due to sufficient rainfall during the crop growth period. The crop was harvested manually at 50% flowering. Crude protein content was estimated by multiplying the nitrogen content by factor 6.25, while the crude protein yield was the result of crude protein content x dry fodder yield. The Fe and Zn were determined using Atomic Absorption Spectroscopy (AAS). The economics including gross return (green fodder yield (qha^{-1}) x Sale rate ((Rs q^{-1}) and net return (Gross return (₹ ha^{-1}) – cost of cultivation (₹ ha^{-1})) were worked out on the basis of prevailing sale rate of the green fodder. The benefit:cost ratio (B:C ratio) was estimated on per hectare basis. The data were analyzed with standard procedures using OPSTAT-Online Statistical Analyzing Tools developed by **Sheoran (2021).** The treatments are abbreviated as given in Table 1.;

Table 1. Treatment details

Treatment	**Details of treatment (Trt)**	**Abbreviated treatment**
T_1	Control (no Zn or Fe application)	Zn_0Fe_0
T_2	10 kg $ZnSO_4$ ha^{-1} (basal soil application)+1% $ZnSO_4$ foliar spray at 45 DAS (days after sowing)	$Zn_{10b}Zn_{1f}$
T_3	10 kg $FeSO_4$ ha^{-1} (basal soil application) +1% $FeSO_4$ foliar spray at 45 DAS	$Fe_{10b}Fe_{1f}$
T_4	10 kg $ZnSO_4$ ha^{-1}+10 kg $FeSO_4$ ha^{-1}(basal soil application) +% $ZnSO_4$+1% $FeSO_4$ foliar spray at 45 DAS	$Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$
T_5	20 kg $ZnSO_4$ ha^{-1} (basal soil application) +1% $ZnSO_4$ foliar spray at 45 DAS,	$Zn_{20b}Zn_{1f}$
T_6	20 kg Zn SO_4 (basal soil application) + 1% $FeSO_4$ foliar spray at 45 DAS	$Zn_{20b}Fe_{1f}$
T_7	20 kg $ZnSO_4$ ha^{-1}+20 kg $FeSO_4$ ha^{-1} (basal soil application) +1% $ZnSO_4$+1% $FeSO_4$ foliar spray at 45 DAS	$Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$

Results and Discussion

a. Effect of Zn and Fe on fodder crops

Sorghum had significantly taller plants and more plants per unit area than maize (Table 2) mainly due to better field emergence and greater tolerance to higher soil moisture in crop seasons, similar to Adesh et al. (2021). Maize had significantly more leaves than sorghum mainly due to higher plant density in sorghum with increased internodes length. Sorghum took more days than maize to 50% flowering. The L:S ratio was significantly greater in maize than sorghum because of broader leaves in maize (Table 3). Vinita et al. (2021) also reported higher number of leaves/plant and greater L:S ratio in maize than in sorghum. Sorghum had significantly higher green fodder yield (GFY) and dry fodder yield (DFY) than maize (Table 3), ascribed to taller plants and more plants per unit area.

Table 2. Effect of Zn and Fe on growth of fodder maize and sorghum (pooled of 2019 & 2020)

Trt	Height (cm)			Plants m^{-2}			Leaves $plant^{-1}$			50% flowering (Days)

Sorghum had significantly higher crude protein content (CPC) and crude protein yield (CPY) than maize (Table 4), similar to Adesh et al. (2021). The crude fibre (CF) was significantly higher in maize than sorghum as maize has more crude protein and soluble sugar. Iron content in both soil and plant as well as Zn in plant was significantly higher in maize, but Zn content in soil was significantly higher in sorghum (Table 5). The gross and net returns as well as B:C ratio was also significantly higher in sorghum (Table 6). Sorghum gave 27.0 and 82.5% higher gross and net returns, respectively than maize, attributed to higher green and dry fodder yield. Asif et al. (2020) concluded that combined foliar application of Ca@3%, Zn@2% and Fe@ 1% improved yield and quality of forage sorghum.

b. Effect of Zn and Fe

The tallest plants of maize were measured at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f,}$ while sorghum was found tallest under that was non-significant with $Zn_{20b}Fe_{1f}$ that was significantly equal to $Fe_{10b}Fe_{1f}$ and $Zn_{20b}Zn_{1f}$ (Table 2). The plants m^{-2} and leaves $plant^{-1}$ did not differ significantly among treatments; however, the highest values were noted at $Zn_{20b}Zn_{1f}$.

Sorghum took significantly more days to flowering than maize with highest days at $Fe_{10b}Fe_{1f}$ and Zn_0Fe_0. The L:S ratio of maize was highest under $Zn_{20b}Fe_{1f}$, while L:S ratio of sorghum did not vary statistically among treatments (Table 2). The GFY and DFY was influenced significantly by fortification of Zn and Fe with significantly higher values under sorghum (Table 2). The highest GFY of maize was recorded at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ that was statistically similar to $Zn_{20b}Zn_{1f}$ and $Zn_{20b}Fe_{1f}$ but the sorghum gave the highest values at $Zn_{20b}Fe_{1f}$ that was non-significant with $Zn_{20b}Zn_{1f}$ and $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$. The higher GFY and DFY was described with better growth attributes because both Fe and Zn improved enzymatic reactions, photosynthesis and finally biomass production (Cabot et al., 2019).

The Zn content in soil both fodder crops was estimated significantly higher in $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$ that was non-significant with $Fe_{10b}Fe_{1f}$ (Table 4). In case of Fe content in soil, maize had significantly higher values than sorghum. The highest Fe content in both soils of maize and sorghum was recorded significantly highest in $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$. The Fe content in maize was measured significantly higher at $Zn_{20b}Fe_{1f}$ which was statistically at par with $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$. Similarly, the Fe content in sorghum was higher at $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$ that was significantly equal to at $Zn_{20b}Fe_{1f}$. The higher dose of Zn and Fe resulted into more nutrient contents in plant and soil after crop harvest.

Table 4. Effect of Zn and Fe on Zn and Fe content in soil and plant of fodder crops (pooled 2019 & 2020)

The biofortification of Zn and Fe had significant effect on crude protein content and crude protein yield (Table 4). The highest crude protein content in maize fodder was recorded at $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$ that was significant with only control treatment, while sorghum had significantly higher CPC at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ that was significant with Zn_0Fe_0 and $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$. The CPY of both maize and sorghum followed almost similar pattern as CPC with highest values at $n_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$ and $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$, respectively. The mean CPC and CPY was significantly higher at $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$ that was significantly similar to $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$.. Chand *et al*. (2017) claimed that soil application of $ZnSO_4$ at 25kg/ha+2% its foliar spray gave maximum CPC because Zn and Fe enhanced CH_2O and protein production. The fibre content in maize and sorghum was found significantly highest at $Zn_{20b}Fe_{1f}$, and $Fe_{10b}Fe_{1f}$, respectively. The mean CF was estimated the highest at $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$.. The results revealed that combined application of Zn and Fe increased the CF because Zn and Fe are essential components of various enzymes involved in plant metabolism. Qadir *et al*. (2017) noted that Zn and Fe content were greatly improved by foliar fertilization of Zn and Fe in sorghum. So, there is the direct and positive correlation between Zn and Fe. Xia et al. (2019) also described that Zn fertilization had positive impact on Fe contents of plant.

The highest gross and net return of maize was calculated at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ that was non-significant with $Zn_{20b}Zn_{1f}$ and $Zn_{20b}Fe_{1f}$, while sorghum gross and net return was significantly higher under $Zn_{20b}Fe_{1f}$ that was significantly similar to $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ and $Zn_{20b}Zn_{1f}$ (Table 5). The mean gross and net returns were highest at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ which was non-significant with $Zn_{20b}Zn_{1f}$ and $Zn_{20b}Fe_{1f}$. The B:C ratio had similar pattern where maize and sorghum had the highest values at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ and $Zn_{20b}Fe_{1f}$, respectively. The mean values of B:C ratio was significantly higher at $Zn_{20b}Fe_{1f}$ that was significantly higher than $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ and $Zn_{20b}Zn_{1f}$. These results enumerate that biofortification of Fe and Zn improved the fodder yield resulting in greater gross and net returns.

Table 6. Effect of Zn and Fe on economics of fodder maize and sorghum (pooled 2019 & 2020)

Treatment	Gross return (₹ ha^{-1})			Net return (₹ ha^{-1})			B:C ratio

Interaction (A X B)	3151	9210			3151	9210		0.07	0.20

Interaction effect

Maize green and dry fodder yield were highest at $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$, which was statically at par with $Zn_{20b}Zn_{1f}$ and $Zn_{20b}Fe_{1f}$. The sorghum fodder yields were highest at $Zn_{20b}Fe_{1f}$, which were significantly equal to $Zn_{10b}Fe_{10b}Zn_{1f}Fe_{1f}$ and $Zn_{20b}Zn_{1f}$. Similar trends were found for gross and net returns of both maize and sorghum. It indicates that maize and sorghum do best with 10kg and 20 kg Zn ha^{-1} while both crops performed better at 1% spray of $FeSO_4$. However, the higher Zn and Fe contents in fodder crops were observed at $Zn_{20b}Fe_{20b}Zn_{1f}Fe_{1f}$ which had higher cost of cultivation and lower B:C ratio.

Conclusion & Implications

Both maize and sorghum, preferably sorghum, could be biofortified with application of 10 kg $ZnS0_4$ ha^{-1}+10 kg $FeS0_4$ ha^{-1}(basal)+1% $ZnS0_4$+1% $FeS0_4$ (foliar 45 DAS) for higher fodder yield and net profit for sustainable livestock production in Himalayan foothills of India and may be replicated in similar ecologies.

Keywords: Rainfed farming system; Rain water harvesting; agroforestry; intensification; Livelihood; Resilience

Abstract

Rainfed areas are the home of millions of resource poor farmers whose livelihood is under continuous threat due to frequent droughts. Assured cropping and imparting livelihood resilience to livestock keepers is a challenge. A study was planned during 2013 – 2019 for livelihood resilience of rainfed farmers through rain water harvesting and silvipasture based interventions. The one hectare rainfed farming system model comprising of rain water harvesting farm pond (25 m x 20 m x 2.5 m), less water requiring food crops (groundnut–barley and sorghum–chickpea), agrihorticulture [*Ziziphus mauritiana*+(*Sesamum indicum*–*Cicer arietinum*)], silvipasture (*Leucaena leucocephala*+Tri-species hybrid grass+*Stylosanthes hamata*) and boundary plantation (*Leucaena leucocephala* and *Opuntia ficus-indica*) was evaluated at research farm. The goat rearing potential of the above model was also estimated under intensive and semi-intensive systems. The rainfed farming system module produced 4979 kg ha^{-1} barley equivalent yield consisting of multiple products like barley, chickpea, groundnut, Indian jujube fruits, sesame, fodder (sorghum, TSH, *Stylosanthes, Leucaena* dried leaf meal and spine-less fodder cactus cladodes) and *Grewia* fruits and resulted in 655 US$ year^{-1} net returns with a benefit cost ratio of 2.1. The carrying capacity of the model was 9 and 35 goat year^{-1} under intensive and semi-intensive rearing systems, respectively. The net returns increased by 36 and 226% with the inclusion of goat under intensive (US$ 892) and semi-intensive rearing system (US$ 2136), respectively in the model. It was evident from the study that inclusion of goat, silvipasture and farm pond for rain water harvesting in the rainfed farming have resulted in higher profitability and resilience to less rainfall and its aberrations. It can be concluded from the study that water harvesting, silvipasture and goat

in rainfed farming systems could enhance the productivity and profitability and impart resilience to the livelihood of rainfed farmers in semi-arid tropics.

Introduction

Rainfed agriculture has special significance in terms of ecology, farm productivity and livelihood for millions of resource poor farmers and livestock keepers especially in arid and semi-arid tropics. Rain water harvesting cum efficient recycling and agroforestry based intensification offer a great opportunity for enhancing productivity, natural resource conservation, risk proofing and sustaining livelihood of farmers practicing rainfed agriculture (Palsaniya et al. 2021). Inclusion of animal components, especially small ruminants like goat, in such farming systems may further improve the profitability and resilience of the production system. However, the systematic information on water harvesting – crop – agroforestry – animal integration under rainfed situation is scanty and therefore, need to be researched upon. There is also a need of exploring and calculating the carrying capacity potential and possible economic benefits of such rainfed models under stall feeding and semi-intensive animal rearing systems. Therefore, the present investigation was carried out to establish the impact of rain water harvesting, agroforestry and goat based intensification on livelihood resilience of rainfed smallholder farming systems of India.

Materials and methods

The field experiment was carried out at the Central Research Farm of ICAR-Indian Grassland and Fodder Research Institute, Jhansi (Uttar Pradesh), India during 2014–2018. The soil of the site was sandy loam in texture, low in available N and K and medium in available P and soil organic carbon (0.58%). The components of one hectare rainfed farming system model are shown in table 1. Boundary plantation of *Leucaena leucocephala* and *Opuntia ficus-indica* was also there. The goat rearing potential of the above model was also estimated under intensive and semi-intensive rearing systems. The animals were stall-fed under the intensive system while they were allowed to graze in community and fallow lands and partially supplemented with farm forages, under the semi-intensive system. The life cycle assessment and process analysis approach was used in the present study (Jianbo 2006; Palsaniya et al. 2023). A detailed inventory of inputs and outputs of all the components of the rainfed farming module was compiled. The production cost and returns from individual components were calculated using prevailing market prices of their respective inputs and outputs. The gross return from each component was calculated by multiplying the quantity of produce by its prevailing market price. The total cost was deducted from the gross return to calculate the net return while the benefit cost ratio (BCR) was calculated by dividing gross returns by total cost.

Table 1 Components of the rainfed farming system model

Enterprise	Area (ha)	Component (ha)	
		Rainy season	Winter season
Food crops	0.55	Groundnut (0.3)	Barley (0.3)
		Sorghum (0.25)	Chickpea (0.25)
Silvipasture	0.2	*Leucaena* + Tri-species hybrid grass + *Stylosanthes*	
Agrihorticulture	0.2	Indian jujube + (Sesame – Chickpea)	
Boundary plantation	-	*Leucaena* and spineless fodder cactus	
Rain water harvesting pond	0.05 (20 m × 25 m × 2.5 m)	*Grewia asiatica* on pond dykes	
Total	1.0		

Results and discussion

The component yield, productivity and economics in rain water harvesting and agroforestry based improved rainfed farming system model are presented in Table 2. The food crops in the model consisted of groundnut, barley and chickpea, which on an average, produced 240, 1021 and 311 kg grain yield, respectively. Among the food crop components, the highest barley equivalent yield (BEY) was observed in barley (1021 kg) followed by chickpea (925 kg) and groundnut (718 kg). On an average of 4 years, 200 kg Indian jujube fruits, 81 kg sesame and 179 kg chickpea grain yield was produced from the agrihorticulture component in the model. The equivalent yield in terms of barley was the highest for chickpea (532 kg) followed by sesame (283 kg) and Indian jujube (144 kg) in the agrihorticulture block. Fodder sorghum produced 2314 kg green fodder which was equivalent to 581 kg BEY. The silvipastoral module recorded 2051 kg green fodder (BEY, 129 kg) from TSH, 2233 kg green fodder (BEY, 180 kg) from *Stylosanthes* and 203 kg *Leucaena* dried leaf meal (BEY, 204 kg). The boundary plantation produced 1600 kg fresh spine-less fodder cactus cladodes (BEY, 115 kg), 110 kg *Leucaena* leaf meal (BEY, 111 kg) and 5 kg *Grewia* fruits. Apart from this, the various food crops in the model produced a total of 2741 kg dry fodder year^{-1} comprising of barley straw (1496 kg), groundnut stover (325 kg), sesame stover (207 kg) and chickpea stover (405 kg from food crop component and 308 kg from agrihorticulture). In total, the rainfed farming system module produced 4979 kg ha^{-1} barley equivalent yield consisting of the multiple products above reported. The total cost of cultivation, gross returns, net returns and benefit cost ratio of the one ha rainfed farming system model were 589 US$, 1244 US$, 655 US$ and 2.1, respectively. The contribution of food crop components (446 US$) was the highest (62.9%) in the total net returns of the model, followed by agrihorticulture (137 US$, 19.3%), silvipasture (75 US$, 10.6%) and boundary plantation (51 US $, 7.2%).

The carrying capacity of the rainfed farming system model was found to be 9 and 35 goats year^{-1} under intensive and semi-intensive rearing systems, respectively (Table 3). Nearly 294 and 459 US$ initial investment was needed for animal shed, fencing, equipment and electric and water tank installations under intensive and semi-intensive rearing systems, respectively. The yearly fixed cost due to the initial investment was found to be 41 and 65 US$ under intensive and semi-intensive rearing systems, respectively. The variable cost under intensive and semi-intensive small ruminant rearing system was 1293 and 3026 US$ year^{-1}, respectively and consisted of animal cost, feed and fodder cost, labour cost, veterinary expenses and other miscellaneous cost. The feed and fodder cost was found to be the major cost (46%) followed by animal cost (30%), labour cost (21%) and others in intensive rearing system while animal cost, labour and feed and fodder constituted 50, 28 and 19% of the total variable cost in semi-intensive rearing system.

The gross return from the intensive rearing system was US$ 2226 and consisted of returns from meat (US$ 1740, 78%), skin (US$ 35, 2%), manure (US$ 75, 3%) and sale of non-edible produce (US$ 377, 17%). On the other hand, the semi-intensive rearing system yielded US$ 5226 gross returns out of which, 87% (US$ 4560) was from animal meat, 3% (US$ 135) from skin, 3% (US$ 179) from manure and 7% (US$ 352) from sale of non-edible produce from the model. The intensive and semi intensive small ruminant rearing system produced US$ 892 and 2136 net returns, respectively with almost similar benefit cost ratio. It is evident from the study that inclusions of small ruminants in rainfed farming model both as intensive and semi-intensive systems can enhance the profitability of the family farm. The net return from the rainfed farming system was US$ 655 which can increase to US$ 892 and 2136 if small ruminants are included under intensive and semi-intensive systems, respectively. The net returns increased by 36 and 226% on inclusion of goat under intensive and semi-intensive rearing system, respectively in the water harvesting and agroforestry based rainfed farming system model.

The inclusion of goat, agroforestry (tree) and farm pond for rain water harvesting in the rainfed farming resulted in higher profitability and resilience to reduced rainfall and its aberrations. In the rainfed farming system model, no crop failure was observed due to the presence of the farm pond, where rain water was harvested and efficiently utilized, when needed, through a sprinkler system for irrigation of crops. Further, the resilience in net income was the highest (2136 US$ ha^{-1}) when goat rearing was included under semi-intensive system followed by intensive system.

The increased and assured production and profitability of the IFS model might be due to the positive interactions and synergies among its components. The proper resources and by-product recycling among various components under the IFS resulted in higher productivity and income. The components in IFS interact synergistically and the by-product or output of one component is used as input in another, which minimizes the external dependence and leads to higher productivity, income and resilience (Palsaniya et al. 2017). Panwar et al. (2018) reported that the perennial components and livestock provide risk proofing to the farmer as they are more stable and less prone to aberrant weather conditions than annual food crops. Other researchers also observed that greater synergies, positive interactions and proper resource recycling among the components of IFS were mainly responsible for enhanced productivity, income and resilience (Kumar et al. 2018; Palsaniya et al. 2022).

It can be concluded from the present study that intervention of water harvesting, agroforestry and goats in the rainfed farming systems could enhance farm productivity and profitability and impart resilience to the livelihood of farmers.

Table 2 Yield, barley equivalent yield (BEY) and economics under rain water harvesting and agroforestry based rainfed farming system (mean of 4 years)

Particulars	Component*	Yield (kg $plot^{-1}$)**	BEY (kg $plot^{-1}$)	Cost of production (US$)***	Gross returns (US$)	Net returns (US$)	B:C ratio
Food crops	Groundnut	240 ± 41 (325 ± 55)	718 ± 72	103	165	62	1.6
	Barley	1021 ± 47 (1496 ± 105)	1021 ± 91	114	298	184	2.6
	Sorghum	2314 ± 170	581 ± 59	55	123	68	2.2

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Pasture Monitoring in the Southern Rangelands of NSW

Plummer, CRE[1]

[1] Western Local Land Services, Buronga, NSW, Australia

Key words: pasture; monitoring; grazing management; livestock production.

Abstract

The Producer Demonstration Site: Pasture Monitoring in the Rangelands, initiated in 2022, showcases the productivity benefits of routine monitoring and targeted management of key pastures species in the southern rangelands of NSW. Utilising a combination of on-ground monitoring and remote sensing data, the project tracks pasture production and groundcover percentages at four producer sites across 237,747 hectares in the Oxley and Booligal areas.

Critical decision points in February and August align with pasture supply and demand for these regions, influencing management decisions such as feed supplementation, destocking determinations, and weaning. Therefore, biannual observations and pasture samples of four key pasture species are taken in late summer and late winter at each site. Pasture samples are collected to analyse the crude protein, digestibility and metabolisable energy through feed test data results. Remote sensing tools, Geoglam RaPP Map and Cibo Labs, are used to measure groundcover and green cover at each observation point. Core producers meet twice each year to discuss their sites and share management learnings.

In the project's second year, notable findings include consistent composition of nutritional plants during autumn and winter across two monitoring sites. On other sites, shifts in plant quality were attributed to seasonal availability rather than nutritional changes. The key contributing plants of higher quality in August 2023 included Burr Medic (*Medicago polymorpha*), Barley Grass (*Hordeum leporinum*) and Bladder Saltbush (*Atriplex vesicaria*). Noting that although these species may represent the greatest nutritional value and availability within a paddock, grazing preferences of sheep/cattle (Graetz and Wilson 1980) mean these species might not contribute the largest portion of the livestock's diet in all cases.

The project will continue to track feed quality and its impact on livestock production in western NSW, further demonstrating the efficacy of proactive monitoring and tactical management practices in enhancing rangeland productivity.

Introduction

Managing productive and palatable plants in the pastoral system in alignment with livestock production requirements and sustainable land management is a constant undertaking for rangeland producers. Rainfall has been noted as one of the largest contributors to pasture and soil health in the Western Riverina district (Eldridge and Stafford 1999; Eldridge and Grant 2004). Considerable biomass and vegetation cover declines were recorded between 1990 – 2003 in the Saltbush range-type where seasonality was a larger driver of pasture growth than annual rainfall totals (Eldridge and Grant 2004). Declines in effective rainfall and the deterioration of pasture were linked to a reduction in pastoral productivity through reduced stocking rates (Eldridge and Stafford 1999; Eldridge and Grant 2004). This is reflective of a reduction in the perennial feedbase composition (Eldridge and Grant 2004) and a greater reliance on annual species and opportunistic rainfall to provide short term productivity benefits. As seasonal rainfall irregularity increases, managing a productive livestock enterprise conducive to maintaining and recruiting supporting perennial species will prove more difficult for producers.

The Pasture Monitoring in the Rangelands project seeks to demonstrate that livestock businesses in the southern rangelands of NSW can enhance productivity by implementing routine pasture monitoring and targeted management of key pasture species. Seasonal monitoring is conducted across four producer sites to collect locally relevant data, which permits producers to make informed and timely production decisions aligned to grazing strategies, supplementary feeding, and stocking rates. The project also facilitates peer-to-peer knowledge exchange within the producer group, where participants collaborate and share insights to improve their grazing management practices. This enables producers to combine personal experience with new tools and information to make more informed choices. The project aims to enhance producers' ability to track pasture health, species composition, and feed quality by integrating monitoring tools, including remote sensing, feed testing, and on ground assessments. Participation in the project is designed to deliver long-term improvements in pasture resilience, boost productivity in rangeland livestock businesses, and promote sustainable grazing practices that can adapt to the challenges of the region's variable climate.

Methods

Pasture Monitoring in the Rangelands commenced in 2022 as an approach to continue the site monitoring, pasture sampling and producer engagement established in the initial intakes of the Improving Tactical Decision Making (ITDM) program. The ITDM program is based on tactical management principles (Campbell and Hacker 2000) which continue to be utilised in this project to guide the methodology.

The project emphasises data-driven decision-making by combining on-ground and remote sensor monitoring. Pasture metrics, including species present, groundcover, and grazing strategies, are tracked with seasonal observations. Utilising property trigger points (Hacker et al. 2006) alongside participant producer consultation, two monitoring periods were identified for February and August, aligned to significant decision-making stages in producer management cycles. Site observations, including photo and step point assessments (Campbell and Hacker 2000), and pasture samples of four contributing pasture species are conducted biannually at each monitoring site. Feed quality is assessed primarily through crude protein (CP %), dry matter digestibility (DMD %) and metabolisable energy (MJ/kg DM) laboratory analyses. Scanning percentages, weaning rates and stock sale numbers will be incorporated into the decision-making process. Remote sensing tools, Geoglam RaPP Map and Cibo Labs, are used to collect complementary biomass, green cover and groundcover data for each monitoring period.

Following each data collection, the producer group is brought together to discuss the monitoring results, seasonal conditions, reflections on production system changes and to review concepts of the ITDM. Group meetings are held online and on-property enabling producers to share ideas, experience and practices with neighbouring businesses guided by data collected directly from their paddocks.

Data collection and producer engagement is still on-going with completion projected for early 2027, therefore, only preliminary results will be presented in this paper.

Results

Step Points

Shifts in groundcover were observed at all sites over the monitoring period to date; Sites A and D declined in groundcover in summer contrasting Sites B and C that increased in cover (Figure 1). Notably, three of the four sites have a greater level of groundcover than at the first measurement.

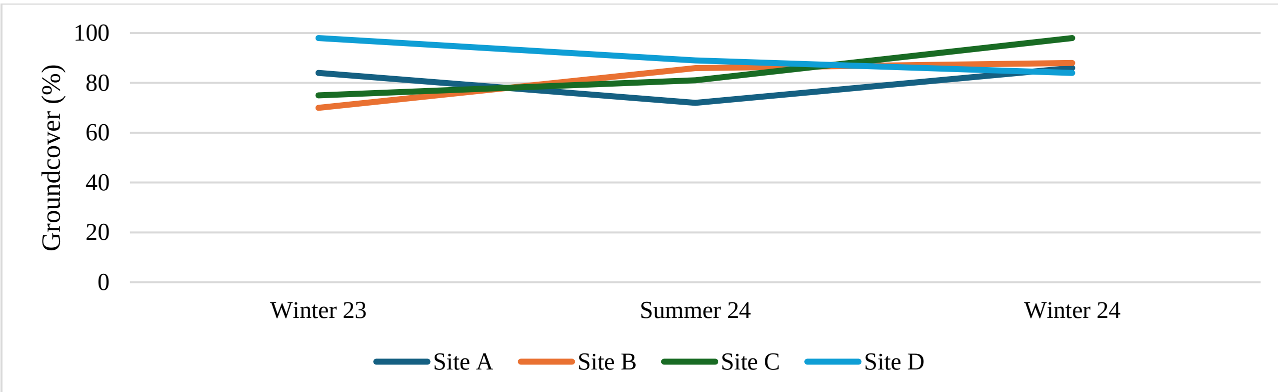

Figure 1. Percentage (%) of groundcover recorded via step point assessment at each monitoring site in Winter 2023, Summer 2024 and Winter 2023. Step point groundcover assessments were undertaken biannually at each monitoring site apart from winter 2022 and summer 2023.

Pasture Sampling

Since the inception of the project, feed testing has occurred biannually with the exception of autumn 2022 at two sites and summer 2023. Demonstrated in the site D results, species availability has changed in all sites across the course of sampling (Figure 2). *Atriplex vesicaria* and *Sclerolaena brachyptera* have consistently been available at site D. Notably at this site, *Atriplex vesicaria* is relatively stable in nutritional value, especially from winter 2023 to winter 2024 (14.6-16.3 CP%, 57-57.5 DMD %, 8.2-8.3 MJ/kg DM) but is nutritionally surpassed by more productive annual plants in winter such as *Sporobolus caroli* (8.9 CP%, 61 DMD%, 8.6 MJ/kg DM) and *Medicago polymorpha* (32.2 CP%, 84.8 DMD%, 12.6 MJ/kg DM)

Photo Points

Permanent photo points have been established at all sites to record the site condition during observational periods. Photographs were taken biannually at each monitoring site with exception of summer 2023. These images provide valuable visual comparison between seasonal conditions and corresponding feed quality data. Comparing site condition through photographs taken in this manner, as demonstrated in the site D photo point, further assists producers in understanding the changes in the timing of effective rainfall, grazing effects and progress of the site towards the grazing management objective (Figure 3).

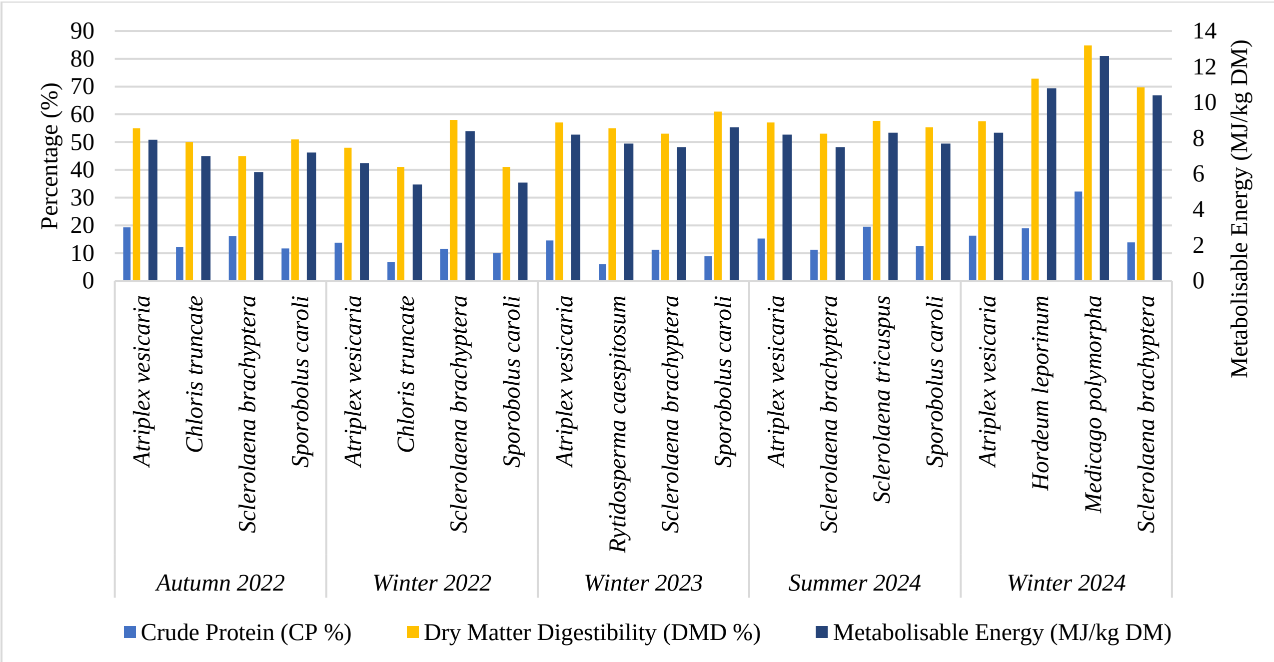

Figure 2. Feed test results summary of monitoring site D (Booligal, NSW) key pasture species at five different sampling periods throughout the project.

Figure 3. Photographs demonstrating the difference in site condition in the same season in different years. The photographs were taken at a permanent photo point at monitoring site D (Booligal, NSW) in August 2023 (left) and August 2024 (right).

Discussion

The pasture sampling process has been impacted by several factors. Sampling where sites were actively utilised by livestock or had recently been destocked resulted in preferred key species unable to be sampled on occasion due to risk of plant defoliation, biomass/height restrictions and lack of individual plants. Furthermore, staff changes early in the project, regional flooding in late 2022 to mid 2023, and shifting producer involvement have all impacted data collection, though these factors are not anticipated to significantly altered the overall findings.

Significant rainfall variability has occurred during the project. Dry winter conditions in 2023, followed by a wet summer did not directly affect the nutritional value of pasture or the feedbase composition. The largest changes were arguably when composition shifted prior to the August 2024 observation period, initiating the growth of annual grasses and forbs, a noted characteristic of effective cool season rainfall in the southern rangelands (Hacker and McDonald 2021). This is consistent with previous findings in the Western Riverina, where seasonal variability played a large role in vegetation growth and rangeland productivity (Eldridge and Grant 2004).

While the pasture species sampled generally offer high nutritional value, the selective grazing habits of sheep and cattle make it challenging to accurately assess diet composition. For instance, *Atriplex vesicaria*, although typically of high quality, was not observed to have been consistently chosen by sheep grazing at the monitoring sites. This aligns with previous findings in the district where shrub species, despite their potential nutritional value, are not commonly preferentially grazed by livestock initially (Graetz and Wilson 1980). Notably, perennial saltbushes appeared to be relatively unaffected by grazing pressure during monitoring, in contrast to annual forbs and grasses, which were more heavily utilised.

Group meetings provide producers an opportunity to discuss their own experience in relation to local literature and the alignment with the monitoring results of this project. Incorporating tools, such as Geoglam Rapp Map and Cibo Labs, into the meetings assists producers to correlate on-ground measurements with previous events and seasonal conditions. Therefore, several knowledge sources and tools are brought together to enable data-driven decisions to be undertaken for rangeland businesses.

Conclusion

Fluctuations in effective rainfall and pasture health have direct implications for pastoral productivity (Eldridge and Stafford 1999). As such, maintaining a sustainable feedbase amidst increasing seasonal variability requires tactical management strategies that account for short-term climatic changes and long-term ecological shifts. The Pasture Monitoring in the Rangelands project aims to demonstrate the role of data-driven decision-making and producer engagement in enhancing the resilience and productivity of livestock enterprises in the southern rangelands of NSW.

Acknowledgements

Pasture Monitoring in the Rangelands is delivered by Western Local Land Services, a NSW Government Agency. The project is a Producer Demonstration Site, an initiative of Meat & Livestock Australia. The author would like to acknowledge the work of past and current team members involved in the development and delivery of this project.

Key words: Pastures; forages; multi-species; biodiversity; management.

Abstract
Agro-Silvo-Pastoralism integrates the knowledge and research of Agronomy, Forest and Extensive Animal Production systems where the soil is the common main factor and looks for application of new technologies on farming systems integrated as a multifunctional way. To improve soil capacity in Mediterranean environments the most efficient process is the improvement of Mediterranean Permanent Pastures and how higher the quantitative and qualitative production of pasture increase the level of Organic Matter in soil and the stocking rate. Also the increase of stock of water in the soil allows the enlargement of the annual cycle in pasture self reseeding plants which means higher biomass production. At some level of soil potential capacity the existence of perennial plants with summer dormancy becomes possible. This means the anticipation of the autumnal start of annual cycle of growth in pasture and decrease of forage supplementation according to the Feeding Scheme of Extensive Animal Production systems. The increase of stocking rates delay the regrowth of shrubs which means the enlargement of Montado Crop Rotation by the increase in variable n (years of pasture). This has positive effect on natural regrowth of tree component because of lower animal pressure and in the balance on vegetal stratus (*arboreus*, *arbustive* and *herbaceous*) with high levels of general biodiversity (animal, vegetal and microbioma). So, increasing the level of bioma in soil which has positive impact on the availability of nutrients and water for plants making easier the sanitary control of vegetal component and increase the general productivity of the whole system. The model of management and multifunctionality can be found in the project of conversion of Mediterranean forest in agro-silvo-pastoral system Montado by Potes et al (2021).

Introduction
Since the VI IRC in Townsville, Queensland, Australia 1999, the Montado ecosystem has been presented as an agro-silvo-pastoral ecosystem with a typical landscape which characterizes the Mediterranean region of Portugal in the Iberian Peninsula. It was built by Man and preserved among centuries by the control of shrubs and usage of natural resources within extensive farming systems. The extensive animal production systems evolved are based on pastures and forest by-products but need to be complemented with forage production and other supplements in order to adapt to semiarid environments to obtain high quality products.

Potes et al, (2021) presented the conversion of the Mediterranean Forest into a Montado ecosystem by the management of the Mediterranean environment focused on the recovery and preservation of the soil. As poor soils are generally dominant in these environments the increase of its potential productivity is essential for the development of distinct phases of the process that characterize the success of a working and balanced ecosystem.

The objective of this paper is to point out the correspondence of several papers submitted to International Congress's in the last twenty years concerning the different phases of implementation of the Montado ecosystem and show the dynamic of the management to achieve technical, environmental and economic sustainability.

Methods

The methodology used for the implementation and management of the Montado ecosystem it is the Agriculture of Conservation or Conservation Farming System which means the focus on the recovery or improvement of the soil. If the soil is considered the common base of any natural system of production in agronomy, animal husbandry or forestry, in the case of Mediterranean environments it is more important because of the level of degradation caused by human activity over plus the natural decrease in the potential productivity of the soil. So Conservation Farming consists in absence of mobilization of the soil, diversification of the rotational annual crops and the residues of crops remaining on the soil.

Results and Discussion

The first approach and identification of the physical and environmental characteristics of the farm is essential to establish the plan of the intervention regarding the stud of the status of the soil, the balance between vegetal stratus and infrastructures for animal and grazing management.

Looking for technical procedures Potes & Babo (2003) proposed the Montado Crop Rotation for combining operations as the mechanical control of shrubs (if necessary), forage crop and pasture improvement process. The implementation of the rotational interventions must be done in an appropriate plan of individualized parcels with easier access, water supply and surface according the level of stocking rates. This means the facility in animal and crops management and very importantly, the dilution on infrastructural investments along the cycle of the rotation. Such process of management is identified as multifunctionality.

The pasture improvement process was presented by Potes et al (2005) focusing on the importance of liming and P fertilisers to adapt the soil conditions to a balanced botanical composition of the flora which favours the increase of annual legumes of self reseeding. This botanical Family is the principal responsible for the increase of N in the soil with direct impact on the increment of levels of pasture biomass. The control and balance of the flora is highly dependent on the grazing management and is only possible with the adequate infrastructural plan of parcels or paddocks. How long the years of permanent pastures (n) decrease animal pressure and increase the regrowth of *arboreus* stratus mainly composed by *quercineas*.

The efficiency of the animal production systems adapted to the Montado ecosystem depends on the contribution of all natural resources for animal feeding and looking to minimize the outsourcing of the system. This is the base of extensive grazing systems which was presented by Potes (2008) as the Feeding Scheme of Extensive Animal Production Systems in the Montado. It shows the contribution of all vegetal stratus for the feeding supply and the irregularity of sources between each season of the year with impact on the different preferences that each animal species reveal for distinct products. The supplements of crop forage are the highest inputs of the scheme and can be reduced or decreased as the total natural biomass of the ecosystem increases and deeply adjusted to the stocking rate.

When the technical procedures are implemented and the dynamism of the process is guaranteed by the results the cycle of the Montado Rotation is closed and it can be possible to start de evaluation of environmental conditions or acquisitions. Potes (2011) discussed the effect of the proposed technical management of the ecosystem in the increase of level of Organic Mater (OM) in soil content and the positive impact of it in the structural and nutritional values. The consequence is the increment of level of water stocked in the soil which combined with more disponible nutrients for plants results in the increase of vegetal biomass. The cycle of water movement within the soil benefits from the distinct distribution of roots system of different stratus of plants (*arboreus*, *arbustive* and *herbaceous*) and the increase of OM in the soil and biomass of plants reveals the increase of sequestration of C in soil which is a relevant environmental service delivered by the ecosystem. The fire prevention becomes as a natural consequence of the control of shrubs (the combustible for fire) by the mosaic disposal of forest parcels (*arboreus* stratus) which represents the main goal for the balance of flora and it's also an important environmental service. Finally the high levels of biodiversity are an instrument for managing the ecosystem because permanent pastures in Mediterranean environments are characterized by high numbers of species from annual plants of self reseeding reproduction which can increase with the longing cycle as consequence of availability of water in the soil. The improved conditions of the soil at some level can even increase the biodiversity of herbaceous flora by the appearance of perennial plants with summer dormancy. The improvement of soil means the increase of bioma in the soil for humification process so micro biota increase of biodiversity is needed for the chemical formation of the soil exchange complex. Concerning the biodiversity of the animal kingdom the use of all domestic species is required because of their distinct characteristics in grazing behaviour and combines with the variable presence of wild animals, reptiles, birds and insects which results in a high level of general biodiversity. In fact it is recognized as a high spot in terms of the world biodiversity.

The Montado ecosystem is a farming system allocated in a low productivity region recognised as extensive system of agriculture and so the economic balance is very hard to achieve if only based in the high quality products it offers to the global market. Potes (2016) presented the environmental acquisitions of the adequate management of the ecosystem with positive impact in soil, water, air, fire and biodiversity as environmental services provided to the society. This is the justification for the High Natural Value (HNV) of the Montado ecosystem. More important is the balance or reduction in sanitary problems in the whole system and so it must be evaluated and valuing looking for a proper payment. Until this mechanism is not offered to the farmers the economic sustainability of the ecosystem was presented as a result of conversion of Mediterranean Forest in the Montado ecosystem (Potes et al. 2021) and can be improved when the HNV would be properly recognized and payee. However the dynamic in positive sense described can be easily reverted by the human abandon that means the natural return to Mediterranean Forest.

Conclusions

The Montado ecosystem is a very successful and dynamic achievement of the human management and conversion of the Mediterranean Forest into an agro-silvo-pastoral system. Its HNV is justified for the technical, environmental and economic sustainability.

The dynamism of the process reveals its own fragilities and economic resilience.

Looking for valorisation of extensively (Potes et al, 2024) and environmental services payment it will be necessary for increase economic sustainability and present Montado ecosystem as a model of modern agriculture.

Bacterial infections in Tamil Nadu's free-range Indigenous cattle: Insight into AYUSH treatments

*Ramachandran, M; Aravind, D; Saminathan, P

National Institute of Siddha, Chennai, India

*Correspondence – marudhu.ramachandran@gmail.com

Key Words: Indian system of Medicine; Siddha, AYUSH; Bacterial infections; Livestock health.

India takes pride in home a large livestock population, with Tamil Nadu alone housing approximately 9.5 million free-range cattle. These cattle are vital for rural livelihoods as they provide natural fertilizer, meat, milk, and even play a role in traditional Tamil bull fighting. However, due to climate change and polluted grazing lands, these animals are at risk of diseases like brucella, anthrax, pneumonia etc. Our study focused on 736, "**Pullikulam**", indigenous cattle breed known for their disease resistance. We found that during winter (June-February), 2.3% of the animals contracted tuberculosis and pneumonia by grazing in shrub jungle. In summer (March-May), 1.08% suffered from diseases caused by organisms such as *Clostridium*, *E. coli*, and Mastitis during grazing in post-harvest wet lands, diagnosed through immunological methods. These herd illnesses not only impact animal health but also cause financial hardship for marginal farmers, with an average daily revenue loss of $125 in our study group. Limited access to veterinary hospitals due to transportation and treatment costs is a major challenge. Indian system of medicine AYUSH (Ayurveda, Yoga, Unani, Siddha and Homeopathy) offers a promising solution. India's rich botanical diversity provides a natural wealth of resources for animal healthcare. For centuries, farmers have relied upon plant-based AYUSH remedies to treat animal diseases. In our study, five different Siddha formulations are administered orally with bananas to symptomatic animals for 21 days which subsequently relieved of infections. These treatments promise to be safe and effective. Additionally, traditional knowledge empowers farmers to develop new herbal formulations for animal health management. This research paves the way for developing eco-friendly and cost-effective veterinary medicines based on AYUSH principles. It highlights the vulnerability of free-range cattle to diseases and the potential of AYUSH treatments as a solution. Furthermore, it underscores the valuable role of indigenous knowledge in preserving traditional veterinary practices

Introduction

India boasts a substantial livestock population, with Tamil Nadu alone has about approximately 9.5 million free-range cattle. These animals are integral to rural livelihoods, providing natural fertilizer, meat, milk, and playing a significant role in traditional Tamil bullfighting. Despite the importance of livestock, many small and marginal farmers face challenges in affording modern veterinary care due to limited income and access to resources. As a result, they often turn to traditional Siddha medicine-AYUSH (Ayurveda, Yoga, Unani, Siddha and Homeopathy) a system of healing with a history spanning over 5,000 years (Shankar, 2016; Ponnulekshmi & Rabinarayan, 2024)

This study develops into the traditional Siddha medicine (AYUSH) and ethno-botanical practices employed to manage bacterial infections in free-range cattle. The primary objective is to document this valuable indigenous knowledge, particularly concerning the seasonal nature of these bacterial infections.

Methods

Area & Period of study: Tamil Nadu State is a tropical region situated at the south eastern extremity of the Indian peninsula. It lies between 8.5° and 13.35° North latitude and 76.15° and 80.20° East longitude. (fig.1) The study was conducted in the Madurai district of Tamil Nadu state, India during March 2023 to July 2023 (Summer season) and October 2023 to February 2024 (Winter season).

Fig1: Tamil Nadu State showing Madurai District

Study Analysis: A seasonal analysis was conducted for five diseases namely Mycobacterial infection, Pneumonia, Clostridial infection, Escherichia infection, and Mastitis, specifically targeting the indigenous disease-resistant Pullikulam cattle breed. Symptomatic animals were diagnosed by analyzing blood and milk samples using commercially available rapid immuno-diagnostic kits based on antigen-antibody agglutination assay for each type of infection.

Siddha (AYUSH) Formulations: Five different Siddha formulations (AYUSH) were used to treat bacterial infections. These formulations were administered orally to animals exhibiting symptoms such as fever, shivering, diarrhea, swollen udder, cough, mucus and phlegm secretion, and joint edema. (Table.1 and 2)

Monitoring and Evaluation: Animal samples were collected periodically (0, 7, 14, and 21 days) before and during treatment. Rapid immuno-diagnostic kits based on antigen-antibody agglutination assay for each type of infection were performed using the slide method and staining to assess the disease and treatment's efficacy. The provided formulations are commonly used by marginal farmers in the region from their traditional knowledge and found to be effective for reducing the symptoms. Hence our study focused for scientific validation through immunodiagnostic Tests.

Table-1: Name of the plants used in Siddha - AYUSH formulation

Botanical Name	Tamil Name	Common Name	Toxicity as per Siddha
Pergularia daemia (Forssk.) Chiov.	Uthamani	Trellis vine	Safe
Aegle marmelos (L.) Correa	Vilvam	Bael, wood apple	Safe
Delonix elata (L.) Gamble	Vathanarayanan	Peacock flower	Safe
Azadirachta indica A. Juss.	Vembu	Neem	Non toxic
Capparis zeylanica L.	Athandai	Ceylon caper	Safe
Leucas aspera (Willd.) Link.	Thumbai	Thumbai	Safe
Zingiber officinale Roscoe	Inji, sukku	Ginger	Safe
Piper nigrum L.	Milagu	Black pepper	Safe
Piper longum L.	Thippili	Long pepper	Safe
Acorus calamus L.	Vasambu	Sweet flag	Some toxicity in fresh rhizome
Ferula foetida (Bunge) Regel	Perungayam	Asafoetida	Safe
Gossypium herbaceum L.	Paruthi	Levant cotton	Safe
Taxus baccata L.	Thalisapatri	Common yew	Safe
Allium cepa L.	Venkayam	Onion	Safe

Table-2: Formulation and Administration of drugs for Bacterial infection

S.No.	Bacterial Infection	Formulation	Method of Administration
1.	Escherichia Infection	juice of Pergularia daemia	Orally given with buttermilk and salt
2.	Mastitis	powder of Aegle marmelos, Delonix elata Azadirachta indica, Capparis zeylanica, and Leucas aspera leaves	Orally given with luke warm water or with banana
3.	Mycobacterial infection	mixture of Zingiber officinale, Piper nigrum, Acorus calamus, Piper longum, Ferula foetida, Azadirachta indica leaf juice, and Gossypium herbaceum fruit juice	Orally given as juice or with banana
4.	Pneumonia	mixture of Piper nigrum, Piper longum, and Taxus baccata	Given with ghee or with banana
5.	Clostridial infection	macerate of Allium cepa, Acorus calamus	Given with castor oil vinegar and salt or with banana

Results

Upon survey through marginal farmers, we found that during the monsoon and winter seasons i.e., October to February, cattle's (2.3%) were prone to tuberculosis and pneumonia while grazing in shrub jungles. As well during the period of summer from March to July the cattle's (1.08%) suffered from diseases such as *Clostridium*, *E. coli*, and mastitis while grazing in post-harvest lands. These diseases were diagnosed through immunological methods and staining. After one week of oral administration of the formulation, there was a significant reduction in symptoms, and the specific pathogen antigen level decreased in agglutination reactions in the immunodiagnostic tests. Mycobacterium found in sputum even after 21 days treatment.

A survey of marginal farmers revealed that during the monsoon and winter seasons (October to February), 2.3% of their cattle were susceptible to tuberculosis and pneumonia while grazing in shrub jungles. During the summer months (March to July), 1.08% of cattle suffered from diseases such as *Clostridium sp, E. coli*, and mastitis while grazing on post-harvest lands. The samples were collected in the morning hours between 6.00am to 7.00am The tests were carried out immediately when there is appearance of clinical signs of the cattle inspected in all the months. These diseases were diagnosed using immunological methods. Following one week of oral administration of the herbal formulation, a significant reduction in symptoms was observed. The specific pathogen antigen levels decreased in agglutination reactions during immunodiagnostic tests. However, *Mycobacterium sp* was still detected in sputum samples after 21 days of treatment. These findings have been tabulated. (Table.3).

Marginal farmers in Madurai district practice traditional Siddha veterinary treatments, and our results demonstrate the efficacy of herbal formulations in reducing the burden of cattle diseases. These Siddha herbal treatments significantly reduced the antigen load in both the blood and milk of the cattle. Based on our study, farmers concluded that these Siddha herbal formulations can be administered prophylactically to all cattle throughout the year to prevent the aforementioned diseases. The study results emphasize the effectiveness of Siddha herbal treatment and offer hope for marginal farmers.

These findings could serve as foundational research for pharmacological studies of Siddha formulations, potentially leading to alternatives to allopathic medications in livestock management. This study focuses on the use of traditional remedies for prompt animal care, as well as the associated social aspects.

Table-3: Slide Agglutination Test Results:

S. No	Types of Infection	Sample from infected animals	Number of Animals	Test Performed	Presence of Bacterial Antigens/ organisms/cattle antibodies			
					0 day	7th day	14th day	21th day
1	Escherichia *Infection*	Serum	17	*E coli* slide agglutination test kits	Positive-	Negative	Negative	Negative
2	Mastitis infection	Milk	17	Slide agglutination test kit/ staining	Positive-	Positive	Positive	Negative
3	Mycobacterium Infection	Milk & Sputum	8	Rapid slide agglutination kit /Staining	Positive-	Positive	Positive	Positive
4	Pneumonia infection	Serum	8	Slide agglutination kit	Positive-	Negative	Negative	Negative
5	Clostridium infection	Serum & Stool	17	Toxin agglutination kit	Positive-	Positive	Positive	Negative

Discussion

The information provided discusses about complete disease recovery for all the bacterial infections listed above after 21 days with both symptoms and antibody titers, except Mycobacterial infection which persist even after treatment. This suggests that the traditional formulation reduced symptoms in a readily observable way. Improved productivity was confirmed by the local farmers using simple inexpensive measurements such as i.e., body weight, fat cover, milk and fighting ability.

Modern veterinary and chemical interventions have improved livestock health and productivity, but they raise concerns about environmental impact, consumer health, and the preservation of indigenous breeds. In contrast, traditional methods, relying on natural remedies, apart from curing the diseases can enrich soil, maintain genetic diversity, and reduce the need for chemicals. Livestock raised traditionally may produce healthier products and support sustainable livelihoods, benefiting small farmers and local economies. However, traditional methods might not prevent major disease outbreaks or match the productivity of modern farming. The solution is a balanced approach that integrates both traditional and modern practices to maximize benefits and sustainability.

Conclusion

Traditional livestock health management in India presents a promising path for sustainable and ethical farming. By combining traditional knowledge with modern scientific methods, it's possible to create holistic approaches that benefit both farmers and consumers. Future research should focus on documenting and assessing the effectiveness of traditional practices, as well as exploring ways to integrate them into contemporary livestock management systems for improved sustainability.

Proximate and phytochemical composition of hay made from three different pasture species (*P. pedicellatum, A. gayanus and C. biflorus*) in Yobe State, Nigeria

*Sani, I; Saidu, A

Department of Animal Production, Abubakar Tafawa Balewa University, Bauchi, Nigeria

*Corresponding author: isani@atbu.edu.ng, +2348038056113

Key words: Nutritive value, Forage, Sahel, Indigenous, Rangeland

Abstract

This study investigated the quality and phytochemical contents of three indigenous grass species for grazing animals in Yobe State a semi-arid region in the sahel, Nigeria. The pasture species *Pennisetum pedicellatum, Andropogon gayanus and Chloris biflorus* were harvested from grazing rangelands in the study area, measured and then analysed for determination of their nutritive quality and phytochemical content. Plants were harvested at bloom stage, sundried to 40% moisture level,shade-dried for ten days, milled into 2 mm particle size and stored in airtight polythene bags until analysis. Results obtained for nutrient composition revealed that *A. gayanus* had higher mean value for crude protein (10.62 g/100g) followed by *P. pedicellatum* (8.94 g/100g) then *C. biflorus* (6.81 g/100g). Nitrogen free extract was highest in *C. biflorus* (50.53 g/100g) and lowest in *A. gayanus* (36.70 g/100g). Phytochemical analysis showed that the concentration of flavonoids in *P. pedicellatum* (0.15 g/100g) was slightly higher than the respective values of 0.07 and 0.04 g/100g obtained in *A. gayanus* and *C. biflorus*. Similarly, *P. pedicellatum* (0.26 g/100g) had higher tannin level than both *A. gayanus* (0.04 g/100g) and *C. biflorus* (0.02 g/100g). The mean concentration of saponins in the three grass species was 0.09 g/100g (*A. gayanus*), 0.10 g/100g (*P. pedicellatum*) and 0.16 g/100g (*C. biflorus*) while that of alkaloids fell within the range of 0.14g/100g in *C. biflorus* and 0.25g/100g in *A. gayanus.* Based on the nutritive value and phytochemical content of the pasture species analyzed, it was concluded that *A.gayanus* could be best used to improve rangeland and livestock productivity in Yobe state, Nigeria.

Introduction

The pastoral system of livestock husbandry is characterized by transhumance and communal grazing. In addition, sedentary livestock rearers' also depend on forage grasses and legumes from range lands in order to meet the nutritional needs of their animals. In essence, most ruminant livestock owners depend on grazed and conserved forage as basic feed resource (Ayodele, 2022).

The main advantages of forage as feed resource are its low unit cost and high availability compared to other animal feed materials. Forage grasses and legumes provide all the nutrients required for maintenance, production and reproduction. However, the low level of animal production experienced, particularly, in the savannah zones of Nigeria, is generally associated with the inability to sufficiently supply high quality forage, especially during the dry season. This has been the main cause of southward migration of herdsmen and the seemingly unending cases of farmers-herder clashes, cattle rustling and banditry that have claimed several lives (Abdena, 2013).

Some of the most available and popularly used forage grasses in ruminant feeding in Northern Nigeria include *Pennisetum pedicellatum* (kyasuwa- Hausa), *Androgogon gayanus* (Gamba - Hausa), *Cenchrus biflorus* (karangiya - Hausa), *Chloris gayana* (kanarin doki - Hausa), *Digitaria horizontalis* (harkiya - Hausa), among others (Garba *et al.,* 2022). However, available data on their chemical composition in the Sahel to assess their nutritional value for animals and possible utilization in traditional medicine is scarce. *Pennisetum pedicellatum, C. biflorus* and *A. gayanus* are some of the most available and used grass pastures for ruminants feeding in the study area. Apart from nutritive value vis a vis the nutritional requirements of livestock, assessment of chemical composition of forages is also useful in the area of phytomedicine. Phytochemicals are plant-based bioactive compounds produced by plants for their protection.

The aim of this research work was to evaluate the proximate composition and some phytochemical profile of three grass species; *P. pedicellatum*, *A. gayanus,* and *C. biflorus* in Yobe State. Results obtained in this study will help animal scientists, pasture agronomists, extension agents and livestock farmers in making informed decisions on effective and optimal utilization of these forage species. It will also help compound ruminant feed millers and livestock farmers with intensive and semi-intensive ruminant production systems properly mix concentrates/supplements with chopped forage to balance rations to meet the nutrient requirements of their animals.

Methods

The study was conducted at Federal Polytechnic, Damaturu, Yobe State. The area is located within latitude 11^0 North and longitude 13.5^0 East. The state shares common boundaries with Borno to the East and South-East, Jigawa to the Northwest and Bauchi and Gombe states to the Southwest (NPC, 2006). The rainy season in Damaturu is short, scorching and starts from the month of June to September with its peak at August. Rainfall could be erratic, epileptic and ranges between 180 - 240mm with relative humidity of 75 % during the rainy season with a mean annual temperature of 28^0C. The vegetation is savannah grassland with grasses, sparse dwarf trees and shrubs. Cattle, sheep and goat are usually the most important animals grazing in the area by Fulani pastoralists (ACReSAL, 2023).

The study area was a natural rangeland and three (3) forage species of *P. pedicelatum, C. biflorus and A. gayanus* were harvested at bloom stage, shade-dried for 10 days, milled into 2 mm particle size and stored in polythene bags ready for laboratory analysis of proximate composition and phytochemistry. Laboratory analysis was done at the Federal Polytechnic, Damaturu, Yobe State using the procedure of AOAC (2005). Crude protein (CP), Crude fibre (CF) and Ether extract (EE) were analysed while Nitrogen Free Extract (NFE) was obtained by calculation using the following formula;

$$NFE\ \% = 100\% - (\%\ CP + \%\ EE + \%\ CF + \%\ Ash + \%\ moisture)$$

Test for alkaloids, tannins, saponins and flavonoids were conducted following the procedures of Sofowara, 1993.

All data obtained from laboratory analysis was analyzed for mean and standard deviation (Descriptive Statistics) using the SPSS v. 25 (SPSS, 2005).

Results and Discussion

Proximate composition of Pennisetum pedicellatum, Androgogon gayanus and Cenchrus biflorus

The results for proximate analysis of *P. pedicellatum*, *A. gayanus* and *C. biflorus* are presented in Table 1. Values for moisture content (g/100g sample) were 7.11 g for *A. gayanus,* 4.27 g for *P. pedicellatum,* and 3.65 g for *C. s biflorus*. Ash content ranged between 11.79 and 21.03 g in *A. gayanus* and *P. pedicellatum* respectively. Crude fibre level was highest in *A. gayanus* (31.23 g) followed by *P. pedicellatum* (21.03 g), then *C. biflorus* (16.42 g). The crude fibre content for *A. gayanus* obtained in this study is lower than 40.70 g/100g reported by Salah *et al.* (2014) and 34.32g/100g (Amada *et al.,* 2020). On the contrary, Rahman *et al.* (2020) reported a lower mean value (18.00 g/100g) for crude fibre in *P. pedicellatum* than obtained in the present study. Furthermore, the mean crude fibre value for *C. biflorus* obtained in this study is slightly lower than 20.80g/100g (Hassan *et al.,* 2018). These differences are probably attributable to the stage of growth at which the grass was harvested. Usually, plants harvested late in their growth cycle contain higher amount of crude fibre than those cut at earlier stage (Reference).

Ether extract was higher in *P. pedicellatum* (3.87 g) than in *A, gayanus* and *C. biflorus* which were identical (2.54 g). Values for crude protein were 10.62, 8.95, and 6.81 g for *A. gayanus, P. pedicellatum and C. biflorus,* respectively. These values are comparable with 9.81 g/100g for *P. pedicellatum* (Salah *et al.,* 2014), 2.60 – 19.0 g/100g for *A. gayanus* (Evitayani *et al.,* 2004) and 3.70 – 22.00 g/100g for *C. biflorus* (Ahmed *et al.,* 2003). Nitrogen free extract, ranged from 36.70 g to 50.53g and. was highest in *C. biflorus* and lowest in *A. gayanus*. However, the value for *A. gayanus* is comparable with 37.84g/100g reported by Salah *et al.* (2014).

Table 1: Proximate composition of selected pasture grass species in Yobe state, Nigeria.

	Grass specie			
Parameter (g/100g)	***A. gayanus***	***P. pedicellatum***	***C. biflorus***	**SD**
Moisture	7.11	4.27	3.65	0.07
Ash	11.79	21.03	16.42	0.02
Crude fibre	31.23	18.93	20.06	0.11
Ether extract	2.54	3.87	2.54	0.19
Crude protein	10.62	8.95	6.81	0.13
Nitrogen free extract	36.70	42.96	50.53	0.15

SD = Standard deviation

Phytochemical Contents of Pennisetum pedicellatum, Androgogon gayanus and Cenchrus biflorus

The results for Phytochemical analysis of *A. gayanus, P. pedicellatum*, and *C. biflorus* are presented in Table 2. Mean values for flavonoids were; *A. gayanus* (0.07 g), 0.15 g (P. *pedicellatum*) and 0.04 g (*C. biflorus*). The widespread distribution of flavonoids, their variety and their relatively low toxicity compared to other active plant compounds (for instance alkaloids) meant that many animals, including humans, could ingest significant quantities in their diet. Tannin content was higher in *P. pedicellatum* (0.26 g), followed by *A. gayanus* (0.04 g), then *C. biflorus* (0.02 g). This is much lower than 10.25 g/100g reported by FAO (2016) and Sulaiman *et al.* (2020) for *A. gayanus* and *P. pedicellatum* respectively. [Why the big difference?] Tannins can reduce feed intake when found in high concentration in feed. They also precipitate proteins in the gut, reducing their digestibility (Mavromichalis, 2020).

Saponin values were 0.09 g (*A. gayanus*), 0.10g (*P. pedicellatum*) and 0.16 g (*C. biflorus*). These values are lower than 0.85 g/100g for *P. pedicellatum* (Clayton *et al.,* 2006), 4.01 g/100g for *A. gayanus* (FAO, 2016) and Cirade *et al.,* (1991) for *C. biflorus.* Saponins are glycosides present in plants, the low concentration of saponin obtained in this study will ensure an effective transverse tubular system and sarcoplasmic reticulum. (Desai *et al*., 2009). Mean values for alkaloids ranged from 0.14 g (*C. biflorus*), to 0.25 g for *A. gayanus*. Grinkevich and Safronich (1983) stated that alkaloids content in plants is usually very low and varies in plant, depending on the tissue. Depending on the type of plant, the maximum concentration is mostly observed in the leaves. This study provides an insight into the concentration of phytochemicals in the three indigenous pasture grasses studied. At harvest, the levels were low, indicating that that species could be selected for healthy animal nutrition without any detrimental effect on livestock fertility (Butkute *et al*. 2018)

Table 2: Phytochemical contents of three pasture grass species form Yobe state, Nigeria.

	Grass specie		
Parameter (g/100g)	***A. gayanus***	***P. pedicellatum***	***C. biflorus***
Flavonoids	0.07	0.15	0.04
Tannins	0.04	0.26	0.02
Saponins	0.09	0.10	0.16
Alkaloids	0.25	0.20	0.14

Conclusion and Recommendation

Based on the results obtained in this study it was concluded that the three grass pasture species *P. pedicellatum, A. gayanus and Cenchrus biflorus* harvested at the bloom stage of growth or life cycle contain appreciable levels of nutrients and secondary metabolites as required by ruminant animals especially during periods of forage and feed scarcity. *Andropogon gayanus* had the highest crude protein content of the three species, followed by *P. pedicellatum. Andropogon gayanus* is therefore recommended for improving rangelands for livestock production in semi-arid rangelands of Yobe state, Nigeria.

Abstract

Chyangra goat is important in the crop-livestock farming system for poverty reduction, livelihood, and nutritional security for smallholder farmers at high altitudes in Nepal. These goats are mainly raised for meat, fiber, and as pack animals. The study primarily aims to assess the effect of non-genetic factors on the growth performance and quality of fiber of Chyangra goats in different rural municipalities of the Mustang district. Kagbeni village of lower Mustang; and Lomanthang and Charang village of upper Mustang were the sampling sites. Chyangra fiber length was measured using a measuring pad and ruler and fiber diameter was analyzed using the Optical Projection Microscope Method whereas weight of different age groups was measured using a digital weighing balance. The fixed effect model was used to analyze the least square mean for fiber length, diameter, and weight from different sexes, locations, and age groups. The overall least square mean and standard error for fiber diameter and fiber length were 15.4±0.7 µm and 44.2±0.2 mm respectively. In contrast, the body weight of 530 Chyangra for one, two, three, four and more than four years were 12.4, 18.7, 23.9, 26.3 and 20.0 kg respectively. Males were heavier than females in all age groups. The results exhibited a wide variation in growth performance and fiber quality parameters indicating the potentiality to improve Chyangra growth rates and fiber quality by adopting proper management and selection methods.

Introduction

Chyangra goats (*Capra hircus*), also known as Himalayan goat, occupies an important place in crop-livestock farming system for poverty reduction, livelihood, and nutritional security for smallholder farmers across Nepal. Goats can be used for production of meat, milk, manure, fiber (*Pashmina or Cashmere*), leather, and as a means of transportation in the mountainous region of Nepal. Demand for goat meat increases during religious festivals of Nepalese people and fetches good price during these periods (Joshi et al. 2018). Four indigenous breeds of goat in the country have been identified and characterized so far: Terai, Khari, Sinhal and Chyangra (Pokharel et al. 2012; Gorkhali et al. 2022). Chyangra goats is the dominant breed across northern trans-Himalayan regions from an altitude of 2500–5000 mean above sea level (masl) from east to west. Chyangra goat population is estimated to be around 1% of the total goat population, i.e. 0.15 million heads in Nepal (MoALD 2024). Though these goats are reared primarily for their high-quality fiber, they are also sought for their meat. Only a limited number of studies have been conducted to determine fiber quality, and the small sample sizes used in these studies constrain their validity and reliability (Bhattarai 2017). Hence, the present study aims to assess the growth performance of Chyangra goats and to assess the effect of non-genetic factors on the fiber quality of Chyangra goats (diameter and length) in different locations of Mustang district.

Methods

Data on growth performance, fiber quality, and production systems were collected from different locations of Mustang district: Lomangthang-5 and Charang (upper elevation) and Kagbeni (lower elevation). Upper Mustang has a trans-Himalayan climate, while lower Mustang has a sub-alpine to alpine climate. Mustang is generally cool and semi-arid, with low rainfall (250–400 mm). A detailed questionnaire and data sheet were used to assess the Chyangra goats' production system, weight, fiber, and livestock management, including nutrition, health, breeding, and housing. Goats were weighed using a digital scale, and age and sex were recorded.

Growth performance from 530 Chyangra goats of different age groups (up to one, two, three, four, and above four years) from two altitudes were measured. Similarly, thirty-eight goats from Upper Mustang and twenty two from Lower Mustang were sampled, with 30 males and 35 females. Fiber samples were collected from each goat and stored in separate Ziploc bags, with location, age, and sex recorded. The sampled animals were assumed unrelated and aged 1-4 years. Sampling took place in early spring (mid-March to mid-April) in 2022 and 2023, before the molting season. Fiber samples were collected using a special combing device, with 5 grams taken from each goat (Figure 1).

Figure 1. Comb, Combing, and collection of fiber and sampling

Statistical analysis of the production system data was conducted using SPSS version 23. To address the issue of disproportionate subclass numbers, growth performance and fiber quality were analyzed using the Least Squares and Maximum Likelihood Method proposed by Harvey (1990), based on the Henderson (1953) model. Mean comparisons were performed using Duncan's Multiple Range Test (Duncan 1955). The fixed effect model was applied to analyze the least square means for various non-genetic factors (location, sex, and age group) in relation to the growth performance and fiber quality of Chyangra goats. The model is outlined as follows:

$$Y_{ijk} = \mu + a_i + b_j + c_k + e_{ijkl}$$

Y_{ijkl}=body weight, fiber length, diameter, wax percentage; μ=overall mean; a_i=fixed effect of i^{th} location (i=Upper and Lower); b_j=fixed effect of j^{th}sex (j=male and female); c_k=fixed effect of k^{th} age(k=<1yr,2yr,3yr,4yr,>4yr); e_{ijkl}=random error

Results

Body weight of Chyangra goat

Among the 530 observations recorded the overall mean body weight was 20.3 kg, with animals from Lower Mustang being heavier. Males weighed more than females, and the highest weights were observed in the 37–48-month age group, followed by 25–36 and 13–24 months. Weights in the 13–24 month group were similar to those over 48 months, with the lowest weights in 4–12 month old animals (Table 1). Chyangra from Lower Mustang had higher weights. Males were heavier than females, showing sexual dimorphism. Body weight increased with age but declined after 48 months (see Table 1).

Table 1. Least Square Mean and Standard Error of Mean (SEM) of body weight (kg) of Chyangra goats from different locations of Mustang district

Factors		Number of observations	LSM±SE
Overall Mean		530	20.3±2.42

Fiber quality of Chyangra goat

The overall mean fiber length was found to be 44.2±0.2 mm. Significant differences in fiber length were observed between locations and sexes, with goats from Upper Mustang having longer fibers compared to those from Lower Mustang. However, no significant difference in fiber length was found with respect to age. The overall mean fiber diameter was observed to be 15.4±0.7 µm . There were no significant variations in fiber diameter by location, age, or sex across these regions. However, samples from Lower Mustang showed lower values compared to those from Upper Mustang.

Table 2. Least Square Mean and Standard Error of Means (LSM±SEM) for fiber diameter and length in different

			Fiber length(mm)	Fiber Diameter (µm)
Factors		n	LSM±SE	
Overall		60	44.2±0.2	15.4±0.7
Location			P <.001	NS
	Upper	38	45.2±0.10[a]	15.6±0.4

Discussion

Bhattacharya et al. (2004) reported similar weights in Ladakh for Changthangi goats (20.0 ± 2.1 kg for males and 18.7 ± 1.9 kg for females at 300 days) as in our present study. The findings align with studies by Pokharel et al. (2012) and Gorkhali et al. (2022). Fiber diameter and length vary based on the goat's breed, age, and sex, with genetics playing the primary role and environmental factors such as feeding, housing, and management contributing to these traits. Thinner diameter fibers are often genetically linked to shorter fiber length (McGregor 2003). The present study demonstrates that Chyangra cashmere fiber is of high quality, with a diameter ranging from 14 to 18 µm (Gorkhali et al. 2023) similar to the finest cashmere produced by Chinese and Mongolian goats (14.5-16.5 µm) (Gurkan et al. 2023). The fiber diameter of Chyangra aligns closely with that of cashmere goats from China, Mongolia, and Afghanistan, which have diameters of 15.1 µm, 15.5 µm, and 15.15 µm, respectively (Kerven & Shrestha 2024; Couchman & McGregor 1983). Fiber length is vital for producers, as longer fibers have high value and directly increase market price. Gorkhali et al. (2023) observed similar findings in Chyangra goats from Mustang. The average fiber length determines its suitability for worsted (spin long, fine fibers into smooth, strong yarn – 30 to 50 mm) or woolen systems (spin shorter, coarser fibers into a bulkier, softer yarn - < 30 mm), with fibers under 30 mm being unsuitable for worsted processing (Ryder 1987). Female goats typically have shorter fibers, likely due to differences in feeding practices (Khan et al. 2012). Nutrition is a key factor in fiber quality (Summer & Bigham 1993), supporting findings by Bhattacharya et al. (2004). Although earlier studies linked fiber length to age, sex, and reproduction (Tuncer 2018), this study found no age-related effects. Seasonal reductions in fiber growth may result from nutrient competition during pregnancy and lactation (Khan et al. 2012), though increased feed intake can mitigate these effects (Oddy & Annison 2000).

Conclusions and implications

Non-genetic factors, including location, sex, and age, significantly influence the fiber quality and growth performance of Chyangra goats. These findings suggest that targeted improvements can be achieved by implementing effective management strategies and selection practices within a flock. By focusing on these factors, farmers can optimize the rearing conditions and selectively breed goats with desirable traits, ultimately enhancing both fiber production and overall growth performance in Chyangra goats.

Carbon balance analysis of a sown pasture in inland arid area, China

Shanning, LOU[1]; Fujiang, HOU[1*]

1 State Key Laboratory of Herbage Improvement and Grassland Agro-ecosystems, Ministry of Agriculture and Rural Affairs, College of Pastoral Agriculture Science and Technology, Lanzhou University, Lanzhou, 730020, China

Key words: Carbon footprint; Food equivalent unit; Grazing; Greenhouse gases

Abstract

Grazing grasslands cover approximately 26% of the Earth's ice-free land surface, making them an important component in maintaining the global carbon balance. Recent research has shown significant carbon losses in soils under intensive pastures, particularly in developing countries where livestock farming is a dominant land use. This study aims to evaluate the net ecosystem carbon balance (NECB) of cultivated grassland grazing sheep pasture in the arid inland region of Northwest China. Based on life cycle analysis of carbon balance in grassland production systems, we hypothesis that grazing systems have a higher carbon sink capacity than hay harvesting systems because of the coupling between grassland and livestock. The sown pasture of wheat and alfalfa-fescue mixture rotationally grazed by sheep was the carbon sink, whilst the harvested pasture was the carbon source (four years). The carbon emissions per food equivalent unit (a food production units calculated based on protein and energy content) in the grazing pasture was 78.84% lower than that of the hay pasture. In grazing annual pasture and perennial pastures, the carbon emissions from livestock, processing and allocation of forage products accounted for 3.95%, 96.05% and 2.01%, 97.99% of the whole carbon emissions, respectively. The carbon emissions from sown pasture, where hay is harvested, mainly came from fertilization, irrigation and the processing and transportation of forage products. Therefore, strategies of carbon mitigation should focus on the greenhouse gas emissions of livestock production in grazing systems, and the processing and circulation of fertilization, irrigation inputs, and forage products in hay-harvesting pasture.

Introduction

Grazing grasslands, which account for 26% of the Earth's land surface and possess a substantial carbon (C) content in soils (Steinfeld et al., 2006), play a crucial role in the global carbon balance. The conversion of grasslands to cropland typically leads to a significant depletion of soil carbon (Davidson and Ackerman, 1993), while establishing pastures on previously cultivated land results in an increase in soil carbon (Post and Kwon, 2000). However, there is limited knowledge regarding the carbon balance of intensively cultivated grassland pastures and the impact of different patterns of grassland use and types on soil carbon. Previous studies have reported varying outcomes including increases, decreases, or no changes (Conant et al., 2001; Wang et al., 2011; Viglizzo et al., 2019; Lorenz et al., 2018). Therefore, this study aims to assess the net ecosystem carbon balance (NECB) of sheep grazing pasture within arid inland regions of Northwest China.

Methods

This study was conducted at Linze Grassland Agriculture Trial Station of Lanzhou University, Linze County, Gansu Province, China. Annual mean precipitation is 121~~.5~~ mm, and annual mean evaporation potential is 2390 mm. An integrated production system for sown pastures and sheep grazing has been established in the experimental area, consisting of two types of grassland: annual pasture (GA) and mixed perennial pasture （GP）. Sheep are rotated between these two types of grasslands, with grazing intensity controlled based on the height of the grass (GS). Grazing begins when the height reaches 20 cm and stops at 8 cm. The experiment covers a total area of 6 ha per grass type with three repetitions each. Additionally, a control group (HS) was set up in each type of grassland(HA, HP) using a 10 m x 10 m fence to harvest hay after maturity.

The carbon balance of a grassland agro-ecosystem is the cumulative sum of the carbon balances across its four production layers (pre-plant production system, PPP; plant production system, PP; animal production system, AP); post-biology production system, PBP) or three interfaces (Interface between herbage and site-interface A, IA; Interface between grassland and livestock-interface B, IB; Interface between grassland livestock system and social and economic management-interface C,IC). The carbon balance of a production layer or interface of a grassland system can be determined according to four parts. Carbon input (CI) refers to fertilizers, machinery, seeds, animal power, manure and other substances imported from outside the grassland system, CO_2 absorption and assimilation by photosynthesis, CH_4 and N fixed by microbial activities, and carbon and nitrogen accumulation by dust fall and soil and water conservation. Carbon emission (CE), human and livestock consumption of grass and livestock products, including food, energy, animal power, daily necessities, manure, is reduced to GHG within a certain period of time. Carbon fixation (CF), herbage, livestock, excrement, exists in a storable form in the grass industry system for a certain period of time. Carbon output (CO) refers to the output of grass and livestock products, seeds, animal power, manure. The carbon balance of the grassland system is CBGAE=CI+CF-CE-CO. If CBGAE > 0, that is, CI+CF > CE+CO, the grassland system is a carbon sink, and vice versa. The carbon balance of a production layer or an interface is calculated in the same way, and the sum of their initial carbon amount and carbon balance is the current carbon amount.

Results

The grazing system (GS) exhibits a positive carbon balance (> 0), indicating its role as a carbon sink. Carbon emissions primarily arise from the greenhouse gas release by sheep in AP, as well as the greenhouse gas emissions during the PPP's production process and livestock product output. Within the animal production layer, 43% of carbon is returned to the grassland through excrement, while 57% is discharged into the environment. The PBPcontributes to carbon emissions mainly through greenhouse gas emissions during its production process and from processing and outputting livestock products. Annual grazing grasslands (GA) demonstrate a higher carbon balance compared to perennial grasslands (GP).

The hay production system (HS) acts as a carbon source with a negative carbon balance. This can be attributed to higher levels of carbon emission in the plant production layer (PP) due to fertilization and irrigation practices. As there are no livestock involved, the animal production layer maintains a neutral carbon balance of zero. Carbon emissions within this system predominantly stem from greenhouse gas emissions during post-biological production processes and from processing and outputting forage products. Additionally, labor and mechanical input requirements are greater in hay production systems compared to grazing systems. Lastly, perennial mowing pasture (HA) exhibit higher carbon balances than annual pasture (HP).

Discussion

Grassland reclamation is the most violent human activity factor affecting soil carbon storage in grassland. The reclamation process will destroy the dense root layer, expose the deep organic carbon in the soil to the air, and accelerate the soil respiration process (Feng et al., 2019). When grassland is reclaimed for farmland, 30%-50% of the original soil carbon pool is lost, and most of this loss is caused by soil respiration emission (Genxu et al.,2002;

Rees et al., 2005). In this study, the emission of annual sown grassland was higher than that of perennial sown grassland, mainly because annual sown grassland needed to be tilled and sowing every year. In this process, the organic carbon in the deep soil was exposed to the air, which accelerated the soil respiration process.

Grazing has different degrees of influence on grassland plants, litter and soil (Li et al., 2024). These factors are not only important factors affecting grassland soil respiration (Kamran et al., 2023; Wang et al., 2023), but also affect the effects of water and heat factors on soil respiration to a certain extent. So far, there are many researches on the effects of grazing on soil respiration at home and abroad, but the results are not consistent. Some studies have shown that grazing can significantly reduce soil respiration intensity (Cao et al., 2004; Li et al., 2024), also found that the vegetation and soil conditions under fenced grazing were superior to those of grazing land, but the impact of grazing on soil respiration was not obvious (Zhao et al., 2016). In addition, studies have found that light grazing can promote soil respiration, while intensive grazing can reduce soil respiration rate (Koncz et al., 2015). It can be seen that grazing is still one of the uncertainties in estimating grassland carbon budget. In this study, the carbon balance of the grazing system is greater than that of the hay harvesting system, which is a comprehensive calculation based on the perspective of the whole ecosystem. The calculation result of the soil respiration part is that the soil respiration carbon emission of the grazing system is small, that is, the grazing reduces the soil respiration intensity and soil respiration emission.

According to the carbon input and output analysis methods of four production layers and three interfaces of grassland agro-ecosystem, the carbon balance of grazing system is the carbon sink, and the carbon balance of harvesting hay system is the carbon source. The contribution rates of the carbon balance of the four production layers to the carbon balance of the grazing system were 0.1% (pre-plant production system, PPP), 84.6% (plant production system, PP), -0.5% (animal production system, AP) and -17.0% (post-biology production system, PBP). The contribution rates to the carbon balance of mowing and harvesting hay system were 0.1% (PPP), 49.7% (PP), 0.0% (AP) and -51.1% (PBP). The carbon emissions of animal production layer and post-biological production layer in grazing system and harvesting hay system accounted for 3.95% (AP), 96.05% (PBP), 0% (AP) and 100% (PBP) of the system carbon emissions, respectively. The carbon balance of the three interfaces contributed 84.7% (BIA), 49.8% (BIB), -0.5% (BIC), 0.0%(BIA), -17.0%(BIB) and -51.1% (BIC) to the carbon balance of the grazing system and the harvesting hay system. The carbon emissions from mowing and harvesting hay, derived from fertilizers, irrigation inputs, and processing and circulation of forage products, are about three times that of grazing systems. The emission reduction of grazing system should pay attention to the animal production layer to reduce greenhouse gas emissions from the range-livestock interface. The hay production system should pay attention to the post-biological production layer, and reduce the carbon emission and carbon output in the process of product processing and circulation from the interface of grass and livestock systems-human activities.

Key words: Pastures; Carbon sequestration; Himalayas; Agroforestry; Sustainability

Abstract

The present investigation was carried out to quantify carbon stock and economic potential of the pastoralsilviculture system along altitudinal gradient in Indian north-western Himalayas during 2019-2021. The area was divided into four altitudinal ranges as per agro-ecological classification of the state viz., altitudinal ranges viz., zone-I (<1000 m amsl), zone-II (1000-1500 m amsl), zone-III (1500- 2500 m amsl) and zone-IV (> 2500 m amsl). Further, farmers practicing pastoralsilviculture system were divided into three farmer categories *viz.* marginal (less than 1 ha land area), small (1-2 ha land area) and semi-medium (2-4 ha land area) as per Government of Himachal Pradesh standards. The results revealed that the total biological productivity (aboveground+belowground) of the pastoralsilviculture system ranged between 24.90-43.24 Mg ha^{-1}, showing an increasing trend along altitude with zone-III having maximum total biomass production. The bio-economic potential of the pastoralsilviculture system was not found to be significantly affected by the farmer category. Soil carbon density was maximum (31.65 Mg ha^{-1}) at zone-I which was significantly at par with soil carbon density at zone-III (30.86 Mg ha^{-1}). Total carbon stock potential, comprising vegetation carbon and soil carbon, of the system was recorded maximum (52.48 Mg ha^{-1}) for Zone-III, while minimum (42.58 Mg ha^{-1}) for zone-IV. Economic potential of the pastoralsilviculture system in terms of output:input ratio was found maximum (3.73) in zone-III which was significantly at par with output:input ratio in zone-II (3.62) and minimum was recorded in zone-IV (3.05).

Introduction

Tree, crop and livestock are the three basis components of agroforestry. Rearing of livestock is an integral part of the rural livelihood in the western Himalayan region that helps in maintaining the sustainability of the farming system. Livestock being an inseparable component of agroforestry is not only helpful in maintaining sustainability of the system but also is an enterprise itself. Livestock to a certain extent depends for fodder on the common property resources which play an important role in providing round the year fodder to livestock through grazing (Pathania and Dev 2011). In the Himalayan region, there is a dynamic relationship between the livestock and common property resources such as forests, water resources and grazing land. The 1.5 million hectare of grasslands constituting around 33 per cent of the land utilization of Himachal Pradesh is suffering from low productivity (GoHP 2020) mainly attributed to the lack of management, overgrazing and weed infestations. This ultimately affects the productivity of the livestock mainly dependent on these natural resources because of dearth of nutritious green fodder along with dry fodder and concentrates (NITI 2018) and widening gap between the demand and supply of the green fodder. Further, under the climate change scenario the low biological productivity of the grasslands also pose challenges to adapt and mitigate the adverse climatic conditions. Integrating grasses with the tree component may address the challenge of biological productivity, dearth of quality fodder along with sustainable land management. Pasture-based land use systems may be the solution to the problems faced by livestock sector and can help in mitigation of the challenges posed by the climate change. Keeping in view the importance of pastures the present study was carried out for determining the bio-economic potential of the pastoralsilviculture system along altitudinal gradient in western Himalayan region.

Methods

The present study was conducted during 2020-2021 at Nauni, Solan (HP), India in Chamba district of Himachal Pradesh located in North-Western Himalayas. The study area was divided into four altitudinal zones representing the four agro-climatic zones found in the state Himachal Pradesh viz., zone-I (<1000 m amsl) (Z1), zone-II (1000-1500 m amsl) (Z2), zone-III (1500-2500 m amsl) (Z3) and zone-IV (>2500 m amsl) (Z4). The pastoralsilviculture system being practiced by the three farmers categories viz., marginal (<1 ha) (F1), small (1-2 ha) (F2) and medium (2-4 ha) (F3), in the study area were identified for the assessment of their bio-economic potential. For herbage and shrubs, destructive method of sampling was adopted by making the plots of standard size 1×1 m^2 and 5×5 m^2 respectively, while, for trees non-destructive method based on the regional volume equations (FSI 1996) was used with sampling in 0.1 ha plot. The method of aboveground biomass (AGB) estimation of trees was as follow:

Stem biomass (Mg ha^{-1}) = VOB x WD
Where, VOB = volume over bark (from volume equations)
WD = volume weighted average wood density

The AGB of a tree was calculated by formula:

AGB (Mg ha^{-1}) = Stem biomass (Mg ha^{-1}) x BEF
Where, BEF = biomass expansion factor

Belowground biomass (BGB) of a tree was calculated by multiplying its aboveground with a standard factor of 0.26 (Cairns et al. 1997). Biomass carbon stock was calculated by multiplying the biomass with the standard factor of 0.5 given by IPCC (IPCC 2003). Soil organic carbon (SOC) stock was calculated using formula given below:

SOC (Mg ha^{-1}) = Soil bulk density (gcm^{-3}) × soil depth (cm) × OC (%) × 100

Where, C: soil organic carbon density

OC: soil organic carbon percent expressed in decimal fraction

Aggregation of vegetation carbon stock along with SOC depicted the total carbon stock (TCS) potential of the system. The economic potential of the system was assessed by dividing outputs obtained from the system with inputs to manage the system and is expressed as output:input ratio (O:I). Inputs include cost per unit area for the establishment and maintenance of system components, labour, land rent and plant protection, while, outputs include the market value per unit area of the various products harvested from the pastoralsilviculture system such as grass, green fodder, fuelwood, small timber and fruit. The data on various parameters were subjected to two way ANOVA using SPSS software for analysis.

Results

Biological productivity of the pastoralsilviculture system

The results revealed that the AGB, BGB and total biomass (TB) were significantly affected by the altitudinal zones (Table 1) and interaction of altitude with farmer category (Table 2). However, no significant effect of the farmer category (Table 1) was found on biological productivity of the system. In case of altitudinal zones, AGB ranged between 19.79-34.72 Mg ha^{-1} with maximum biomass recorded at Z3 and minimum at Z1. BGB ranged between 5.11-8.52 Mg ha^{-1} with trend similar to that followed in AGB. TB, being combination of AGB and BGB, also followed the same trend and ranged between 24.90-43.24 Mg ha^{-1}. In case of interaction, AGB (37.34 Mg ha^{-1}), BGB (9.33 Mg ha^{-1}) and TB (46.66 Mg ha^{-1}) were recorded maximum for the combination Z3F1, while, minimum AGB (15.76 Mg ha^{-1}), BGB (4.05 Mg ha^{-1}) and TB (19.81 Mg ha^{-1}) were recorded for Z1F1.

Carbon stock potential of the pastoralsilviculture system

In case of SOC, altitudinal zones and interaction between the factors have shown significant variation with farmer category not having any significant contribution towards SOC (Table1 and Table 2). Maximum SOC was recorded at Z1 (31.65 Mg ha^{-1}) which was significantly at par with SOC at Z3 while, minimum SOC was recorded at Z4 (22.20 Mg ha^{-1}). In case of interaction, SOC was recorded maximum for Z1F2 (34.41 Mg ha^{-1}) significantly at par with Z1F3 and Z3F1 while, minimum was recorded for Z4F2 (19.91 Mg ha^{-1}) significantly at par with Z4F3. The higher soil organic carbon may be because of the lesser dependence on biomass as fuel, better decomposition as well as management of the system which results in the production of more biomass and its incorporation in the soil. The TCS of the system was found to be significantly affected by altitudinal zones, while, farmer category didn't affected TCS significantly. Z3 resulted in maximum (52.48 Mg ha^{-1}) storage of the carbon stock in pastoralsilviculture system, while, Z4 was found to have least (42.58 Mg ha^{-1}) carbon storage in the pastoralsilvilculture system which was significantly at par with carbon stock at Z1 and Z2. Considering interaction, TCS was recorded maximum (55.09 Mg ha^{-1}) for the Z3F1, while, minimum (38.51 Mg ha^{-1}) was recorded for Z1F1.

Economic potential of the system

Considering economic potential of the pastoralsilviculture system, only altitudinal zone was found to have significant effect on the O:I. The O:I of the system varied between 3.05-3.73 with maximum O:I recorded at Z3 which was significantly at par with O:I in Z2 while, minimum ratio was recorded in Z4 which was at par with Z1.

Table 1: Bio-economics of different farmer categories practicing pastoralsilviculture along altitude

Parameters / Factors	AGB (Mg ha^{-1})	BGB (Mg ha^{-1})	TB (Mg ha^{-1})	SOC (Mg ha^{-1})	TCS (Mg ha^{-1})	O:I

Discussion

Biomass production may be the result of physiographical features, compositional differences, age, density of trees, interaction, farmer preferences, needs as well as ecological conditions as reported by Gupta et al. 2017 and Kumar et al. 2021, along altitude in Himalayan region. At Z3, the perennial components were dominated by the mature tree species having higher biomass production such as *Cedrus deodara*, *Pinus wallichiana*, *Salix spp* etc. which may be the reason for the increased biomass production. Marginal farmers being subjected to the dearth of the land availability make intensive use of the available resources in order to fulfill various needs, which may result in the higher biological productivity under the influence of intensive land management as can be predicted from higher biomass production in Z3F1. Carbon stock of the system is the aggregation of the carbon stored in the biomass as well as in the soil. The biomass carbon is just the fraction of the biological productivity of the system so it is obvious that it will show variations similar to that recorded for the biomass production of the system. Reduced soil carbon stock along altitude may be because of intensive utilization of the litter as well as biomass (Goswami et al. 2017) for fulfilling the fodder and fuel requirements. Further, decrease in temperature along altitude may reduce the rate of decomposition which under the influence of steep slopes may cause movement of the organic matter to the lower regions. Although soil carbon stock was higher at lower elevations yet the broad contribution of the biomass to total carbon stock of the system resulted in maximum carbon stock at Z3. The higher carbon stock at Z3F1 may be the cumulative effect of the farming intensity with the composition as well as density of the perennials in the system as reported by Singh et al. 2018; Adhikari et al. 2020. Pasture based systems are remunerative from the perspective of marginal lands where farmers may get multiple products along with the prevention of land from degradation. However, higher economic potential of the pasture based land use systems can be availed by incorporating agriculture and horticulture components as reported by Tiwari et al. 2021.

Thus, it can be concluded that pastoralsilviculture is the prominent pasture-based land use system in the study area having highest bio-economic potential at zone-III. The system can serve as an important land management option to reclaim the degraded land areas as well as a viable option for the mitigation and adaptation to climate change.

Abstract:
Natinal Mission on Natural Farming aims at creating institutional capacities for documentation and dissemination of best practices to implement self sustainable self generating natural farming systems to cut down cost of cultivation ,resource conservation, healthy soils,environment and food. Cell have been created for effective implementation at state level and distrct level. Project Co-ordinator and Technical Co-ordinator at HQ unit is an implementating Government nodal agency to implement the schemes of diversified agriculture support project in Uttar Pradesh. Namami Gange mega project launched by Honrable P.M. of India in 2022-23. The article is based on scheme implemented in different 28 districts of Western Uttar Pradesh. Corresponding author is the Technical Coordinatior in Government of Uttar Pradesh, under Co-ordination Department, Lucknow,(U.P.). Trials were conducted under natural farming in Bareilly district. It is recorded that Lentil , Gram, Mustard perfomed better in yield q / ha followed by old variety of Rice and Wheat. Andhra Pradesh 5.92 lakh, Himachal Pradesh 1.53 lakh and Gujrat 2.0 lakh number of farmers, and 3.73, 3.56, 8.50 Village Panchayat and 2.68 lakh ha, 9192 ha, and 2.5 lakh ha area has been covered respectively under natural farming. Cost and yield under natural farming in comparision to oragnic and conventional farming is lower.The trials have been conducted in different locations because of standisation of subhash palekar's model of BPKP (ICAR-Report,2017-18).Uttar Pradesh has coverd 97460 ha area and 05 lakh farmers during last two years (Niti Ayog Report,2024-25).Project: Uttar Pradesh Agriculture Growth and Rural Enterprise Ecosystem Strengthening (AGREES) has been launched in 28 district of eastern Uttar Pradesh state .The Government of India has applied for financing in the amount about US$ 350 Million equivelent from World Bank toward the cost of the IPF Project.The project has included the components are-Productivity enhancement,commodity clusters,digital and financial ecosystems and project management ,learning and partenerships.Cow dung based bio-stimulant was prepared locally by fermenting with cow urine,jaggery and pulses flour about 400 kg for an acre of land applied to fields increased the microbial count in the soil,which supplies the plants with essential nutrients (Jivamrit).

Introduction:

Natural farming offers a solution to various problems, such as food insecurity, farmers' distress, and health problems arising due to pesticide and fertilizer residue in air, food and water, global warming, climate change and natural calamities. It provides opportunity to use homemade seeds, local cattle's dung, urine, local vegetation and agriculture produce based formulations for plant nutrition, crop protection from pests and stress thus reduces the cost of cultivation and dependence of the farmer on market. It also has the potential to generate employment, thereby stemming the migration of rural youth. Natural farming, as the name suggests, is the art, practice and, increasingly, the science of working with nature to achieve much more with less. Natural farming is a chemical-free alias traditional farming method. It is considered as agro-ecology based diversified farming system which integrates crops, trees and livestock with functional biodiversity. In India, Natural farming is promoted as Bharatiya Prakritik Krishi Paddhati Programme (BPKP) under centrally sponsored scheme- Paramparagat Krishi VikasYojana (PKVY). BPKP is aimed at promoting traditional indigenous practices which reduces externally purchased inputs. It is largely based on on-farm biomass recycling with major stress on biomass mulching, use of on-farm cow dung-urine formulations; periodic soil aeration and exclusion of all synthetic chemical inputs. According to Department of Animal Husbandry, Dairying and Fishries Report (DADF, 2018-19),GOI, natural farming will reduce dependency on purchased inputs and will help to ease small holder farmers from credits burden. Natural Farming will be compared with Organic Farming and Conventional Farming where external inputs will be used as per requirement.The project envisions to trasform agri supplyand value chains to empower key stakeholders including Farmer Producer Organizations (FPOs),MSMEs,and Agribussiness players to srengthen market infrastructure and promote climate resilient agriculture practices to revive natural ecosystems and to develop climate resilience.

Materials and Methods:

Bhartiya Prakratik Krishi Padhati is a zero external input system of organic agriculturebased on farm biomass recycling,use of on farm cow dung-urine formulations(Bijamrit and Jivamrit). Selection of farmers dry lands, rainfed areas and tribal areas are to be given prefrence. The proposals under BPNP 409400 ha area and Rs 5599.32 lakh have been released for different states of the India. Keeping in view growing acceptance of BPKP has been updated as National Mission on Natural Farming.NF initiatives by GOI and States in FY 2022-23 nearly 9.40 lakh ha area initiated under natural farming in 17 states. More tnan 28 lakh farmes participating in NF. Namami Gange-total 1.48 lakh ha sanctioned to Bihar, Jharkhand, UP and Uttrakhand for 5 km on each side of River Ganga. Uttar Pradesh Diversification of Agriculture Support Project (UPDASP) has been implemented 28 districts of western uttar pradesh through Government of U.P. since 2014-15 (UPDASP, Report, 2014-15, 2022-23). The objective of crop productivity enhancement is to focuses on strengthening agricultural productivityagainst the backdropof high levels of climate risks and variability in prouctivity across the project areas.To support the integration of smallholder farmers into value chainsto select high-value commodities ,thereby increasing productivity,value additionand farmers' income.

Natural farming is a sustainable way of farming agriculture is at epicentre of the country's journey towards Atma Nirbharta (Self reliance) with farmers at its core. The efforts of the government have consistently focused upon upliftment, empowerment and stability of farmers in the technical, economic and social realm. It is in this endeavour that we continuously explore various methods to achieve ecologically sustainable and economically viable methods. Natural farming is one such method that holds potential to realise all these goals. It is backed by our rich traditional knowledge, and is a practice of agriculture based on locally available resources, which makes it a sustainable and viable practice. Tarai Region of the district comprised clay, clay loam and loam soils with high fertility, high rain fall and most suited for paddy, wheat and sugarcane cultivation. Out of 15 development blocks of Bareilly district, 5 blocks viz. Baheri, Damkhoda, Shergarh Nawabganj and Bhadpura falls in this agro climatic zone IV. Project area falls under Tarai agro-climatic zone of Bareilly District.The eastern UP and Bundelkhand are two economic regions that lag behind the rest of the state in agriculture, UP-AGREES project will focus on attention on 28 districts in these two regions.The project will target the participation of of women across all the interventions.At block level,the support organization is responsible for taking the package of information to the farmers/farmer producer groups.At district level, a district coordination coomittee,headed by the District Magitrate.

Table -1: Positive Effects of Natural Farming

Natural Farming Implementation	Significance of Natural Farming
➢ Urine based farming system that did not involve any external Chemical or Organic fertilizer. ➢ It is known by various names like; Zero Budget Natural Farming, PrakritikKrishi, Cow Based Natural Farming, Shashwat Kheti, Chemical Free Agriculture, etc. ➢ GoI is promoting Natural Farming through a scheme named Bhartiya Prkritic Krishi Paddhati (BPKP).	➢ Reduced cost of cultivation ➢ Reduced water requirement of crops ➢ Climate change resilient, reduced risks in farming ➢ Rejuvenateted of farm lands ➢ Safe and healthy food for citizens ➢ Utilizing the available cattle (Desi Cow) as valuable resources ➢ Helped in arresting growing weeds for fertilizers and reduce subsidy burden.

Results:
Government of India mission on national farming 2022-23 has been implemented in different states as depicted in table-2.This farming method also usesa host of other interventions.Seed treated withcow dung based stmulant which protected young roots from fungs and other soil and seed borne diseases (Beejamrit) improved germination counts.

Figure 1: Sowing of crops under natural farming at UPDASP farm

Table-2 : Implementation of the Scheme in different states of India

Paramparagat KrishiVikasYojna (PKVY)	Bhartiya prakritik Krishi Paddhati (BPKP)
➢ 30,934 clusters (20 ha each) formed since 2015-16, ➢ 6.19 lakh ha area and 15.47 lakh farmers were benefitted, ➢ A detailed online web portal- www.jaivikkheti.in	➢ GoI is promoting natural farming through a sub-scheme named BPKP since 1920-21 ➢ BPKP same as PKVY with focus on hand holding and capacity building ➢ Area covered – 4.09 lakh ha (980 clusters of 500 ha each
Namami Gange scheme	Large Area Certification
➢ 1657 Gram Panchayat in Uttarakhand, Uttar Pradesh, Bihar, Jharkhand and West Bengal for development of Organic Farming in the villages along the river Ganga, ➢ Under Namami Gange Programme- 6181 clusters and 1,23,620 ha area covered	➢ Large area under traditional organic farming systems with no synthetic input / chemical input use history are declared as certified organic under union territory: ➢ Car Nicobar – 14,445 ha ➢ Lakshdweep – 2,700 ha ➢ Ladhak -5,000 ha area

Figure 2 : Preparation of fermentate, stimulant and its application in weed crop

Table 3 :Status of Natural Farming in three states of India

Andhra Pradesh State	Himachal Pradesh State	Gujarat State
➢ Initiated in 2015 by Rythu Sadhi kara Samthi (RySS), ➢ Knowledge dissemination to Community Resource Persons, ➢ Started with 900 acers grew to 18,000 as best practitioner of Natural Farming	➢ 4 Mega farmers sensitisation programme for 6 days each, ➢ Farmer experience led to development of local crop wise package of practice	One day workshop for 10,000 farmers in 2019 followed by seven days training of 21,861 Master Trainers, Large scale dissemination of Natural Farming techniques and Success Stories through pamphlets and video(s) (Niti Ayog, 2022)

Discussion:-

In different states, number of farmers covered and implementated area in hectares under natural farming mission has been depicted in table 3.The fields were managed to have some green cover round the year to aid carbon captureby plants from the air and nurture the soil-carbon-sponge.This might kept the microbesand other organisms like earthworms,alive which helps the soil become porous and might retained more water (Whapsa).

Table 4 : Farmers and Area Covered under Natural Farming:-

Sl. No.	State	Farmers Covered	Gram Panchayat	Area Covered	Implementing Agency
1.	Andhra Pradessh	5.92 Lakh (12.3%)	3,730 (28%)	2.68 Lakh ha (4.6%)	RySS, State Govt. Coorporation
2.	Himachal Pradesh	1.53 Lakh (16%)	3,563 (98.2%)	9192 ha (0.96 %)	State Project Implementing Unit
3.	Gujrat	2 Lakh (3.76%)	8,500 (59.6%)	2.5 Lakh ha (2.5%)	State Govt.

Source : Neeti Ayog Report, 2022-23.

During the cultivation of main crops,crop residueswere used as mulch (Acchadana or Mulching) to retainsoil moisture and which could prevent the growth of weeds.This practice of farming is being adopted in different states of India. The results are similar to there findings.At block level support organisation will take the technologies and agronomic practices to the farmers/farmer groups. Implementation is shown in above tables.

Conclusion:

Natural farming comes under priority of the Central as well as the State Governments. . BPKP is aimed at promoting traditional indigenous practices which reduces externally purchased inputs. It is largely based on on-farm biomass recycling with major stress on biomass mulching, use of on-farm cow dung-urine formulations; periodic soil aeration and exclusion of all synthetic chemical inputs. Natural farming will reduce dependency on purchased inputs and will help to ease marginal and small holder farmers to doubling the farm income. Diversification of agriculture through natural farming practices in uttar pradesh as well in other states of India is under the policy of minimum support price. It is understood that required inputs are wholey farm based . Implementation data shows that yield and cost of natural farming is lower than conventional farming . Farmers need support price for their produces of natural farming as well as other seasonl crop produce.The project is managed and implementing by the Uttar Pradesh Diversified Agricultural Support Project (UPDASP) Society.Growing multiple crops in the same patch of land also raised soil fertility (MANAGE,2023)

Indigenous Jaffna Local sheep production system as a mean of changing driver

Somasiri, SC.[1]; Wijayawardhana, D[2]

[1] Department of Animal and Food Sciences, Faculty of Agriculture, Rajarata University of Sri Lanka; [2] Department of Plant Sciences, Faculty of Agriculture, Rajarata University of Sri Lanka

Key words: Endangered indigenous sheep; Nomadic pastoral system; Sustainability dimensions

Abstract
Jaffna Local sheep (JLS) is an endangered indigenous sheep population in Sri Lanka. They have been identified as a breed that has a negative population trend. A study was undertaken to identify the sustainability dimensions of JLS production system. Socio-economic data were collected using a pre tested questionnaire from three leading sheep farms in the Jaffna peninsula, Sri Lanka. The results show that the farmers were having more than 40 years of experience in sheep farming. The sheep were reared with minimum inputs in a nomadic pastoral system. They were reared mainly for manure purpose. On request of the crop farmers, sheep are night paddocked in farm lands such as fallow paddy fields, coconut and palmyra lands. In addition, when the stocking rates are high the excess sheep are sold for meat purpose. Only extensive management is undertaken with a low input system. The sheep are hardy and well adapted to the hot and humid climate in the Jaffna peninsula, Sri Lanka and they convert the low-quality fibrous feed (weeds and crop residues available in the feeding grounds) into nutrient-rich meat with low contamination of medications (antibiotics). The dung and urine enrich the soils with nutrients enabling the crop farmers to cut down on the use of inorganic fertilisers. The household income is stabilized via the earnings from sheep system. Overall, the system showed that the resources are shared among the farming community with less negative impact on the environment. Main drawbacks in the system were the reluctance of the younger generation to be engaged in the JLS farming and the scarcity of feed during the drought period and main paddy cultivation season.

Introduction
Most of the developing countries rear indigenous sheep on small- or large-scale, either under extensive or nomadic pastoralism systems. Indigenous species are mainly reared under low-input low-output production systems with a minimum investment. Most of these indigenous sheep breeds are reared in African, Asian and European countries. Indigenous sheep breeds have the ability to survive in harsh environments where water and grasses are scarce and also where there are arid or semi-arid environments with low-quality forages. These indigenous breeds are reserves of valuable genetical materials that have the ability to adapt to such harsh environmental conditions and be resistant to the available nutrient fluctuations at different seasons, pest and disease outbreaks (Kosgey & Okeyo 2007).

Among all sheep breeds available in Sri Lanka (Bikenary, Bannur, Red Madras, Dorset), there is a traditional indigenous sheep breed called as *Jaffna local* sheep (JLS) restricted to the Jaffna Peninsula in the Northern part of Sri Lanka. *Jaffna Local* sheep is an endangered indigenous sheep population in Sri Lanka (ICAR- NBAGR 2016;

Kurukulasuriya et al. 2022). They have been identified as a breed that has a negative population trend (Vijitha & Silva 2013). They are well adapted to the hot and humid climate in the Jaffna peninsula. Even though the origin of Jaffna local sheep is not well documented, according to Goonewerdene et al. (1984) they may have been introduced to Sri Lanka many years ago by the traders from South India. The geographical nature of the peninsula restricts the movement of JLS and may have led to an uncontrolled inbreeding within the herd resulting in the existing ecotype of JLS with its unique morphological and genotypic characteristics (Goonewerdene et al. 1984; Silva et al. 2009). Main feed available for JLS are the low-quality roughages such as grasses and shrubs in the roadsides, unused lands and other governmental lands and the dried stubbles in the fallow paddy lands (Silva et al. 2009). Thus, the present study was designed to identify the sustainability dimensions (aspects related to environment, economy and society) of JLS production system in Sri Lanka.

Methods

Study area

The study was undertaken in three *Jaffna Local* Sheep (JLS) farms each situated at Kaithady (9.6884 ^{0}N, 80.1010 ^{0} E) and Tellippalai (9.7911 ^{0}N, 80.0339 ^{0}E) at Chawakachcheri (9.6665° N, 80.1321° E) Divisional Secretariat in the Jaffna district which is located in the Northern province of Sri Lanka. The three farms were belonged to Agroecological zone of low country dry zone (LD3) and had red-yellow latosol soil type (Punniyawardhena 2008). Mean annual rainfall was 1,105mm and mean annual air temperature was 31^{0}C. The study was undertaken from July to October 2022.

Farmer Survey

Data related to *Jaffna Local* sheep (JLS) rearing farmers were collected from the Divisional Veterinary Office, Jaffna District. Many farmers were restricted to the Divisional Secretariat, Chavakachcheri. Thus, two farms at Kaithady and one farm at Tellippalai village were selected for the survey on socio-economic status related to JLS farmers.

To collect the socio-economic data, a pre tested questionnaire included with both open and close ended questions was used. The questionnaire consisted with five main sections; the first section included demographic information (age, gender, level of education, income). The second section included information related to the JLS farm (objective of rearing JLS, herd size, rearing system, feeding, vaccination, mortality rate). The third section was related to the farmers' socio-economic status (income from the JLS farm, expenditure). The fourth section was related to the potentials and drawbacks for rearing JLS and the fifth section about suggestions for popularizing the farming of JLS.

Statistical analysis

Descriptive statistics (mean, mode, frequency and percentage) were used to analyze the following data related to JLS farmers; demographic information (age, gender, level of education, income), information related to the JLS farm (objective of rearing JLS, herd size, rearing system, feeding, vaccination, mortality rate), farmers' socio-economic status (income from the JLS farm, expenditure) and the potentials and drawbacks of rearing JLS and the suggestions for popularizing the farming of JLS.

Results

The farmers belonged to Tamil community and their religion was Hinduism. They were having more than 40 years of experience in sheep farming. The sheep were reared with minimum inputs in a nomadic pastoral system. They were reared mainly for manure purpose. However, when the stocking rates are high the excess sheep are sold for meat purpose to the buyers coming from the southern part of the country as there is no demand for *Jaffna Local* sheep meat from the local population.

Only extensive rearing system is undertaken and the flock of sheep is night paddocked on farmlands such as fallow paddy fields, coconut and palmyra lands on request by the owners of the agricultural fields. The owners pay a premium price (LKR 45,000 per unit of paddy field) for night paddocking the sheep. This method provides the much-needed organic matter to the agricultural soils through dung and urine enriching them with macro and micro nutrients. This practice reduces the requirement of inorganic fertilizer input during the paddy cultivation. Overall, the resources are shared among the sheep and crop farming communities with less negative impact on the environment.

Most of the instances farmer and the flock stay at one land/field for a maximum of three days and shift to another location on request. The flock of sheep is restrained to a paddock using temporary fences made up of either thatches or metal polls. The farmer may hire one or two other helpers to take care of the flock during day and night depending on the size of the flock.

Main sources of feed were the roughages available in the fallow paddy fields, other agricultural fields, road sides and play grounds. Main sources of water were the dug wells and seasonal ponds available in the grazing pathways. Farmers used some cultural methods to treat the sheep and they were annually vaccinated against foot and mouth disease. However, restraining individual sheep for disease treatment was the most cumbersome activity as the sheep were not used to human touch and handling.

Main potentials available are the JL sheep who are well adapt to Jaffna peninsula, availability of feed and water in majority of the months and the availability of feeding land areas while the drawbacks include; unwillingness of labourers to stay with the flock and move them to feeding grounds and lack of sources of feed and water during the dry months.

Figure 1: Jaffna local sheep resting on a fallow paddy field

Conclusions

The objective of this study was to identify the sustainability dimensions (aspects related to environment, economy and society) of the *Jaffna Local* sheep production system in the Northern part of Sri Lanka. This sheep is reared in a nomadic pastoral system with minimum inputs. The main purpose of rearing *Jaffna Local* sheep is for manure and meat. The sheep is fed with feeds available in fallow paddy fields, other agricultural fields, road sides and play grounds and water which is freely available in the dug wells and seasonal ponds in the feeding grounds. The flock of sheep is night-paddocked on farmlands on request by the owners of the agricultural fields. The sheep is confined to an agricultural field with temporary fences to restrict the animal movement during the night time. This method provides the much-needed organic matter to the agricultural field through dung and urine enriching them with macro and micro nutrients. This practice reduces the requirement of inorganic fertilizer input during the crop cultivation. Overall, the resources are shared among the sheep and crop farming communities with less negative impact on the environment.

In addition, the disease incidences are also less in this production system as *Jaffna Local* sheep are well adapted to the harsh environmental conditions prevailing in the area as they were reared for generations and generations in the peninsula.

Compared to the indigenous goat breeds in Sri Lanka, *Jaffna Local* sheep breed is less exploited and popular due to their inherently lower production capacity. In contrast, to mutton from goats, there is no demand for *Jaffna Local* sheep meat from the local population and thus sold the extra animals for meat purpose to the buyers coming from the southern part of the country. Thus, only a limited number of farmers daringly invest in the management of *Jaffna Local* sheep but those farmers earn a considerable profit from this farming system.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Using biodiversity to connect rangeland forage nutritive values and methane production potential

Spiess, JW[1a]; Taylor, JB[1]; Wilmer, H[1]

[1] Range Sheep Production Efficiency Research Unit, United States Department of Agriculture - Agricultural Research Service, Dubois, Idaho, United States

Key words: forage nutritive value; methane; transhumance

Abstract

In the western United States, extensive rangeland livestock grazing systems rely on the diversity of rangeland plant communities to provide vegetation structure and forage nutritive value. With an increased interest in enteric methane production from rangeland livestock across production systems, managers and policy makers need accurate and actionable information about how forage nutritive value influences enteric methane production from native rangelands. Currently, efforts to quantify and mitigate enteric methane from grazing livestock have not accounted for the spatially and temporally dynamic nature of rangeland forage resources used in extensive rangeland production systems. We clipped rangeland forage biomass at the US Sheep Experiment Station in Dubois, Idaho, USA at monthly intervals from sample points along a biodiversity gradient to quantify the nutrient value (crude protein, fiber, and organic matter). We will then estimate methane produced from each rangeland forage sample using an *in vitro* incubation system to simulate ruminant digestion. Using a combination of mixed-effect models and ordinations, we will determine the relationship between nutritive value and enteric methane potential. Understanding this relationship can help livestock managers make grazing decisions to mitigate enteric methane production when possible.

Introduction

The biodiversity of rangeland plant communities is a primary indicator for determining ecosystem integrity and the ecosystem's ability to provide goods and services that support food security, rural livelihoods, wildlife conservation, and carbon management (Ahlering et al., 2020; Pellant et al., 2020). Heterogeneity in rangeland vegetation is essential for ecosystem provisioning. As biodiversity diminishes, susceptibility to climatic variability increases, threatening short- and long-term output of important services. In the western U.S., extensive livestock production systems graze a variety of lands ranging from intact, heterogenous native plant communities to those that have been converted to more homogeneous communities. Such conversion may be intentional, e.g., introducing new plant species to enhance forage production, or unintentional, e.g., invasion of invasive species. Regardless, loss of heterogeneity reduces adaptive capacity by coupling rangeland management outcomes to just few or even a single plant species.

The nutritive value of available rangeland forage is spatially and temporally dynamic with the composition, phenology, and management driving intra-year variability (Ganskopp and Bohnert, 2009; NASEMR, 2016;

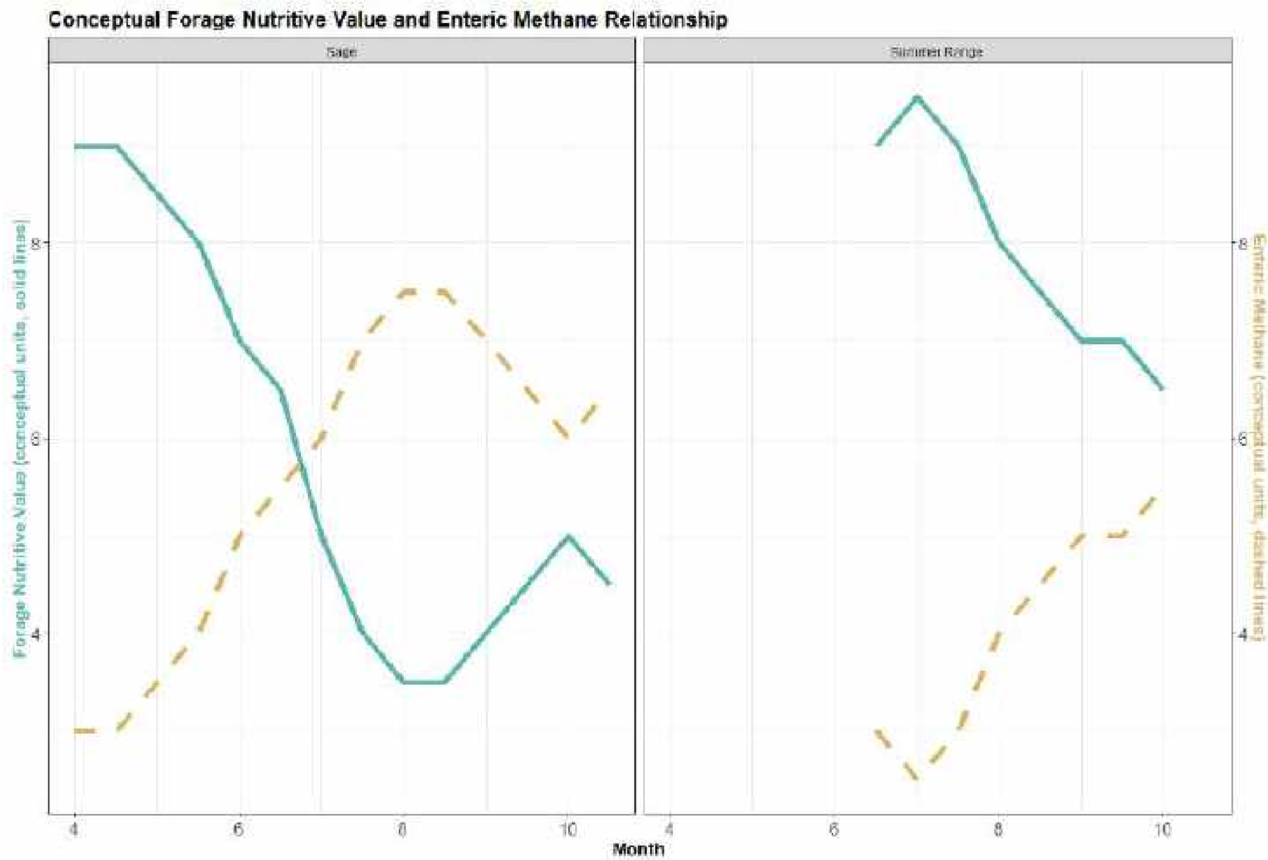
National Research Council, 2007; Spiess et al., 2024). As plant communities shift, or are altered over time, we would expect the nutritional profile of the plant community to also change. For rangeland managers, conservationists, and livestock producers, understanding how the nutritive value of a plant community shifts over the growing season within a year can inform management decisions to meet outcome expectations.

Forage nutritive value is also an indicator for enteric methane potential once digested by ruminants (Bezabih et al., 2014; Khan et al., 2021; Thompson and Rowntree, 2020), which include both domestic and native (wild) species. Of the commonly measured nutritive profile parameters, neutral detergent fiber has previously been found to have a significant, positive relationship with enteric methane production (Bezabih et al., 2014; Khan et al., 2021). With increased focus on greenhouse gas fluxes in rangelands (Recktenwald and Ehrhardt, 2024; Sanderson et al., 2020; Thompson and Rowntree, 2020; Wang et al., 2021), an understanding of intra- and inter-year variability in enteric methane potential for rangeland plant communities will facilitate long-term rangeland management towards vegetation diversity goals to minimize enteric methane potential. This research will also help expand the discussion of enteric methane production from rangelands given that the intra-season variability of rangeland forage nutritive value is currently missing from the broader discussion of enteric methane production of rangelands. As this project progresses into plant communities along the elevation gradient in the region, we will be able to compare nutritive trade-offs in grazing at different points in the growing season or losing grazing access to higher elevation communities (Wilmer et al., 2024).

For this paper, we outline our initial rangeland forage pilot project that we are currently analysing and then transition into describing the broader rangeland forage project. We are working towards documenting and quantifying the community composition, structure, and nutrition profiles of vegetation across temporal, elevation, and biodiversity gradients bedded within an extensive rangeland livestock system. We will address broader interests and issues in greenhouse gas emissions, rangeland management, animal production, and adaptive management capacity to begin filling a critical knowledge gap relevant to a variety of stakeholders that include livestock producers, land management agencies, wildlife conservationists, and policy makers. Our approach will include direct comparisons of the forage nutritive value and enteric methane potential profiles among native sagebrush steppe rangeland plant communities along biodiversity gradients. Results will provide a foundation for evaluating how losing, maintaining, or improving biodiversity affects the provisioning potential of extensive rangeland systems.

Methods

For the pilot project, we collected rangeland forage samples from two adjacent sagebrush steppe management units to compare differences in forage nutritive value and enteric methane potential between a burned and unburned area in July 2024 and then between summer (July 2024) and early fall (September 2024) for the unburned management unit. We clipped available forage in 0.25 m^2 frames at sample points distributed across each management unit after determining the species composition by cover for each frame. We then ground all samples through a 2-mm sieve using a Wiley Mill to prepare for nutrient and methane analyses. At this point in time for the project, we are transitioning to sample analysis. A subsample of each sample will be sent off for crude protein and fiber analyses and a subsample will be used to determine *in vitro* digestibility and enteric methane potential. In addition to traditional wet chemistry methods, we are also using near-infrared spectroscopy to prepare spectral calibration curves for future nutritive value analysis. We are using a Gas Endeavour *in vitro* rumen incubation system (Liu et al., 2018) to determine enteric methane potential.



Conceptual figure for the expected forage nutritive value and enteric methane potential relationship over the potential grazing seasons in eastern Idaho, USA sagebrush steppe and higher elevation rangeland plant communities. Based on existing research, we are expecting to find that forage nutritive value is inversely related to enteric methane potential. The shorter grazing season for the summer range panel is related to the shorter growing season and access logistics due to snow at higher elevations than in the sagebrush steppe panel.

Using a combination of mixed-effect models and ordinations, we will determine the overall relationships between nutritive value parameters (crude protein, acid detergent fiber, neutral detergent fiber, and acid detergent lignin), digestibility, and enteric methane potential (Spiess et al., 2024). We expect enteric methane potential to be inversely correlated with nutritive value (Khan et al., 2021; Thompson and Rowntree, 2020). For the pilot project data, we expect the available forage in the burned management unit to have a higher nutritive value (higher protein, higher digestibility, lower fiber) than the adjacent unburned management unit. We also expect the samples from the unburned management unit in July to have a higher nutritive value than samples collected from the same unit in September.

Next Steps & Discussion

Following the pilot project, we will be expanding to a manipulative experiment in summer 2025 to target the biodiversity component of this relationship between forage nutritive value and enteric methane potential in addition to temporal variability of the forage base. At the experimental study sites, we will manipulate the community within subplots through a combination of herbicide treatments to target different functional groups and investigate how removing species from the community will affect the nutritive profile. The full subplot treatment factorial at each experimental site will include: no herbicide – control, forb-targeted herbicide, shrub-targeted herbicide, forb & shrub-targeted herbicide. To capture the temporal progression of the forage, we will clip frames from each factorial subplot at monthly intervals from May through October.

We expect that the reduction in biodiversity will correspond to an overall reduction in forage nutritive value due to fewer species and functional groups contributing to the overall growth curve of the respective subplots. Similarly, we expect that samples from later in the growing season will have lower forage nutritive value and higher enteric methane potential than samples from earlier in the growing season. This will help illustrate how grazing similar plant communities at different times of the year can meet, exceed, or fail to meet an animal's nutritional needs (Wilmer et al., 2024).

Seasonal grazing distributions of livestock in the communal rangelands of Namaqualand

Tapela, MH[1,2]; Samuels, IM[1,2]; Finca, A[1]; Engelbrecht, A[1,2]

[1] ARC-LBD: Range and Forage Unit, c/o Department of Biodiversity and Biological Conservation, University of the Western Cape, P Bag X17, Bellville 7535, South Africa; [2] Department of Biodiversity and Conservation Biology, University of the Western Cape, P Bag X17, Bellville 7535, South Africa

Key words: Pastoralism; Indigenous Knowledge Systems; Semi-Arid; Transhumance; Spatial perceptions; Sustainability

Abstract

The role of indigenous grazing management practices in flexible and sustainable resource use has been widely identified and recognised in the literature. However, these grazing management practices in the semi-arid pastoral areas in Namaqualand in South Africa have not adequately been studied in terms of GPS-based seasonal grazing distribution. This study aimed to assess the seasonal livestock grazing distributional patterns across three communal rangelands in Namaqualand using GPS collars. The objectives were to: 1) generate grazing distributional maps to identify patterns of seasonal rangeland use, 2) compare home range and grazing intensity of livestock between seasons, 3) delineate different grazing zones at different times of day known descriptive model of daily indigenous grazing management practices of Namaqualand and 4) contrast seasonal differences within these grazing zones regarding grazing activity. Catlog GPS collars were mounted on livestock and T-LoCoH R package and Google Earth was used to generate grazing distributions maps showing areas most frequently used by livestock (grazing intensity) and daily livestock movement patterns. The results showed that Namaqualand herds grazed a small proportion of their home range regardless of season. Wet-season herds had smaller home range. The area associated with high grazing intensities in both seasons was significantly smaller than at lower grazing levels. No significant differences in mean area associated with seasonal variation within each level of grazing suggests herders are not seasonally altering areas associated with grazing intensity to prevent seasonal over-exploitation of resources. Grazing activity is lower in the herded zones than in when unherded. Grazing activity and distance travelled in the herded zones is lower in the wet season but area covered is less as resources are abundant. This suggests that indigenous herding practices in Namaqualand requires vast ecologically aware decision-making processes associated with effective sustainable resource use. We argue that due to the flexibility and adaptability of indigenous grazing managements Namaqualand, herders may increase the area covered at high grazing intensities during the wet season will improve livestock productivity without compromising rangeland condition. Furthermore, contemporary of grazing management systems should be more inclusive of indigenous management as aspects of holistic grazing management have embedded in these practices for a long time.

Introduction

Poor grazing management in arid rangelands can lead to rangeland degradation through overgrazing. In Namaqualand, and South Africa more broadly, historical management practices were shaped by perceptions such as 'The Tragedy of the Commons,' which inaccurately blamed overgrazing on ineffective indigenous grazing systems (Hardin 1968). These misconceptions disrupted the transhumance mobility patterns of subsistence livestock owners, undermining their ability to adapt to changing environmental conditions (Samuels et al. 2008). As a result, indigenous communities were significantly hindered in their efforts to manage rangeland resources effectively.

Despite these perceptions the Namakwa herders maintained their highly mobile indigenous grazing management practices. Effective grazing management of communal rangelands requires mobility from both herders and their livestock across various spatio-temporal scales (Samuels et al. 2007). Indigenous communal farmers and herders navigate the landscape with their livestock, guided by ecological knowledge refined over generations (e.g., transhumance) (Allsopp et al. 2007). This mobility enables herders to flexibly adapt resource use to fluctuating ecological and environmental conditions."

While the flexibility and sustainable resource use of indigenous grazing management practices in Namaqualand have been widely recognized in the literature (Asheenafi and Leader-Williams 2005; Samuels et al. 2007; Allsopp et al. 2007), these practices have not been sufficiently represented through GPS-based seasonal grazing distribution maps. To better assess the flexibility and adaptability of these indigenous practices, it is crucial to investigate GPS maps of grazing distribution patterns.

This study aims to assess the livestock grazing distributional patterns across three communal rangelands in Namaqualand. The objectives of this study are to:

1. Generate grazing distributional maps to identify patterns of rangeland use between wet and dry seasons.
2. Use different times of the day within grazing course to delineate different grazing zones.
3. Contrast seasonal differences within these grazing zones regarding grazing activity.
4. Compare home range and grazing intensity of livestock between seasons.

Methods

To determine seasonal livestock grazing distribution patterns in space, two data collection field trips were undertaken in the wet season (Winter and Spring) and dry season (Summer), where two CatLog GPS (Global Positioning Systems) tracking devices were attached to two random adult animals (sheep and/or goat) in every herd.

Additionally, the Catlog GPS trackers also record animal velocity which is essential for determining the specific daily livestock activity along the grazing course based on the descriptive model of indigenous grazing practices model from Debeaudoin (2001) [Unpublished Master's thesis]. The collars were left to record daytime movements for duration about three months and GPS data was retrieved.

GPS positional data from each animal was extracted and analysed using the CatLog Software and the R package Time Local Convex Hull (T-LoCoH) (Getz and Wilmers 2004) to generate isopleths which represent the varying proportions of the total grazing distributional extent used by the animals of interest. Google Earth Pro (2023) was used to map the isopleth data.

T-LoCoH is an R package that creates isopleth diagrams showing an object's range in space and time using the Minimum Convex Polygon (MCP) method. Each polygon within the isopleth represents the extent of the areas utilized and the frequency of use over time at each location (Gusha et al. 2018; Gwate 2018). These polygons, or hulls, were assigned categorical classes (iso levels) and color codes to indicate the proportion of the total area utilized and the corresponding frequency of use. Based on the iso levels and their color codes, grazing intensity was categorized into three levels: high, moderate, and low

Two-way Wilcox-Mann-Whitney t-tests or Kruskall-Wallis tests and a relevant post-hoc tests were used to analyse significant seasonal variations spatio-temporal variables.

Results

Livestock movement during the wet season and dry seasons in the study area

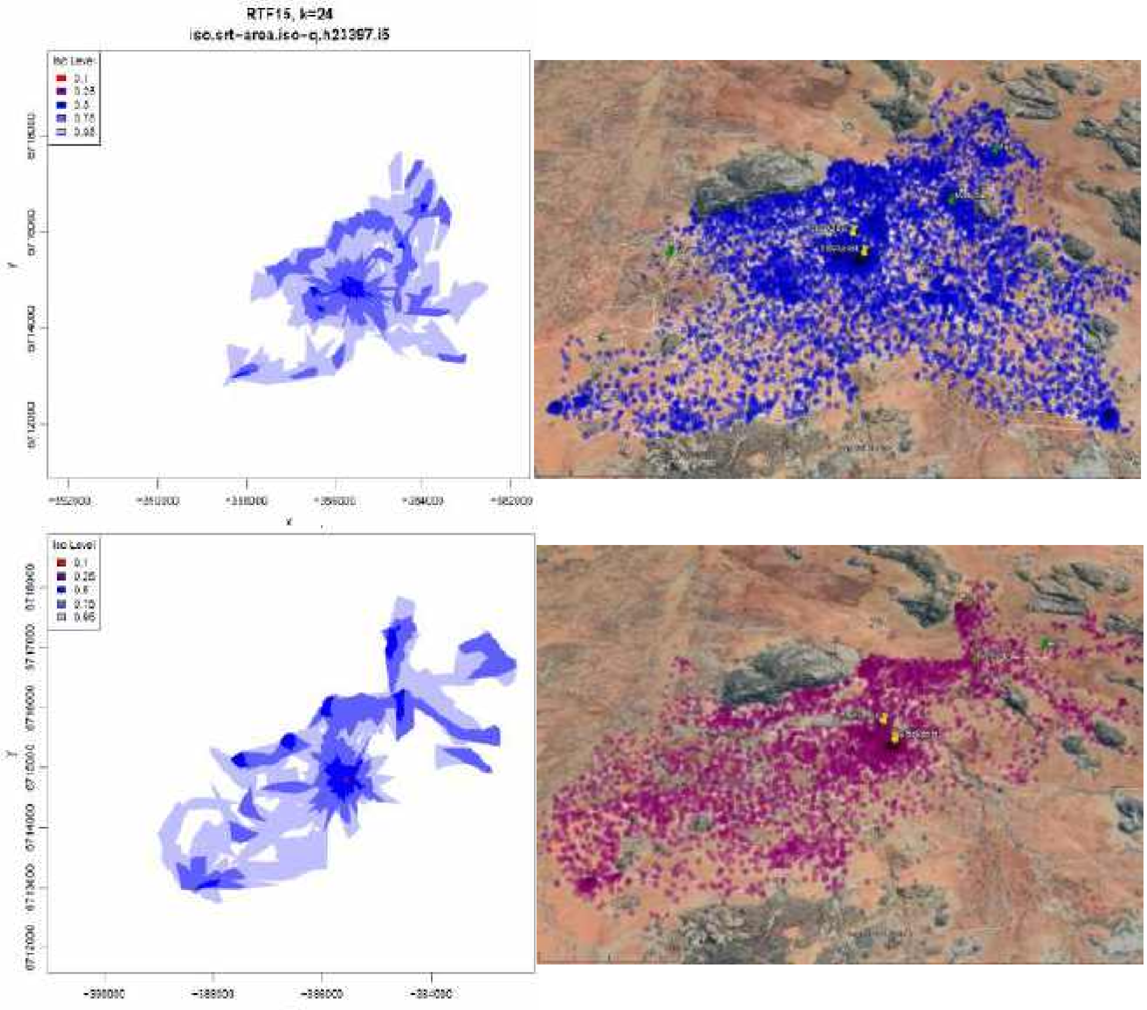

Fig. 1: Isopleth diagrams produced from hulls arranged by area denoting the frequency of occurrence and proportions of the total area occupied by an adult *Capra hircus* during the wet season (bottom left) and *Ovis aries* in the dry season (top left) in Concordia. Google Earth maps (right) depicting the grazing distribution of a *Capra hircus* (purple dots) during the wet season and *Ovis aries* (blue dots) during the dry season in Concordia. Stock post (Yellow pin) and grazing intensity levels (Green pins).

The home range appears larger in the dry season compared to the wet season in Fig. 1.

Spatial data: and grazing intensity during dry seasons of the study area

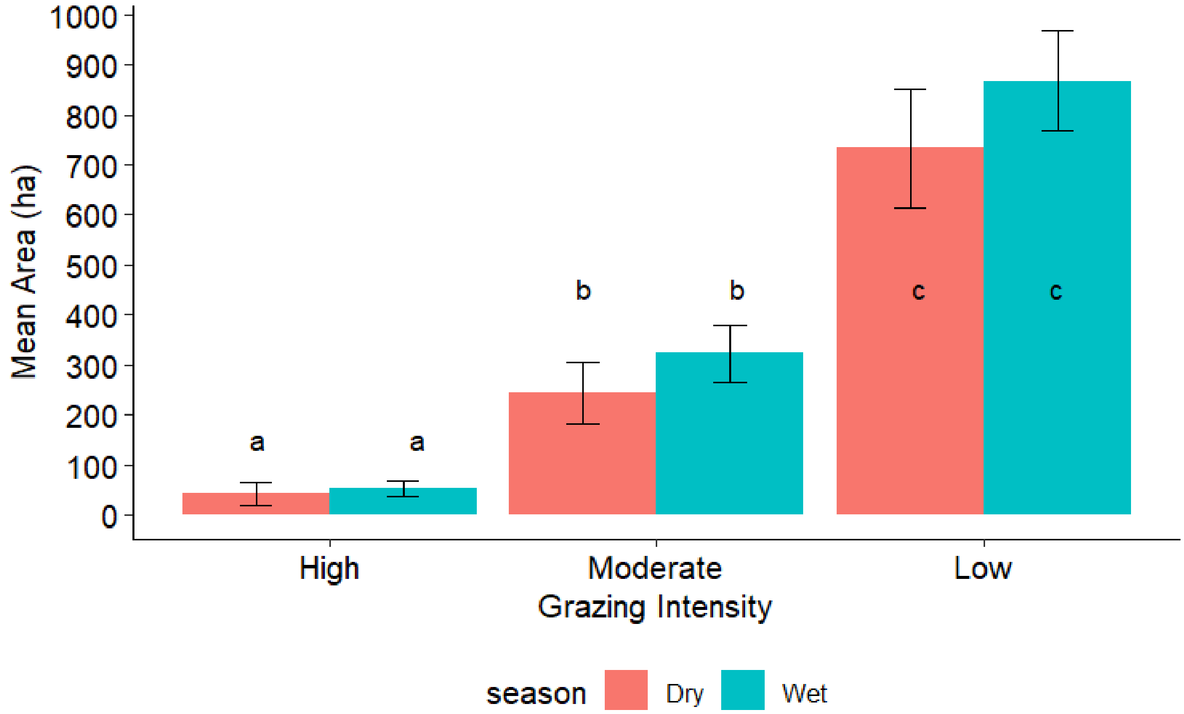

Fig. 2: Mean area grazed at every level of grazing intensity between wet and dry seasons across all three communal areas.

Fig. 2, shows there are significant differences in mean area covered at different grazing intensities ($X^2 = 46.327$, df = 2, p-value < 0.05). Mean area covered is lowest at high grazing intensity (48.1±13.5 ha) and there are no significant differences in mean area associated with seasonal variation within each level of grazing (z-value = 0.785, p-value = 0.432).

In Fig. 3, each of the grazing zones indicate particular time classes within a daily grazing course. The Excitement/appetite moderation zone (EAM) is between 07:00 – 11:00, Target Zone and waterpoint (T) is between 10:00 – 14:30 and the Late Afternoon Meal zone (LAM) is between 14:30 -17:00.

Fig. 3A, indicates the mean speeds of livestock associated with grazing zones along the daily grazing route in Namaqualand. The bar plot shows mean speed is significantly slower in LAM (0.852±0.0010 km/h) than in the other zones (both p-values < 0.05).

Fig. 3B, shows there is significant difference in mean grazing speeds between seasons only at EAM and T zones only (p-value < 0.05), where livestock move faster during the wet season (Wet: 0.945±0.006 , Dry: 0.907±0.008).

Grazing activity of livestock and speeds along daily grazing course during the wet and seasons

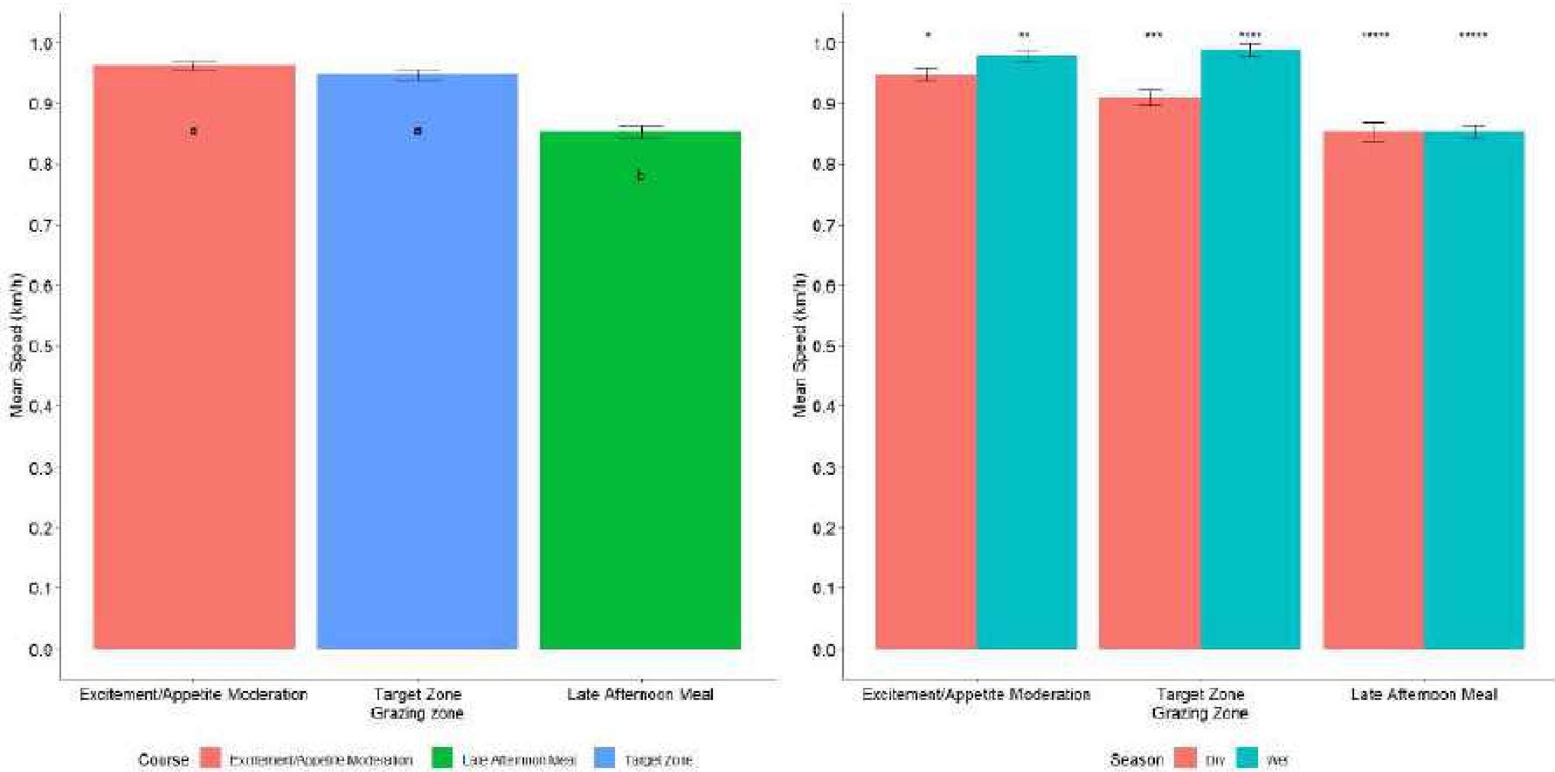

Fig. 3: Shows the differences in mean grazing speeds of livestock at different time specific zones along daily grazing route. (A) depicts the grazing speeds across all seasons. (B) indicates the grazing speeds between seasons. Letters (a, b) and (*) indicate significant differences in bar plots A and B respectively.

Discussion, Conclusions & Implications

Some of the historical perceptions indigenous herders derived from the ‘tragedy of the commons’ on indigenous herders is that they are selfish and do not have the skills to manage communal rangelands effectively.

However, the data shows that indigenous herders in Namaqualand are practicing ecologically sustainable grazing management (Fig. 3). This is because the mean area grazed differs at every level of grazing intensity such that high grazing intensities occupy the smallest areas (Fig. 3). Although this may be because palatable succulent karoo vegetation is limited to small patches, it is more likely that high intensity grazing is spatially limited by herders to allow for longer resting periods to conserve these palatable patches.

Furthermore, there is evidence (Fig. 3) that Namakwa herders are ecologically aware regarding sustainable use of resources not just in space but also in time as the mean areas grazed at all grazing intensity levels remains unchanged across seasons. This suggests that herders are preventing seasonal exploitation of resources to promote accumulation of available forage for their livestock. This allows flexibility for potential future exploitation of palatable plants.

Therefore, the spatial and temporal restrictions on grazing within the home range by Namakwa herders while maintaining livestock production improves the quality of both the livestock and rangeland condition. These are principles similar to those in holistic and adaptive grazing management (Mann and Sherron 2018) though these concepts are already embedded into the vast indigenous ecological knowledge of Namakwa herders. The success of this though requires vast ecological knowledge at various spatio-temporal scales by Namakwa herders and, contrary to historical perceptions, is an example of effective grazing management.

Furthermore, this study indicates that there are significant differences in mean speeds of livestock differs in the mid-afternoon (T) along a daily grazing route (Fig. 2A-B). This finding is similar to that found in the Richtersveld National Park by Hendricks (2004), where there was a significant difference in herd speeds between morning and afternoon. Speeds in different zones (Fig. 2) suggest variations in grazing activity, with slower speeds indicating more intense grazing activity. The reduced speed from the mid-afternoon reflects peak grazing activity during this time. This is likely because the animals are unherded during this time as studies by Debeaudion (2001) and Samuels (2006) show many Namakwa herders leave their animals once they reach the (T) in the afternoon as they have other duties to perform. This ensures animal well-being through limited free-range grazing on good quality forage and allowing for effective rumination.

Conversely, in the morning and early afternoon grazing activity is lower because animals are moving faster as they are being actively herded. This is similar high intensity short-duration grazing (Chaplot et al. 2016; Louhaichi et al. 2021), where herders take all their and are constantly moving. This permits longer resting periods and evenly distributes grazing impacts. This emphasises the flexibility and adaptability of the indigenous grazing management system in Namaqualand.

Additionally, grazing activity changes in the herded zones (EAM and T) between seasons (Fig. 2B), where grazing activity is lower in the wet season. Moreover, distance travelled may also be inferred from speed as a greater speed suggests more ground is covered in the same time. Thus, herds travelled further in the wet season but this is contrary to many studies which state livestock should instead travel further in the dry season as resources are limited (Lawrence et al. 1988; Hulbert et al. 1996; Sieff 1997; Samuels 2006; van Beest et al. 2011).

However, this finding aligns with existing literature only when seasonal resource availability and spatial perceptions are correctly interpreted (Fig. 2B). Specifically, it is essential to distinguish between the distance travelled and the area covered. For instance, during the wet season, when resources are abundant, livestock may travel further but cover a smaller area due to the concentrated availability of palatable vegetation. Conversely, in the dry season, when resources are scarce, livestock may not travel as far but cover a larger area as they forage for dispersed vegetation. The alignment of this observation with broader literature underscores that Namakwa herders have preserved their seasonally adaptive farming practices over time, despite evolving perceptions.

Effective grazing management in Namaqualand requires deep ecological knowledge across scales. As climate variability intensifies (Thornton et al. 2014), adaptive indigenous grazing practices offer valuable insights for mitigating climate change impacts. Modern management strategies should prioritize indigenous knowledge and involve local communities in shaping future approaches.

Key words: Clostridium; Bacteroides; PCR; DGGE; Solid-Liquid Fractions

Abstract

The aims of this study were to examine bacterial communities in relation to the rumen digestion of rice straw and to understand how concentrate supplements affect gut bacteria involving the digestion of a rice straw-based diet. The substrates were rice straw (RS) alone (experiment 1) and RS with 25% concentrates (barley and kidney beans) (experiment 2). The genomic DNA was collected to determine bacterial diversity by conducting denaturing gradient gel electrophoresis (DGGE). V6–V8 region group-specific (Clostridium and Bacteroides) primers were employed in the analyses. The DGGE band pattern was subjected to cluster analysis to demonstrate the similarity and difference between dietary treatments and solid-liquid fractions. Fiber digestibility, gas production, and volatile fatty acid (VFA) concentration were increased with incubation time. The differences between solid and liquid fractions were significant in total bacteria, Clostridium, and Bacteroides communities. These results indicate a stable community structure of Clostridium and Bacteroides groups involved in the digestion of rice straw-based diets in the rumen.

Introduction

Ruminant animals rely on forage as a primary nutritional component, but forages like rice straw are high in fiber, low in protein, and poorly digestible, which presents a challenge for Afghan farmers who primarily feed their cattle such roughage during the dry season (Van Soest 1994). Afghanistan's livestock population includes approximately 3.7 million cattle and 18 million sheep and goats, many of which are fed low-quality, high-fiber feed (Fitzherbert 2007). To improve meat and milk production, diets need higher nutritional density through increased concentrates, but this affects the gut bacterial community (Chesson 1988). This study focuses on understanding the relationship between fiber digestion, rumen bacterial communities, and the effects of concentrate supplements on the digestion of rice straw in cattle (Beever and Mould 2000).

Methods

In this study, a randomized factorial design was used with two experiments. In experiment 1, 12 rice straw samples from four locations in Afghanistan (Nangarhar and Khost provinces) were collected, and in experiment 2, one rice straw type was selected with barley (25%) and kidney beans (25%) used as supplements. All samples were analyzed in triplicates. The chemical composition was analyzed in the laboratory at Kabul University, and rumen fluid was collected from Holstein dairy cows in Japan (McManus et al. 1976). The *in vitro* gas production technique was employed using 87 glass vials, with samples incubated for various time points (Pell and Schofield 1993). Gas production and fermentation parameters like pH, VFA, and bacterial communities were measured. Microbial DNA was extracted and amplified using PCR, and microbial community profiling was done using DGGE (Yu and Morrison 2004). Scanning electron microscopy (SEM) was used to analyze rice straw morphology, and bacterial populations were monitored through nested PCR techniques (Hatfield et al. 1999).

Table.1. VFA concentration (mmol/l) of four types rice straw in different incubation of periods

Incubation period	Ingredient				
VFA	RS-1	RS-2	RS-3	RS-4	P Value
24 h Incubation period					
Acetic acid	31.38± 3.78	19.78±1.58	21.59±7.92	17.58±1.04	*
Propionic acid	12.65±1.75	8.02±1.58	11.49±4.94	6.30±0.21	*
Butyric acid	3.81±0.56	2.54±1.03	2.05±0.05	2.08±0.62	NS
Total VFA	49.075	20.6	35.12	26.62	*
48 h Incubation period					
Acetic acid	39.90±0.59	30.15±4.09	35.42±7.94	28.34±1.44	*

The four types of rice straw from different provinces of Afghanistan, RS-1; rice straw of Ningarhar sorkhrood, RS-2; rice straw of Ningarhar behsood, RS-3; rice straw of Khost mandozai, RS-4; rice straw of Khost shamal. Data are mea1 ± SD. *P<0.05, NS; not significant.

Results

Fermentation Parameters

The fermentation parameters for rice straw alone showed that cumulative gas production increased over the incubation period, with significant differences observed at 72, 96, and 120 hours. RS-3 produced the most gas, followed by RS-1, and RS-2 produced the least. NDF digestibility increased over time, but no significant differences were found between the straw types. The total VFA concentration increased with incubation, with RS-

1 achieving the highest concentration, followed by RS-3. RS-1 and RS-3 also exhibited higher acetate concentrations throughout the incubation, while propionic acid was higher only at 24 hours. When rice straw was supplemented with concentrates (barley and kidney beans), cumulative gas production increased significantly, especially with barley (RS-BR) and kidney beans (RS-KB) after 48 hours. The pH decreased with supplementation but not significantly. RS-KB showed a significant increase in total VFA concentration, followed by RS-BR, with propionic and butyric acids significantly higher in RS-KB. Acetic acid, however, was unaffected by concentrate supplementation.

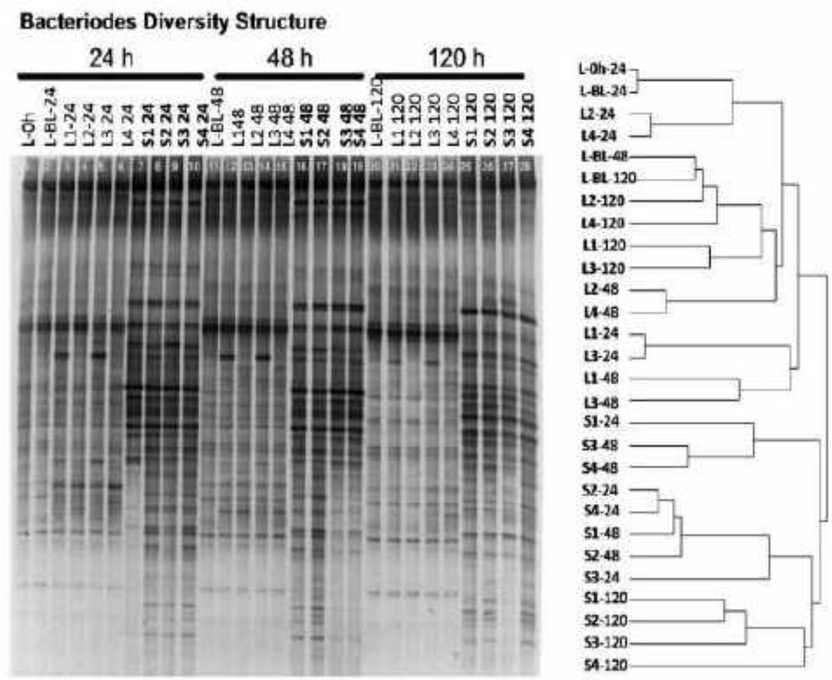

Figure 1. Liquid- and solid-associated bacterial communities determined by DGGE employing group specific primers for *Bacteroides-Prevotella*. The first letter stands for liquid (L) and solid (S)-associated bacteria, the second letter for 1,2,3,4 is the four types of rice straw, and the following description in parenthesis for 24, 48 and 120 hours of

Scanning electron microscopy (SEM) & PCR-DGGE

Scanning electron microscopy analysis revealed that rice straw had smooth hyphae at the beginning of the incubation, but over time, the hyphae became increasingly degenerated and damaged, with the damage size growing at 24, 48, and 120 hours. PCR-DGGE analysis of the bacterial communities showed that, for rice straw alone, there was no significant change in the Clostridium and Bacteroides-Prevotella groups throughout incubation. Solid-associated bacterial fractions showed a higher density of dominant bands, with RS-1 and RS-3 showing distinct band patterns in the liquid fraction compared to RS-2 and RS-4. In the rice straw and concentrate treatments, the bacterial community profiles showed clear differentiation between solid and liquid fractions, with Clostridium groups in the liquid fraction affected by both barley and kidney bean supplementation, and the Bacteroides-Prevotella group showing changes only in the liquid fraction with RS-KB. However, there was no significant impact on the solid-associated bacterial community by either concentrate.

Discussion

The cumulative gas production varied significantly between the types of rice straw, with differences linked to the chemical composition, especially fiber content (Hatfield et al. 1999). Straw with lower lignin and higher hemicellulose content (RS-3 and RS-1) showed better fermentation parameters, including higher NDF digestibility, which increased over the incubation period. This slow digestion is attributed to the complex interactions between lignin and structural carbohydrates, which are challenging for microorganisms to break down (Chesson 1988). The increased VFA concentration also reflected the improved fermentation rate, which was consistent with higher gas production (Plaizier et al. 2008). The rice straw varieties exhibited variability in chemical composition, with differences in NDF and ADF content affecting gas production and VFA concentration (Beever and Mould 2000). The degradation of rice straw cell walls increased over time, with visible differences in degradable tissue zones correlating with fermentation parameters and gas production (Van Soest 1994).

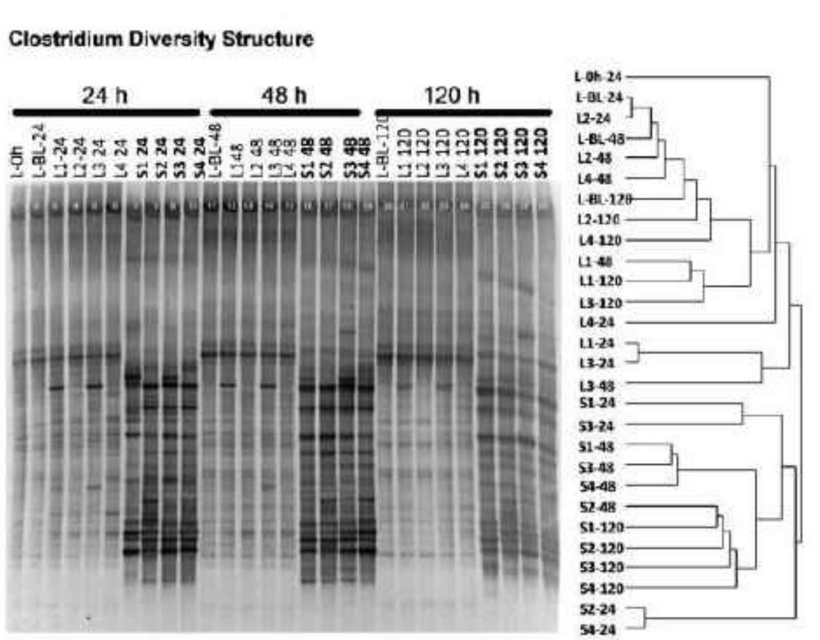

Figure 2. Liquid- and solid-associated bacterial communities determined by DGGE employing group specific primers for *Clostridium*. The first letter stands for liquid (L) and solid (S)-associated bacteria, the second letter (1,2,3,4) is the four types of rice straw, and the following description in parenthesis for 24, 48 and 120 hours of

The bacterial communities in the solid and liquid fractions showed distinct profiles, primarily due to the attachment of fibrolytic bacteria to solid particles, which are predominant in rumen fiber digestion (Silva et al. 1987). Solid-associated microbes were more abundant throughout the incubation periods, aligning with findings that fiber digestion is mainly driven by these microbes (Jung and Varel 1988). The addition of concentrates (barley and kidney beans) led to increased gas production and propionic acid concentration, while acetic acid was unaffected, suggesting that starch-enriched diets favor propionate production (Pell and Schofield 1993). The lack of significant changes in the solid-associated bacterial community may be due to the low concentrate proportion in the diet, as evidenced by the relatively stable pH (Nagaraja and Titgemeyer 2007). However, the liquid-associated bacterial communities, particularly in the Clostridium and Bacteroides-Prevotella groups, were affected by the concentrate treatments, likely due to the presence of undigested solid particles in the liquid fraction (Yu and Morrison 2004).

The results indicate that although the digestibility of rice straw was not notably improved by the concentrate supplementation, the changes in microbial communities and fermentation parameters underscore the role of microbial dynamics in fiber and starch digestion (Chen et al. 2008).

Key words: Grazing activity; Energy expenditure; Feed intake; Rangeland productivity

Abstract

Understanding how grazing management practices affect the livestock productivity in steppe is a key issue to the sustainable rangeland. We conducted a grazing experiment in 2022 and 2023 at the steppe of Inner Mongolia. Five grazing managements included light (LGL, 0.38 sheep units·ha^{-1}·yr^{-1}), moderate (MGL, 0.75 sheep units·ha^{-1}·yr^{-1}), and heavy (HGL, 1.06 sheep units·ha^{-1}·yr^{-1}) grazing of lambs, moderate grazing of ewes (MGE, 0.75 sheep units·ha^{-1}·yr^{-1}), and the mixed grazing of both (MIX, 0.75 sheep units·ha^{-1}·yr^{-1}) in a randomized block group design with three replicates. Of these, LGL, MGL and HGL were the grazing intensity treatments, MIX, MGL and MGE were the flock treatments, and the MIX treatment consisted of mix-grazing lambs (MML) and mix-grazing ewes (MME). The results showed that there were significant differences ($P<0.05$) among the daily grazing time (DGT) of lambs with different grazing intensities, and the DGT of lambs under MGL treatment was the shortest. There were significant differences in DGT of sheep with different flocks, where MGL treatment was the highest while MGE was the lowest. Besides, significant differences were found in daily overall dynamic body acceleration (DODBA) of sheep with different flocks, with MME treatment being the highest and MML being the lowest. There were significant differences among daily feed intake (DFI) and average daily gain (ADG) of sheep with different flocks. Among them, DFI was significantly higher in ewes (MGE, MME) than in lambs (MGL, MML), while ADG was significantly lower. The linear mixed models showed that ADG in lambs was mainly positively influenced by DFI under various grazing intensities. Differently, ADG was mainly positively affected by DGT and negatively affected by DODBA under various flocks. In conclusion, different grazing managements had significant effects on sheep productivity and their grazing activities. And the grazing intensity regulated productivity by influencing the feed intake, whereas flock had effects by influencing the activity level. These provide new ideas to guide the grazing management practices in steppe.

Introduction

Understanding how grazing management practices affect grassland livestock productivity is a key issue in achieving sustainable rangeland development. Among these practices, grazing intensity and flock structure are two key guiding parameters that are of great concern to pastoralists in practical production. These parameters regulate grazing patterns and livestock productivity within pastures (Animut et al., 2005; Grace et al., 2019). During grazing, the livestock productivity is closely related to their behavioural characteristics (Portugal et al., 2021; Yu et al., 2024). This is because animals maintain a trade-off between energy expenditure and nutrient intake, specifically balancing their activity levels and feed intake (Charnov, 1976). With the advancement and maturation of animal kinematics and related supporting technologies, overall dynamic body acceleration (ODBA), calculated by triaxial acceleration, has been proposed as a metric to characterise animal energy expenditure (Green et al., 2009; Wilson et al., 2006). Furthermore, machine learning models built on accelerometer datasets can classify animal behaviour with accuracies exceeding 90% (Yu and Klaassen, 2021). Therefore, to determine whether there were significant differences in the productivity and grazing activity of sheep under different grazing management practices, and to explore the intrinsic relationships between these factors, we conducted the following study using triaxial accelerometers.

Methods

The study was conducted in Xilinhot City, Xilingol League, located in the Inner Mongolia Autonomous Region of China. The experimental site represents a typical steppe ecosystem, predominantly composed of *Stipa krylovii* and *Leymus chinensis*. The experiment was conducted from July to September in both 2022 and 2023, utilising crossbred *Ujimqin* and *Dorper* sheep with comparable body sizes as experimental animals. Five grazing managements included light (LGL, 0.38 sheep units·$ha^{-1}·yr^{-1}$), moderate (MGL, 0.75 sheep units·$ha^{-1}·yr^{-1}$), and heavy (HGL, 1.06 sheep units·$ha^{-1}·yr^{-1}$) grazing of lambs, moderate grazing of ewes (MGE, 0.75 sheep units·$ha^{-1}·yr^{-1}$), and the mixed grazing of both (MIX, 0.75 sheep units·$ha^{-1}·yr^{-1}$) in a randomized block group design with three replicates (FIG.1). Of these, LGL, MGL and HGL were the grazing intensity treatments, MIX, MGL and MGE were the flock treatments, and the MIX treatment consisted of mix-grazing lambs (MML) and mix-grazing ewes (MME). For each experimental treatment, six sheep were fitted with Druid NANO collars (Chengdu, China) to record real-time triaxial acceleration data. These data were subsequently used to calculate the daily overall dynamic body acceleration (DODBA) and daily grazing time (DGT) of the sheep. Additionally, five 1 m × 1 m grazing exclusion cages were randomly distributed across each experimental plot to estimate the daily feed intake (DFI) of the sheep using the exclusion cage method. And the sheep were weighed at each mid-month in order to determine their average daily gain (ADG). The experimental design was conducted in accordance with the established ethical guidelines for animal research. All statistical analyses in this study were conducted using R software (version 4.3.0).

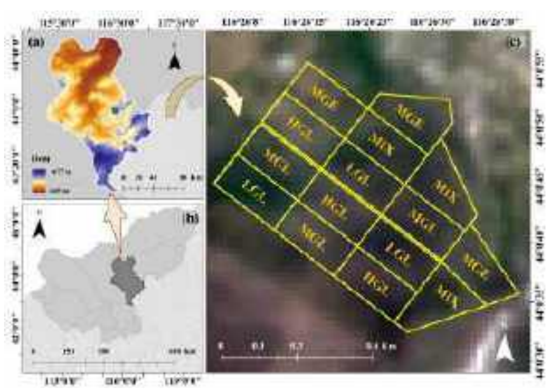

Figure 1 Study area and experimental design. Figure a showed the elevation of Xilinhot and the location of the study area, Figure b showed the location of Xilinhot in the Xilingol League, and Figure c showed the plots arrangement of the experimental design.

Results

DODBA and DGT under different grazing managements

The DODBA of lambs under different grazing intensities showed no significant differences (FIG.2-a). However, DODBA exhibited a significant decreasing trend over the months ($P<0.05$). In contrast, significant differences in DODBA were observed among sheep from different flocks (FIG.2-b; $P<0.001$), with the highest values recorded in the MME treatment and the lowest in the MML treatment. Significant differences were observed in the DGT of lambs across different grazing intensities ($P<0.05$), with the MGL treatment exhibiting the shortest DGT (FIG.2-c). And a significant decreasing trend in DGT was observed over the months ($P<0.05$). Similarly, the DGT of sheep varied significantly among different flocks (FIG.2-d; P<0.001), with the longest DGT recorded in the MGL treatment and the shortest in the MGE treatment.

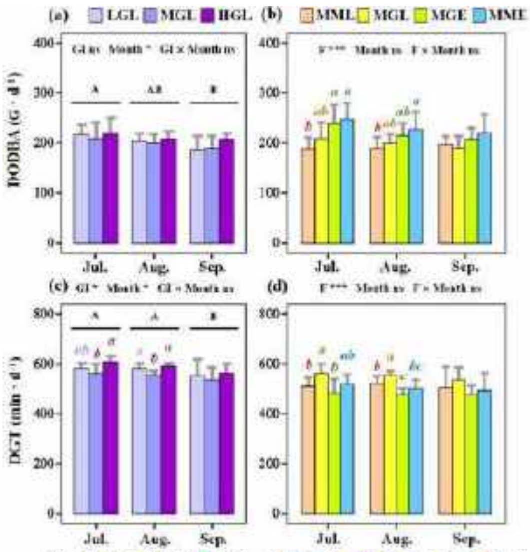

Figure 2 Differences in the sheep grazing activity among various grazing managements. Figures a,b represented the differences in daily overall dynamic body acceleration (DODBA) of sheep under different grazing intensities (GI) and different flocks (F), respectively. Figures c,d represented the differences in daily grazing time (DGT) of sheep under different grazing intensities and different flocks, respectively.

DFI and ADG under different grazing managements

There were no significant differences were detected in the DFI or ADG of lambs under different grazing intensities (FIG.3-a,c). However, both DFI and ADG exhibited a significant decreasing trend over the months (P<0.01). Conversely, significant variations in DFI and ADG were observed among sheep from different flocks (FIG.3-b; P<0.001). Specifically, ewes (MGE, MME) had significantly higher DFI compared to lambs (MGL, MML), while their ADG was significantly lower.

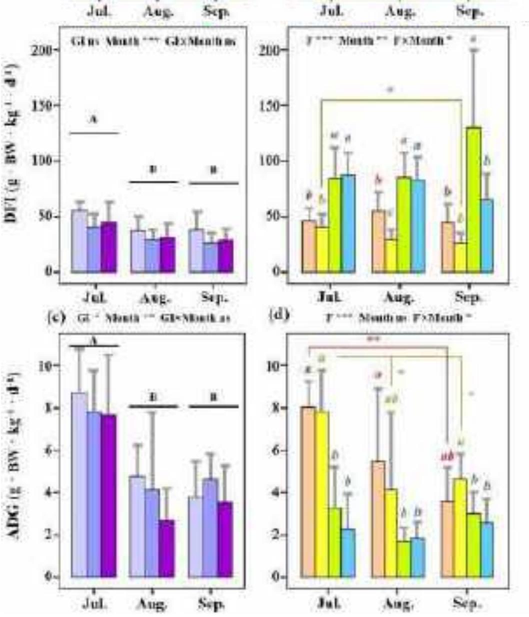

Figure 3 Differences in the sheep productivity among various grazing managements. Figures a,b represented the differences in daily feed intake (DFI) of sheep under different grazing intensities (GI) and different flocks (F), respectively. Figures c,d represented the differences in average daily gain (ADG) of sheep under different grazing intensities and different flocks, respectively.

Relationship between sheep productivity and grazing activity under grazing managements

The generalized linear mixed model revealed that, under varying grazing intensities, the ADG of lambs was predominantly influenced by the positive impact of DFI (Fig.a; P < 0.001). Conversely, within different flocks, ADG was predominantly influenced by the positive effect of DGT (FIG.4-b; P < 0.01) and negatively influenced by DODBA (P < 0.01).

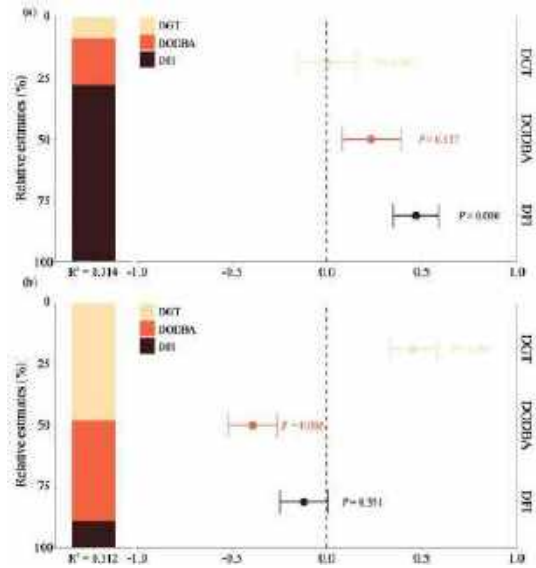

Figure 4 Effect of grazing activity of sheep on their productivity under different grazing managements (GLMM). Figure a showed the effects of grazing behaviors of sheep on their productivity under different grazing intensities, and Figure b showed the effects under different flocks.

Discussion

According to the results of the GLMM, grazing intensity influenced ADG through DFI. However, no significant differences in DFI were observed among lambs under different grazing intensities. This lack of variation could be attributed to the comparable growth stages of lambs across treatments, as factors such as body size and age–which were key determinants of feed intake and weight gain–were similar. Consequently, no significant differences in DODBA or DFI were detected among the treatments, resulting in non-significant differences in ADG (Charnov, 1976). Significant differences in ADG were observed among sheep from different flocks, with ewes displaying significantly lower ADG compared to lambs. Moreover, the DGT in the MGE treatment was significantly shorter than that in the MGL treatment, whereas the DFI of ewes was significantly higher than that of lambs. According to the GLMM, flock influenced ADG through DGT and DODBA. This could be attributed to the similar grazing intensities across treatments, which provided comparable access to pasture resources. Simultaneously, ewes, due to their greater grazing experience, exhibited higher foraging efficiency, spending less time while consuming more feed (Thórhallsdóttir et al., 1990). However, the larger body weight of ewes relative to lambs resulted in higher energy expenditure during grazing, as reflected in the higher DODBA (Mysterud and Austrheim, 2016). Additionally, the presence of ewes and lambs grazing together may have introduced lactation-related behaviors, with lambs benefiting from additional nutrition through nursing (Pullin et al., 2017). The interaction of these factors, in conjunction with the physiological stages, led to the lower ADG in ewes compared to lambs. In conclusion, grazing management significantly influenced sheep productivity and grazing behavior, with grazing intensity affecting productivity through feed intake and flock structure influencing activity levels, offering insights for optimizing steppe grazing practices.

Effects of fermentation time of natural-pasture-based total mixed ration on slaughter performance and organ development of sheep

Zhuo, X; Wang, Y; Wang, L; Chen, X; Yu, Z

China Agricultural University, College of Grassland Science and Technology, NO.2 Yuanmingyuan West Road, Haidian District, Beijing 100193, China.

Key words: Fermenting total mixed rations, spleen, production, health

Abstract

Fermenting total mixed rations (FTMR) is an important method for changing traditional extensive livestock farming practices, improving animal health, and enhancing the quality of livestock products. It offers several advantages, including a wide source of feed raw materials, a long and safe storage time, labour and time savings and providing nutritionally balanced feed for pastoralists throughout the year. However, the existing data are insufficient about how FTMR with different fermentation durations affect animal performance and health. Therefore, this study aims to evaluate the effect of natural forage silage-based FTMR with different fermentation durations on production and health of sheep. In Hulunbuir, total mixed rations were formulated with natural forage silage on a fresh weight basis, and fermented for 0 day, 10 days and 20 days respectively. Eighteen sheep were selected and randomly divided into three groups of six sheep. The three groups were fed TMR (CK), FTMR fermented for 10 days (FTMR1) and FTMR fermented for 20 days (FTMR2) over a period of 75 days, respectively. Results showed no significant differences in carcass weight, carcass yield, longissimus dorsi muscle (LDM) area and GR value among the groups (P>0.05). The FTMR2 group had a significantly higher spleen weight and proportions to carcass weight than the other groups, with no significantly differences between CK and FTMR1. Other organ weights and proportions to carcass weight showed no significant differences (P>0.05). In conclusion, FTMR provides similar effects to TMR without harming organs. FTMR fermented for 20 days promotes spleen development and immune function, benefiting livestock health.

Introduction

In the Mongolian Plateau, native grass serves as the primary fodder source for livestock production. Apart from making hay, ensiling native grass is seen as an emerging new trend (Hou et al., 2023; Y. Li et al., 2022). Total mixed ration is an ideal method for meeting the growth requirements of livestock by combining native grass silage with other roughage, concentrates, vitamins, and minerals. It can reduce selective feeding, increase dry matter intake, and stabilize the rumen internal environment, compared with the traditional feeding model (Beigh et al., 2016; Bharanidharan et al., 2021). However, TMR is susceptible to aerobic spoilage (Seppälä et al., 2013), and requires a high level of mechanization in the production process (Bueno et al., 2020). These factors limit the circulation and promotion of TMR, especially in some Asian countries. Currently, in Asian countries, livestock farming operates at a household or small-scale farm basis is typical. Due to constraints in funds, technical knowledge, and production equipment, farmers find it is challenging to adopt TMR for livestock feeding.

Nevertheless, fermented total mixed ration (FTMR) can save labour in the TMR preparation process, enabling long-term storage and distant distribution of TMR (Weinberg et al., 2011). Compared with TMR, FTMR improves the aerobic stability (Wang et al., 2016) and nutrient digestibility of the diet (Miyaji et al., 2017), while reducing methane emissions (Cao et al., 2010).

Throughout the FTMR distribution process, farmers often purchase and store large quantities of FTMR at once. In this process, the nutritional composition of FTMR could be influenced by factors such as raw material composition, storage time, and storage conditions. Studies indicate obvious changes in the soluble protein and soluble sugar fractions in FTMR; solubilization of the protein fraction in FTMR is enhanced with prolonged storage and higher storage temperatures, while most soluble sugars are lost during the fermentation process (Weinberg et al., 2011). However, the existing data are insufficient about how FTMR with different fermentation durations affect animal performance and health. Therefore, this study aims to evaluates the effects of natural forage silage-based FTMR with different fermentation durations on production and health of sheep.

Methods

Animals, diets, and experimental design

Eighteen sheep of similar weight (33.55 ± 0.86 kg) were randomly divided into three groups of six head. The groups were fed either a total mixed ration (CK), a short term fermented total mixed ration (FTMR1, fermentation time for 10 days), or a long-term fermented total mixed ration (FTMR2, fermentation time is 20 days). Total mixed rations were formulated according to the nutrient requirement of a meat-type sheep (NY/T816-2021). The main components of the native pasture species are *Leymus chinensis*, *Bromus inermis*, *Potentilla bifurca*, *Astragalus laxmannii*, and *Artemisia argy*i. The experiment lasted for 75 days, including a 14-day pre-feeding period and a 60-day formal study period. The pre-feeding period was the same as the test period in terms of feeding management and formula composition. The animals were fed twice a day at 08:00 and 18:00, with free access to water.

At the termination of the experiment, sheep were then slaughtered using commercial methods. The sheep were weighed (LWBS) after fasting for 12 h before being processed for slaughter. Carcase weight was recorded after removal of the hide, head, hooves and viscera. The heart, liver, spleen, lung and kidney were separated, and the proportion of each organ weighed. An organ weight to LWBS index was calculated. The GR value was measured by vernier caliper to measure the tissue thickness between the 12th and 13th ribs of sheep at the 110 mm from the midline of the dorsal spine. Eye muscle area (EMA) was the cross-sectional area of the LDM between the 12th and 13th ribs of the carcass.

Data were analyzed using Excel 2021 to calculate means and standard errors, and SPSS 25.0 software was employed for statistical analysis. Multiple comparisons of measured data were conducted using Tukey's method.

Results

The effects of TMR fermented for different durations on the slaughter performance of meat sheep are shown in Table 1. No statistically significant differences ($P > 0.05$) were observed among the three treatment groups for any of the indicators. However, the groups fed fermented total mixed rations (FTMR) showed higher live weight before slaughter, carcass weight, and slaughter yield compared to the group fed non-fermented TMR.

The effects of TMR fermented for different durations on the organ development of meat sheep are shown in Table 2. The FTMR2 group exhibited significantly greater spleen weight and spleen index when compared with CK and FTMR1, while no statistically significant differences were found between the TMR and FTMR1 groups. For the other organs, there were no significant differences in organ weight or their proportion to carcass weight among the three treatment groups ($P > 0.05$).

Table 1 Effects of FTMR with different fermentation duration on the slaughter performance of sheep

Item	CK	FTMR1	FTMR2	SEM	*P*-value
LWBS (kg)	41.45	42.10	43.83	1.53	0.711
Carcass weight (kg)	17.69	18.09	19.78	0.79	0.602
Carcass yield (%)	42.64	43.01	45.11	0.86	0.534
EMA (cm^2)	18.88	19.41	16.15	0.15	0.622
GR value (mm)	4.30	5.63	5.27	0.31	0.165

EMA = Eye muscle area of the longissimus dorsi.

In the same row, mean values with different superscripts were significantly different ($P < 0.05$).

Table 2 Effects of FTMR with different fermentation duration on organ development of sheep

Item	CK	FTMR1	FTMR2	SEM	*P*-value
Organ weight (g)					
Heart	229.50	231.75	269.33	4.84	0.366
Liver	495.00	564.00	535.33	18.21	0.365
Spleen	39.50b	45.75b	59.67a	21.86	0.010

In the same row, mean values with different superscripts were significantly different ($P < 0.05$).

[1] Percentage relative to empty BW (%) = (the organ weight/empty BW) × 100%.

Discussion

Slaughter performance is a direct reflection of the production efficiency of livestock, serving as a key indicator of their economic value. Common metrics for assessing slaughter performance include carcass yield, EMA and the GR value. The EMA is an indicator of carcass quality, while the GR value serves as an indicator of carcass fat cover. In the present study, no significant differences were observed in slaughter yield, eye muscle area, or GR values across different treatment groups, suggesting that feeding meat sheep with fermented total mixed rations (TMR) yields results comparable to those achieved with non-fermented TMR.

Visceral organs play a fundamental role in an animal's metabolism. The weight and organ index of these organs reflect the animal's metabolic and developmental status. Under normal circumstances, organ development is closely coordinated with overall growth (Su et al., 2022). In this study, with the exception of the spleen, there were no significant differences in the weight and organ index of other organs between treatment groups, indicating that TMR fermented for varying durations does not adversely affect organ development. The spleen, a primary site for immune cell generation, differentiation, maturation, and immune responses, is crucial for immune function. Notably, the FTMR2 group exhibited a significant increase in both spleen weight and spleen index, suggesting that long-term fermentation of TMR promotes spleen development in sheep. Previous research has shown that lactic acid bacteria can significantly enhance spleen development in livestock (Sun et al., 2024), likely due to their proliferation during the fermentation process. As probiotics, lactic acid bacteria produce a range of bioactive compounds, including organic acids, short-chain fatty acids, and extracellular polysaccharides(A. Li et al., 2024), which may modulate the immune system and bolster immune responses (Vieco-Saiz et al., 2019).

The study demonstrates that FTMR maintains comparable slaughter performance to TMR in meat sheep while enhancing spleen development.

3R's: Regenerative rangeland ranching in southern north America

Muir, JP[1,2]; Thetford, SK[1,2]; Murray, DB[2]; Tolleson, DR[1]

[1] Texas A&M AgriLife Research, TX USA; [2] Tarleton State University, TX USA

Abstract
Our research team proposes a sea change in southern North American rangeland from ranching solely for production to husbanding for stable, regenerative grasslands. Rangelands in southern North America are too often ecologically, biologically and economically dysfunctional, degenerating ecosystems. Plows, cows and bankers dominate, supported by equally short-sighted, discipline-focused academia and industry. We propose regenerative rangeland ecosystems research based on long-term, multi-functional, flexible-use goals sustained by interdependent hydrology, soil, climate, vegetation and animal components and carried out by multi-disciplinary teams. Flexibility in meeting food, energy and ecosystems service markets can take rangeland systems beyond niche production and its inherent inexorable degradation to stable, multi-functional rangelands in southern North America. Our research and development team brings together social and biological scientists with stakeholders focused on medium and long-term regenerative rangeland management.

Introduction

We propose a sea change in southern North American rangeland research from ranching solely for production to husbanding for stable, regenerative grasslands. We define regenerative ranching (RR) as herbage-based ruminant agriculture that uses resilient, ecologically and economically sustainable grasslands management with minimal environmental disruptions or outside inputs. According to Jayasinghe et al. (2023), regenerative agriculture restores and maintains ecosystem (hydrology, soils, plants, animals etc.) health while still feeding human populations. Our multi-disciplinary team proposes research that focuses on multiple functions within RR (Fig.1).

Figure 1. Multi-disciplinary research for multi-functional regenerative ranching.

One of the basic tenets we adopt as a multi-disciplinary approach to regenerative ranching research, outreach and implementation is biodiversity. Biodiverse grassland ecosystems, from soil to vegetation to animals and the human dimension, tend to be more resilient biologically and socioeconomically (Picasso et al. 2022).

Methods

Human dimensions of regenerative rangeland ranching

We have learned the hard way that we are far more successful when we incorporate human dimensions in RR research. These involve the social, cultural, and economic aspects that influence relevance, adoption and success of regenerative practices in rangeland management. These dimensions emphasize the importance of understanding landowners, communities, policymakers, public perception, and consumers interacting with, and depending on, rangelands (Tolleson and Metman 220; Giwa et al. 2024). Before initiating biological research efforts, we believe we should identify local challenges and priorities through key informant interviews, structured surveys and questionnaires, community meetings, participatory mapping, and data analysis aid in aligning ranching operations with community goals, such as improving soil health, increasing biodiversity, supporting livelihoods, preserving cultural heritage, and ensuring regenerative practices meet both ecological and socio-economic needs (Donaldson and Franck 2016).

The significance of human relationships and connections to the community and ranching itself directly benefits or undermines regenerative rangeland ranching efforts. Humans influence all decisions, and regenerative ranching trajectories starts and ends within communities, organizations, and government, most local to the system of interest (Berkley and Beratan 2021). Any effort at directed system change requires coordinated actions among our diverse participants, academic, management and government. This decision-action context means community and personal relationships are crucial to developing workable, adoptable regenerative ranching solutions (Lu et al. 2024).

Restoring rangeland health

Woody plant cover across semi-arid and sub-tropical grassland savannas is increasing on a global scale; multiple drivers contribute to this encroachment, including, but not limited to, land use changes, fire suppression, cattle grazing practices, and climate change (Archer et al. 1988). Most of these changes involve dramatic increases in native woody taxa that were historically present in low densities.

Such changes in woody cover impact overall system biodiversity, ecosystem function and related ecosystem services, including food production but not always in a negative way, as it can also add resilience. A review by Eldridge et al. (2011) indicated that encroachment had mixed effects on ecosystem structure and functioning at global scales, and that woody plant traits influence the functional outcome of encroachment. A simple designation of encroachment as a process leading to degraded ecosystems is not supported in every instance. The literature on the negative effects of woody encroachment has been strongly influenced by the prevalence of a single land use, for example pastoralism involving grass-feeding livestock. Woody plant expansion will likely continue based on past trends and future projections, especially in arid and semiarid ecosystems (Asner et al. 2004, Van Auken 2009). If animals are matched with the landscape, woody plants may add an aspect of resilience, given their resistance to long-term drought and their resilience with respect to overgrazing (Estell et al. 2012).

Adapting ranching to landscape rather than landscape to animal production

As an essential part of RR, we propose adapting extractive or environmental management goals to the ranch ecosystems rather than the other way around. Instead of manipulating grasslands to fit unsuitable agricultural practices, we seek to research and support land managers to utilize what the ecosystem is best adapted to producing for human needs. For example, if browse dominates plant populations in a ranch ecosystem, then manage for ruminants that prefer converting dicots into consumable products (Irob et al. 2021). This is far more regenerative than manipulating vegetation, at high economic and environmental costs, to favor monocots for mono-specific grazing ruminant herds.

On the animal side, we propose adapting ruminant species, both domesticated and native, to ranch soil and vegetation strengths (Muir et al. 2015). If Eurasian cattle, for example, prove detrimental to RR ecosystems, then we will consider non-traditional domesticated ruminants from Asia, Africa and the Americas. If quasi-domesticated species, both native and introduced, are best suited to an ecosystem, then these will replace cattle, goats or sheep. Likewise, if native bees are best adapted to a biodiverse rangeland, for example, then European bees will not be purposely introduced. If native wildlife are better adapted to the ecosystem, then white-tailed deer, elk and bison can replace cows, sheep and goats.

No matter how much we would like to think the contrary, native wildlife and domesticated animal grazing are not always compatible on North American Rangelands (McGinn et al. 2022). There is a preponderance of evidence, however, that well-managed domesticated livestock herbivory can contribute to regenerative rangeland conditions that favor a return to complex, native animal trophic levels based on healthy soils and diverse native plant communities (Gordon et al. 2021), by replacing extirpated native bulk grazers and browsers. Wildlife resources, whether as primary land-management efforts (e.g. food harvest) or secondary (e.g. conservation and ecosystems services), are a priority in regenerative ranching in southern North America.

Ecosystems services and other economic incentives

Ecosystem services (ES) are generally categorized as: a) provisioning, b) cultural, c) supporting, and d) regulating. Rangeland based examples of each are: a) animal source protein, b) open space, c) biodiversity, and d) pollination (SRM 2023). Modern ranchers not only produce food and fiber, but they also support wildlife habitat, enable watershed function, provide recreational opportunities, mitigate wildfires, and address their operation's impacts on climate change. And they do so under increased scrutiny from a public that typically does not understand who they are and what they do (Nolte 2021).

Fortunately, ecosystem goods and services are what "good" ranchers have always done. They have long understood that ranching begins with taking care of the soil, which retains the water and produces the vegetation that feeds and shelters the animals (Lien et al. 2017). Many have known that a variety of plants are required to keep rangelands, especially in drier climes, healthy. An appreciation for wild places and wild things has always been an integral part of their culture.

However, as with any human undertaking, not all ranchers have been good stewards (Angerer et al. 2023). Additionally, ranching is changing. New ownership demographics are evolving (Lopez et al. 2023). These new ranch owners may vary from large investors or companies who want to improve their "green" footprint, the next generation in a ranching family that has moved back to the ranch, or to new landowners who may or may not have the required knowledge and experience to effectively manage a ranch and often have different motivations for land ownership than traditional ranchers.

It is therefore incumbent on the scientific community to address the challenges facing modern ranchers, regardless of goals, background, and experience. Rangeland-based ranching decisions in North America have historically been driven by manager demographics and economic necessities (Peterson and Coppock 2001). More recent data indicate that public (economic incentives) as well as changing private (cultural priorities) initiatives factor into environmental concerns in some regions such as California, especially in regard to ecosystems services and conservation (Oyama and Huntsinger 2019) inherent in regenerative ranching approaches. If researchers have any chance of convincing rangeland managers to implement regenerative ranching in southern North America, we must be at the forefront of designing, testing and promulgating novel economic and cultural motivations.

Conclusions

Our proposed multidisciplinary, multi-objective and flexible approach to RR ultimately seeks to restore and maintain ranching sustainability while maximizing outputs. Through research and education, we hope to diversify management goals and socioeconomic outputs to include not just the traditional domesticated ruminants but flexible goals such as bioenergy, wildlife, ES, and human dimensions.

Irrigated and rainfed cropping on northern Australian rangelands

Zund, PR[1]; Petheram, C[2]; Watson, I[3]

[1] CSIRO, St Lucia; [2] CSIRO, Sandy Bay, [3] CSIRO, Townsville

Key words: Agricultural development; Analysis of fodder, fibre and food production areas; Cropping expansion; Growth rate; Percentage of rangelands

Abstract

Over the last quarter of a century a small part of the northern Australian rangelands has been converted to cropping for fodder, fibre and food production. The expansion of cropping onto rangelands has been slow and still is small in percentage terms (0.04 %) when compared to the area of northern Australia (300 million hectares). Much of the cropping area is being used to grow fodder crops, however, cotton, grain sorghum, table grapes, citrus, watermelons, sweet corn, potatoes and vegetables are also being grown. State and Territory governments are encouraging development in cropping and horticulture on rangelands by undertaking research into water and soil resources and funding feasibility studies for development of new regional infrastructure such as cotton gins and water supplies. This paper analyses the changes that are happening, specifically in rangelands, and is based on a broader study that has assessed all cropping, horticulture and plantation forestry across northern Australia in 1999 and 2023 using Sentinel and Landsat imagery as well as other publicly available information. Irrigated cropping, horticulture and sandalwood plantations on northern Australian rangelands occupied 5,393 Ha in 1999 expanding to 17,481 Ha in 2023, a three-fold increase over 24 years, a net annual increase of 504 Ha or an annual compounded growth of 5 %. Rainfed cropping and forestry occupied 11,878 Ha in 1999 expanding to 94,963 Ha in 2023, an eight-fold increase over 24 years, a net annual increase of 3462 Ha or an annual compounded growth of 9 %.

Introduction

How much of northern Australian rangelands have been converted to cropping? At what rate are the rangelands being converted? Where is the conversion taking place and why? To be able to answer these questions we require land use data. Since 1990, State and Territory agencies have been mapping land use (DAFF 2024) however, this data is a mosaic of mapping products with varying time stamps and resolutions (ABARES 2023). It has, therefore, been impossible to answer the above questions without methodically examining satellite imagery. The objective of the original study was to adjust the publicly available land use data to a consistent time and resolution using satellite imagery and other publicly available information and map the changes that have occurred in cropping, horticulture and forestry on northern Australian rangelands. This rangelands analysis is based on the data collected in the broader study.

Methods

Scope

This analysis of fodder, fibre and food cropping was to analyse the expansion of cropping and horticulture onto rangelands in northern Australia (north of the Tropic of Capricorn). This analysis excluded the cropping and horticultural occurring in the Ord River Irrigation Area, Carnarvon Irrigation Area, Skuthorpe, Mataranka, Katherine, Douglas – Daly, Darwin, Gilbert River Agricultural Precinct and Julatten area. We also did not include catchments that drain into Great Barrier Reef lagoon (northeastern Queensland). Results are expressed to at least the secondary level of the Australian Land Use Classification (ABARES 2016) and are expressed in hectares (Ha) of land rather than crop yields or commodity values. For growth or decline in area, annual compounded percentage is used. For absolute change between 1999 and 2023 area is used.

Method

Land use data was collated from existing mapping undertaken by State and Territory agencies (ABARES and DPIRD 2018; DEPWS 2022; QLUMP 2024) and adjusted with publicly available Sentinel and Landsat satellite imagery from 1999 (Geoscience Australia 2022) and 2023 (Fuqin *et al.* 2019). Cropping or horticulture on rangelands was deemed to be present if it was visible on the satellite imagery at any time during the calendar years 1999 and/or 2023. Cropping or horticulture was not accounted for if it was established after the year 1999 and ceased before the year 2023. Cropping or horticulture that appears abandoned was not included in the data. However, land that appears fallow between crops and the crop can be identified using nearby fields was included. Commodity was confirmed where possible using publicly available data on the world wide web or local knowledge.

Results

Irrigated and rainfed fodder, fibre and food crops occupied 17,271 Ha in 1999 expanding to 112,368 Ha in 2023. This was a 6.5-fold increase in area or nearly 4000 Ha per year resulting in a compound growth of 8 % per annum. Fodder, broadacre cropping and forestry accounted for the largest percentage of this area. Most of the forestry was restricted to Melville Island as a plantation of *Acacia mangium* for pulp wood.

Irrigated cropping and horticulture occupied 5,393 Ha in 1999 expanding to 17,481 Ha in 2023, a three-fold increase over 24 years, an increase of 504 Ha per year resulting in a compound growth of 5 % per annum. Rainfed cropping occupied 11,878 Ha in 1999 expanding to 94,963 Ha in 2023, an eight-fold increase over 24 years, an increase of 3462 Ha per year resulting in a compound growth of 9 % per annum.

Most of the expansion in irrigated cropping has been to produce fodder such as hay and silage, pasture and forage sorghum. Irrigated horticulture is mostly restricted to single enterprises and has changed little over the 24 years of the study. Most of the expansion in rainfed agriculture has occurred as cropping to produce fodder mostly as forage sorghum (1894 Ha per annum). Expansion in rainfed broadacre cropping has occurred as grain sorghum and cotton (274 Ha per year). Plantation forestry (Mangium) on Melville Island and African mahogany (Daly catchment) are excluded from this summary but results are shown in the Table 1.

Cropping varies between regions and is affected by local drivers. In the Pilbara, water from mine dewatering activities has caused an expansion in irrigated fodder cropping. On the grazing country between the Great Sandy Desert and the Indian Ocean, fodder cropping and horticulture (sweet corn and melons) using groundwater resources was being grown. A single sandalwood plantation exists in the Ord River catchment using water from their own large gully dam. Cotton is establishing in the Daly catchment as well as vegetables and melons. Melons and table grapes are being grown in remote areas of central Australia. Cotton is expanding in the southern Gulf of Carpentaria catchments. Hay is being produced in the northern parts of the Channel Country of Queensland.

Table 1 Area and change in fodder, fibre and food crops on northern Australian rangelands

	Land use / Year	1999 (Ha)	2023 (Ha)	Change (Ha)	Growth* (%)
Rainfed	Forage sorghum	n/a	44,724		
	Hay & Silage	2,329	3,038	709	1.1
	Fodder	**2,329**	**47,762**	**45,433**	**13.4**

	All fodder, fibre and food	**5,393**	**17,481**	**12,088**	**5.0**

*Compound growth **Including mango, citrus and date plantations

Discussion

This research provides a more quantitative analysis of fodder, fibre and food cropping on northern Australian rangelands than has been done previously. This study has attempted to adjust / correct / update the available data as far as practical without doing a field survey and thus we believe provides more authoritative information on state and trend currently about fodder, fibre and food cropping on northern Australia rangelands. An ultimate inventory of land use would require a field survey, however, even a field survey can not provide the historical data for 1999. We used Sentinel satellite imagery to confirm land use in 2023, but we were limited by the lower resolution Landsat imagery available for 1999. Because ACLUMP is a multi-agency program with varying levels of implementation of the Australian land use and management classification (ABARES 2016), it is difficult to make a detailed assessment of current state and trends from their data.

Despite much recent interest and activity in northern Australian development, the increase in rainfed and irrigated cropping away from existing schemes and other clusters of development is relatively low in comparison to the area of rangelands as a whole. This is due to several factors including regulatory and legal constraints to land clearing and land use as well as access to water for irrigation. The economic viability of cropping also constrains expansion. Long distances to milling, markets or ports results in high transport costs which need to be offset by higher value crops. Commodity crops, or other crops of low value struggle to be viable. More promise is held for higher value crops or higher value horticulture aimed at supply gaps in southern Australian (or other markets).

What might the next decade or two look like? Two factors may limit increased area. Tighter restrictions on diversification of pastoral leasehold land may limit expansion. Some of the 'low hanging fruit' may have been developed in the past 24 years. By contrast, the construction of two new cotton processing facilities in northern Australia will make cotton production more viable, which may cause rapid increases in the area of (particularly rainfed) cotton.

Grazing with Trees: upscaling silvopastoralism for improved dryland management

Herrera Calvo, PM[1]; Haddad, F[1]; Gerbaldo, L[1]; Valenzi, V[1]; Hofer, T[1]

[1] Forestry Division, Food and Agriculture Organization of the United Nations (FAO)

Key words: silvopastoral systems; drylands; rangelands; sustainable land management

Abstract
This presentation describes the first results of the Grazing with Trees (GWT) initiative, promoted by FAO as a response to the Committee on Forestry (COFO) 26th session request to "promote greater and inclusive policy coherence between the agriculture and forestry sectors, including through integrated land use planning, landscape approaches". The main target of the initiative is to promote enabling environments for dryland Silvopastoral Systems (SPSs). These agroforestry schemes provide multiple benefits and ecosystem services in dryland regions as evidenced by the recent FAO publication *Grazing with Trees*, which seeded the initiative. Being uniquely adapted to landscapes with water scarcity and climatic variability, SPSs can evidently improve the resilience of landscapes and communities to the impacts of climate change, combat desertification, improve watershed management and provide diverse food sources and livelihood opportunities for dryland communities.

The GWT initiative aims to strengthen, at country level, the capacity to mobilize resources and investment tools to incorporate SPSs into Land Degradation Neutrality commitments and Intended Nationally Determined Contributions under the Paris Agreement. GWT seeks to improve effective policy, legislation and institutional arrangements supporting climate-resilient silvopastoralism, especially those adopted by pastoralist and forester communities. The presented outcomes include participation-based silvopastoral policies, strategies and land-use management plans developed and adopted by communities in target landscapes and additional outcomes related to improved governance, participatory institutions and enhanced investment options identified through multistakeholder consultations and application of FAO assessment tools and knowledge products.

Introducing the Grazing with Trees initiative
Drylands and presumed drylands account for approximately 48% of the Earth's land surface and are home to 25% of the human population. They support 50% of the world's forests, 50% of global livestock and 44% of global cultivated systems. Furthermore, they harbour 46% of global carbon reserves and 36% of the earth's biodiversity hotspots.

Woody vegetation and trees provide essential ecosystem services in dry areas, including animal feed, timber, fruits, shade and regulation of soil and water cycles. Equally, livestock production, in particular pastoralism, is critical for livelihoods and food security and supports the resilience of about one billion people throughout the Earth's dryland ecosystems.

Forests and livestock have been widely considered as antagonists; the latter considered a driver for the degradation of forests. Regardless whether it is important to address the real environmental footprint of pastoralism and encourage an adequate responsibility-sharing with other production systems, the impact of livestock also needs urgent action. Between 2000 and 2018, 68 Mha of dryland forests were cleared in South America and 49 Mha of dryland forests were cleared in Africa (FAO 2019). Cropland expansion was the highest driver of deforestation, accounting for almost 50% (many of them fodder-oriented), but it was closely followed by livestock production, accounting for 38.5% of the deforestation. Livestock is also considered a major source of greenhouse gas (GHG) emissions, accounting for almost 14.5% of the total.

Accordingly, there is an urgent need to adopt improved livestock management practices to both improve efficiency of natural resource use and decrease environmental impacts. FAO estimates that improved management practices alone could reduce net emissions from livestock systems by about 30% (FAO 2016). Halting deforestation and maintaining forests could avoid emitting 3.6 +/- 2 gigatons of carbon dioxide equivalent (GtCO2e) per year between 2020 and 2050, including approximately 14% of what is needed before 2030 to keep planetary warming below 1.5 °C, while safeguarding more than half the Earth's terrestrial biodiversity (FAO 2022b).

Integrating livestock with trees and other woody vegetation results in a complementarity of agroforestry systems – a silvopastoral system (SPS) – that can boost the local ecosystem, representing a positive transition towards an integrated perspective of livestock and forest production. SPSs support high-value food sources for livestock that can increase productivity, especially milk production, while acting as a primary pathway for forest restoration in dryland areas.

Being uniquely adapted to landscapes with water scarcity and climatic variability, SPSs can improve the resilience of landscapes and communities to the impacts of climate change, combat desertification, improve watershed management and provide diverse food sources and livelihood opportunities for dryland communities.

This paper describes the first results of the Grazing with Trees (GWT) initiative, started by FAO to develop enabling environments for mainstreaming dryland SPSs. This initiative is seeded by the FAO publication: *Grazing with Trees* (FAO 2022a) aimed to support silvopastoral approaches and develop enabling environments for dryland SPSs.

This initiative specifically responds to the Committee on Forestry (COFO) 26th session request to "promote greater and inclusive policy coherence between the agriculture and forestry sectors, including through integrated land use planning, landscape approaches" The initiative also answer the request of the country members of the COFO Working Group (WG) on Dryland Forests and Agrosilvopastoral Systems to generate evidence on how SPSs could contribute to the restoration of woody ecosystems in drylands, mitigating desertification and drought. Accordingly, the GWT initiative will strengthen countries' capacity to design on-the-ground drought-resilient SPS investment proposals and to mobilize resources to achieve their Intended Nationally Determined Contributions under the Paris Agreement. In doing so, it will enhance pastoral agrifood systems in dryland areas and improve communities' resilience to climate change and other crises. By building partnerships with communities, development actors and governments, the initiative will also facilitate South–South dialogue and investment fora so that communities can share challenges, opportunities and lessons learned, encouraging collaboration to strengthen drought-resilient and gender-responsive silvopastoral value chains in selected countries.

Methodological approach: first steps for a multilevel strategy

GWT focuses on creating enabling environments for developing SPSs in dryland areas. Its methodology intends to gather together country members to coordinate action. To this end, successful implementation requires well-designed, integrated cross-sectoral strategies with effective policies, governance and land management. Several pilot countries will implement those strategies at different levels: country, state and local and report to the project for analysis and discussion.

The first step is sourced by the GWT publications and delivers the rationale for mainstreaming silvopastoralism, gathering and operationalizing the conclusions and recommendations of the report.

A second step consists in delivering a roadmap for willing countries to promote enabling environments by improving effective policy, legislation, institutional arrangements, multistakeholder platforms and pilot experiences supporting climate-resilient dryland SPSs, especially those adopted by pastoralist and forester communities. This way, silvopastoral management could be integrated and mainstreamed into national grazing and forest policies, legislation and institutional arrangements in target countries. Specifically, a clear line of action is sought regarding the potential of SPSs for climate action, addressing at the same time adaptation to and mitigation of climate change. This line of work was derived to a new initiative focused on potential of SPSs for decarbonization.

The third step targets actual implementation on the field. While dryland developing countries often have or are able to develop policies that can support SPSs, effective implementation is generally lacking, and investment is not a priority, often due to a lack of awareness and appropriate investment solutions, and limited capacity for implementation or sustaining communities' practices and traditional systems. Investment is a bottleneck for dryland projects and, accordingly, improving financial and investment tools will be a critical outcome of the project. SPS investment opportunities are identified through multistakeholder consultations on targeted and inclusive value chains, to be assessed against the financial needs of the silvopastoral projects.

In addition, this initiative also addresses critical cross-cutting issues, often by close collaboration with other ongoing FAO Drylands projects, including knowledge management, gender equality and governance. For example, knowledge management tries to build capacities of stakeholders and decision-makers, but also targets the co-construction of knowledge with farmers, pastoralists and local communities (including grassroots associations and indigenous groups) in effective, integrated and silvopastoral management for sustainable production and forest and agricultural biodiversity.

First results

SPSs can derive multiple benefits from the ecological relationships between animals and woody plants (Plieninger & Huntsinger 2018). These benefits combine improved food production and security with increased livelihood adaption and resilience, while acting as a primary pathway for forest restoration and sinking carbon in dryland landscapes by enhancing the above- and below-ground carbon capture through improved pasture management, tree planting and assisted natural regeneration. The integration of trees in SPSs – where trees are introduced into grazed pastures – can be very effective in capturing and temporarily storing carbon. It also enhances productivity and protects against the extreme weather conditions (Agethen et al. 2021).

Benefits evidenced from previous projects in dryland regions that introduced SPSs were documented in *Grazing with Trees* (FAO 2022b). For example, microclimate measurements show lower soil temperatures in pastures with trees (2.2–2.3°C at 5 cm from the surface). Economic analysis of various intensified SPSs in Latin America found that the income generated was far higher than the investment in all cases (Chara et al. 2017). In India, the Jhansi dryland areas have increased their production tenfold using a ten-year silvopastoral rotation plan (Yadav et al. 2019). In Senegal, hundreds of villages have protected their common grazing lands over the last 30 years, transforming degraded shrubs into savannah landscapes and increasing woody cover by up to 65% (Pasiecznik & Reij 2020).

The scoping accompanying the production of the roadmap has also provided some results and key lines of work targeting the links between forests, agriculture and agroforestry systems. A first finding indicates that agroforestry systems constitute a clear asset for mitigation by sequestering atmospheric carbon dioxide both in roots and soil but also in aerial plant parts, (de Stefano & Jacobson 2018) in a way that crops and grasslands cannot. Agroforestry systems store more carbon in woody plant biomass, on average, 46.1 Mg/ha more than sole cropland or pasture-based land uses without trees, which shows a great potential to adopt mitigation measures while providing a wide span of options for increasing their capacity of adaptation (Zomer et al. 2016). This way, SPSs can enhance biomass as well as soil C storage in pasturelands through addition of woody components (Aryal et al. 2022). Precisely, increasing the complexity of crops and pasturelands by implementing agroforestry systems significantly increases soil organic carbon (SOC) (de Stefano & Jacobson 2018). Once this baseline is established, the incorporation of the role of domestic herbivores through agrosilvopastoral and silvopastoral approaches also has the potential to increase SOC stored in herbaceous plants roots, due to the effects of grazing on the plant communities.

The pathway to deliver those results was also established in the report and marks the key lines of action for adapting the project to a multi-country scale:

1) Monitoring, data gathering and assessment of the situation of targeted SPSs
2) Policy work, specifically the development of supportive and participatory policies and legal frameworks that allow the creation of enabling environments
3) Securing tenure rights and improving governance through upgrading and support of traditional governance systems and implementation of participatory and multistakeholder institutions
4) Co-creation of knowledge, capacity building, training and education to empower pastoralist communities and generate the conditions to allow their full participation in decision-making
5) Adopting a gender-sensitive approach to sustainable land planning and management, recognizing the role of people in risk of marginalization, women, youth, employees, elders...

Discussion and conclusion

Silvopastoralism emerges as an innovative solution for improving management and restoring dryland ecosystems. Both traditional and modern SPSs can contribute to increased productivity and income, while preventing erosion, protecting the soil from land degradation and improving other ecosystem services. Moreover, silvopastoralism has evolved in drylands and co-evolved with its ecosystems, as a climate-coping and risk-management system, to maintain production and natural resources even in the occurrence of drought periods and extreme weather conditions (Soni et al. 2016). The main lines of the project – policies, governance, capacity and planning – offer a roadmap for implementation at a country level. In parallel, as the project targeting the role of SPSs for decarbonization is advancing with the first results from a literature review and model-building, Grazing with trees has completed its rationale and global assessment so the project is ready for local implementation.

Diversification of uses in South Australia's pastoral lands

Peacock, S; Wickes, R

[1] Department for Environment and Water, South Australia; [2] Pastoral Board of South Australia

Key words: rangelands; diversification; pastoral; South Australia

Abstract

Recent changes to South Australia's legislative framework are designed to enable a diversity of new industries and activities on pastoral land. These changes open up new opportunities for collaboration and diversification of a pastoralist's income streams, supporting the sustainable operation of pastoral businesses, improving long term conservation in a changing climate and increasing use of pastoral lands for a range of different purposes.

South Australia's pastoral lands have been developed from the 1850s to provide a sustainable resource for cattle and sheep grazing, producing high quality food and fibre as part of the state's thriving agriculture industry.

There are 322 pastoral leases making up 219 stations over an area of 40 million hectares, roughly 40% of South Australia.

However, pastoralism is now only one industry thriving on our pastoral lands, and pastoralists have increasingly needed to work in partnership with a range of other users, including First Nations, mining, tourism, and conservation. Major new industries and markets are also emerging on pastoral land, including carbon farming, renewable energy and nature markets, providing new opportunities and challenges.

Regulation of South Australia's pastoral lands commenced in 1842 and legislation has been regularly updated to reflect changing community values and uses. Recent changes to the *Pastoral Land Management and Conservation Act 1989* were made to clarify that pastoral leases can be used for conservation and carbon farming. The *Hydrogen and Renewable Energy Act 2023* has also been introduced to provide the ground rules for a major renewable energy industry that will be developed in collaboration with pastoralism.

Introduction

South Australia's pastoral lands have been developed from the 1850s to provide a sustainable resource for cattle and sheep grazing, producing high quality food and fibre as part of the state's thriving agriculture industry.

However, pastoralism is now only one industry thriving on our pastoral lands, and pastoralists and First Nations people have increasingly needed to work in partnership with a range of other users, including mining, tourism, and conservation organisations. Major new industries and markets are also emerging on pastoral land, including carbon farming, renewable energy and nature markets, providing new opportunities and challenges.

Regulation of South Australia's pastoral lands commenced in 1842 and legislation has been regularly updated to reflect changing community values and uses. Recent changes to the *Pastoral Land Management and Conservation Act 1989* were made to clarify that pastoral leases can be used for conservation and carbon farming. The *Hydrogen and Renewable Energy Act 2023* has also been introduced to provide the ground rules for a major renewable energy industry that will be developed in collaboration with pastoralism.

Discussion

Background

To enable the development of the pastoral industry, this Crown (government) land was allocated via pastoral leases (originally for 14 years under the Waste Lands Act 1846, then for 21 or 42 years under the first Pastoral Act in 1893). There are currently 322 pastoral leases making up 220 stations over an area of 40 million hectares, roughly 40% of South Australia. Pastoral leases originally enabled the occupation and use of Crown (government) land for the purpose of grazing or raising livestock (pastoralism).

Pastoral leases exist alongside Native Title, which protects the rights of First Nations peoples to access and use this land for traditional purposes. Native Title exists over most of the state's pastoral lands. Some Native Title owners also own pastoral leases or manage them under sub-lease from another lessee.

The *Pastoral Land Management and Conservation Act 1989* regulates pastoral land. Leases are issued by the Minister (on behalf of the Crown) for 42 years. The Pastoral Board oversees management of these leases, undertaking assessments of the condition of each lease every fourteen years. Providing the land condition remains good, the lease is extended again to 42 years, providing certainty for lessees. It also provides the opportunity for the Board to intervene and change the lease conditions if that land is at risk of degradation.

Changing land uses

After this land was allocated as leases for pastoralism, a range of other industries and demands have grown over time. Historically, mining and tourism have been the other major industries utilising these lands, generating significant economic returns for the state.

- Mining is managed through a separate regulatory system, which also recognises the important role of pastoral lessees and First Nations people. There are important interactions between these systems, to enable access, operation and rehabilitation of mining operations on pastoral land in a way that accommodates the other uses of the land.
- Tourism has included a mix of activities, some based on pastoral leases, and others needing access through pastoral leases, travelling on station tracks, camping or staying in lodgings. Many of these activities benefit pastoralists by adding an income source. Outback tourism has been considerably boosted in recent years as travellers have had a greater choice of inexpensive equipment for remote area travel.

In recent times, both external and internal drivers are also demanding new, flexible approaches to pastoral land.

- Within the industry, pastoralists have increasingly sought to diversify their businesses, seeking other revenue sources that can help to provide stability and resilience to offset the seasonal and market variations that continue to challenge agricultural enterprises. This need for diversification is likely to increase in the future as climate change continues to increase risks to production.
- Outside the pastoral industry, there is also strong demand for pastoral land to support carbon emissions mitigation, take advantage of emerging renewable energy industries, and enhance conservation measures to help to address the biodiversity crisis.

Carbon farming

Carbon farming is a growing industry in Australia, and potential for carbon storage in rangelands provides for the mitigation of carbon emissions, which can help producers achieve carbon neutral agricultural production, and/or provide an alternative revenue stream to provide pastoralists with greater resilience and options to complement their livestock businesses. With low rainfall and low rates of vegetation growth, carbon storage per hectare is low, but with projects over very large areas, there is still potential for significant vegetation-based sequestration. Carbon farming projects have been approved on eleven leases to date, mainly in the Gawler Ranges and Murraylands & Riverland districts. Carbon storage assessment is based on a change in management practice such as changing the extent and intensity of grazing which can include the control of feral animals. This may also include the exclusion of livestock at times but dual use of rangelands for carbon and pastoralism is encouraged. Existing methods which recognise these activities, are currently being reviewed by the Australian Government.

Renewable energy

The renewable energy industry is seeking to use pastoral land, which provide some of the world's best solar and wind resources. The industry is developing at a very significant scale, particularly to support the emerging hydrogen industry. The South Australian Government has established a new legislative framework to enable this industry to flourish on both pastoral and other land, while accommodating the existing uses of land, including pastoralism. The initial focus for projects will be in the Gawler Ranges area where it is close to electricity transmission infrastructure and to a new hydrogen production hub on the Eyre Peninsula.

Development of these industries are likely to provide significant benefits to pastoral leaseholders and Native Title holders, through increased revenue streams that will help to complement their businesses. However, there is also likely to be significant impacts on these landscapes, such as development of track networks which alter water flow, spread of weeds and a reduction in the area available for grazing. Regulators are working with developers and pastoralists to manage these impacts and support sustainable outcomes.

Conservation

The increasing prominence of the global and national biodiversity crisis has placed emphasis on the need to look after these lands. While grazing has transformed the region's landscapes over the last 175 years, there remains significant biodiversity on South Australia's pastoral lands which have been less intensively developed than densely settled areas. This complements several large and valuable protected areas established in the region, such as the Kati Thanda – Lake Eyre, the Ikara-Flinders Ranges and the Munga-Thirri-Simpson Desert National Parks.

Many pastoralists work to protect this biodiversity alongside their pastoral operations, supported by regulatory instruments such as Heritage Agreements and funding from biodiversity offsets associated with mining and other developments in the region.

Several leases have also been purchased by conservation organisations in a range of land systems, to dedicate large areas of private land to conservation. Many of these purchases were supported by national and state government funding to protect biodiversity on pastoral land, and in more recent times crowd funding has also been used to support the purchase and operation of these leases.

Currently, 21 pastoral leases, are wholly used – with the Pastoral Board's approval – for conservation, and a further nine pastoral leases include part of their area dedicated to conservation purposes. In total, around 14,400 square kilometres or 3.4% of pastoral land is dedicated to conservation purposes.

Regulatory change

Mining and renewable energy is managed under separate legislation, but otherwise, alternative uses must be approved by the Pastoral Board.

There has been debate in recent years over whether the *Pastoral Land Management and Conservation Act 1989* gave primacy to pastoral uses, and therefore whether any other uses can override pastoralism as the primary use of a pastoral lease.

Similarly, debate arose in recent years about whether pastoralists could undertake carbon farming projects on pastoral land, given the length of tenure is limited to 42 years.

The Government undertook to clarify that pastoral leases could be used for conservation and carbon farming purposes, and in 2024 the *Pastoral Land Management and Conservation Act 1989* was updated to address the areas of doubt and confirm that these activities were valid.

While there is provision to remove land from the pastoral estate and convert it to a different tenure, the preference in South Australia is to retain pastoral leases, under the oversight of the Pastoral Board, to provide a consistent set of tenure requirements and a single body to oversee it, rather than increasing the level of fragmentation and potential for conflict between neighbouring landholders.

The Board will continue to assess the condition of land on these leases every 14 years. This will help to ensure that lessees are actively managing their land and addressing issues that may be emerging in the landscape.

Lessees will still be required to meet their obligations under other legislation, such as controlling weeds and pest animals, and managing water resources.

While there is sometimes tension between pastoralists and conservation organisations, there are also opportunities for collaboration and shared learning. Joint efforts to sustainably manage pastoral landscapes and protect biodiversity, and develop new techniques, such as measuring carbon storage and vegetation growth, provide opportunities for shared outcomes.

Challenges for the future

Further challenges and opportunities will continue to test the system for managing pastoral lands. Climate change is expected to affect South Australia's rangelands dramatically, with substantial increases in temperature and changes in rainfall patterns. Vegetation growth and distribution, livestock production and biodiversity conservation are all likely to be significantly impacted, testing the ability of native species and grazing systems to adapt. Regulation will need to be alert to the changing requirements to maintain sustainable grazing regimes in the long term.

Conclusion

Building on the state's long history of adapting to emerging needs, recent changes to South Australia's legislative framework for pastoral land are designed to enable a diversity of new industries and activities. These changes create new opportunities for collaboration and diversification of pastoralist income streams, supporting the sustainable operation of pastoral businesses, improving long term conservation in a changing climate and increasing use of pastoral lands for a range of different purposes.

Examining the dynamic shift between pastoralism and agropastoralism: comparative insights from South Africa and south Asia

Samuels, I*; Louhaichi, M**

Keywords: Land use; livestock; drylands; climate change; governance

Abstract

Often, pastoralism conflicts with cropping for land and other resources, leading to tensions between these two land uses. Nevertheless, pastoralism and agropastoralism can coexist, with the same people often engaging in both land use practices. However, the dominance of each land use is dependent on various factors, which are often dynamic. In South Africa's arid zone, pastoralists have become spatially constrained through land grabbing during colonialism and apartheid, and due to the smaller size of the grazing lands, both land uses operate in proximity but vary according to climatic and socio-economic conditions and the governance of the land. Due to increases in rainfall variability and a reduction in rainfall, and drought recurrences, dryland cropping has declined whereby only about 12% of all croplands are utilized. These croplands are located within a matrix of arid, yet biodiverse shrublands that have been used by indigenous Nama pastoralists for centuries. On the other hand, in the arid zone of Rajasthan, India, livestock mobility as practiced by the Raika people is a mechanism to cope with climate change in search for better forage and water resources. Our results indicate that 80% of the grazing time was spent on cropland and fallow land along migration routes. In both cases, the rapid decline of cropping practices has had negative implications for livestock and concerted efforts needs to be undertaken to support this historic land use in rangelands that have shown to complement pastoralism in the face of rapid environmental and socio-economic change.

Introduction

Rangelands cover about 54% of the globe's terrestrial surface and these agroecological systems are key for maintaining planetary health including their ability to sequester carbon, sustaining biodiversity, water regulation, and other services (ILRI et al., 2021). For millennia, livestock grazing managed by pastoralists, have been the dominant land use in rangelands and this has shaped the ecological, cultural and economic character of those regions (Reid et al. 2014). As such, these landscapes are also support more than two billion livelihoods worldwide, along its value chain. Despite its importance, rangelands are under threat from various competing land uses such as urban development, mining, agriculture, conservation etc. and these make rangelands very dynamic. However, some land uses are complementary to the pastoral way of life in rangelands.

Dryland cropping, particularly in semi-arid and arid regions have co-existed, became integrated and therefore complemented livestock farming for centuries resulting in new agropastoral societies that have diversified income streams. For example, crop residues are used by livestock during the dry periods whereas livestock manure act as a fertilizer for crops (Samuels et al. 2008). This is particularly true in southern Africa where small-scale dryland cropping has been practiced by the indigenous Nama people to grow winter cereals that they use to make bread and to grow supplementary forage for their livestock (Samuels 2013). In the south of India, livestock provide draught power, transportation, milk and manure for crop farmers and crops serve as food for livestock. This mutualistic interaction has allowed agropastoralists to adapt to the variability in their climate, local economy, and socio-political contexts (Rangnekar 2006).

Then again, the relationship between cropping and livestock farming is dynamic and has been influenced by numerous factors that can shift the balance in favour of the other. For example, large expansions of cropping areas will encroach onto valuable rangelands and fragment grazing areas whereas the absence of cropping could lead to forage shortages in times of drought. The integration of cropping and livestock farming is one of the fundamental elements for climate change adaptation and sustainable land use in drylands around the world (Valbuena et al. 2012). Therefore, understanding the dynamic shift between these two land uses is important for policy development and programmatic interventions. This paper assessed the changes in cropping activities in two dryland pastoral regions in South Africa and South Asia and makes policy recommendations.

Materials and Methods

The research on agropastoralism in South Africa was done over two decades as part of larger national and international projects. Thus, the information reported on in this paper reflects the experience and observations of the authors who were part of that research working with pastoralists using quantitative and qualitative methods. Results also reflect information conveyed by local and indigenous knowledge holders. A stratified random sampling method was applied to select households across districts, tehsils (administrative units), and villages. Villages were chosen based on their livestock migration patterns to neighbouring states. A comprehensive inventory of migratory and non-migratory livestock households was conducted in the selected villages (Louhaichi et al. 2014).

Description of the Study Areas

The study in South Africa was conducted in the Leliefontein communal area that is 192,000 ha in size. The climate is semi-arid with predominantly winter rain from May to August. In summer, temperatures exceed 40 ^{0}C and in winter, it often falls below freezing point in the uplands above 1,000m above sea level. The vegetation falls within two global biodiversity hotspots, namely the Mediterranean shrubland called Fynbos, and the semi-arid Succulent Karoo, which comprises about 90% of Leliefontein. The pastoral area is divided into ten villages with each having associated (unfenced) grazing lands, cropping units and watering points. The cropping units are 12% of Leliefontein and about 10% had been used actively (Samuels 2013). Crops grown are wheat and oats and sometimes lucerne, rye, and barley. The primary livestock kept are goats and sheep, which are herded daily from corrals.

Rajasthan state in India is semi-arid with 70% being desert. Rajasthan has four seasons: summer, monsoon, post-monsoon, and winter. The climate varies from arid to humid. June is the warmest, with temperatures nearly 40°C. The state hosts extensive rangelands, forming the core of its pastoral system, which also relies on croplands. The vegetation is predominantly xerophilous and includes several grass and scrub-type vegetation of low trees species. Livestock serve as food security, and protection against economic and environmental shocks.

Results

In South Africa, environmental factors such as increases in rainfall variability and drought recurrences have resulted in a decline in dryland cropping (Table 1). However, during good rainfall periods, agropastoralists will attempt to plant winter cereal crops for their livestock. Socio-economically, the lack of seed, farming implements, and labour, have also contributed to a decline in cropping. Poor governance that led to the neglect of infrastructure further added to this decline. The erosion of indigenous knowledge amongst Nama agropastoralists has resulted in the inability to know when and how to plant cereal crops.

Rajasthan faces unique vulnerabilities to climatic extremes. Unlike South Africa, recent pre-monsoon rainfall in Rajasthan has caused severe flooding. Despite increased mechanization in India, much agricultural work remains labor-intensive. In irrigated areas, farmers rely on flood irrigation, while micro-irrigation is mostly used by larger landholders. Improper cropping systems and continuous cultivation have depleted soil quality, leading to land degradation, high production costs, and low productivity.

Table 1: Drivers of cropping abandonment in the study areas.

Drivers	**South Africa**	**South Asia**
Environmental		
Reduced rainfall	✓	
Increased rainfall variability	✓	✓
Soil fertility depletion		✓
Socio-economic		
Lack of seed	✓	
Lack of farming implements	✓	
Lack of labour	✓	
Poor adoption of mechanization		✓
Poor irrigation facilities		✓
Stray livestock incl. donkeys	✓	
Older agropastoralists passing on	✓	
Cheaper & convenient to buy feed	✓	
Lack of marketing		✓
Inadequate access to crop insurance schemes		✓
Indigenous knowledge		
Lack of farming skills to plough & threshing of chaff	✓	
Lack of knowledge to read weather conditions on when to plough	✓	
Breakdown in indigenous livestock management to protect crops	✓	

Discussion

While dryland cropping has declined in Leliefontein, it persisted over recent decades due to the need to maintain exclusive cropping rights and to continue to earn its benefits such as supplementary fodder. Here, cropping is one of the major drivers of livestock mobility as herders move their animals away to protect growing crops (Samuels et al. 2008). In western Rajasthan, livestock rely heavily on common grazing lands, fallow fields, and post-harvest crop areas. Livestock mobility is critical for local livelihoods, trade, and coping with climate change (Clifton and Louhaichi, 2015). Cropland and fallow land comprised the majority land type utilized by cattle, totaling 80%. Grasslands, deciduous trees, and scrub forest lands accounted for >10% of the area utilized by cattle (Louhaichi et al. 2015).

If rainfall variability, droughts, poor governance, and other constraints persist, it is uncertain whether cropping will continue in both regions. This outcome will have consequences for Nama and Rajasthani agropastoralists and there is a need to work towards solutions to continue cropping in these dryland systems. These include co-developing early warning systems based on science and local ecological knowledge, preservation of Indigenous and local knowledge, development of drought resistant indigenous fodder crops as in the case of South Africa from the diversity of native forage legumes found in the winter rainfall region (Muller et al. 2017). Furthermore, we need to protect the rights of crop farmers, implement policies that encourage cropping, and support croppers financially and technically.

In both cases, the rapid decline of cropping practices had negative implications for livestock and a concerted efforts needs to be undertaken to support this historic land use in rangelands, that have shown to complement pastoralism in face of rapid environmental and socio-economic change.

Agriculture and water resource assessments in the extensive rangelands of northern Australia

Watson, I[1]; Petheram, C[2], Bruce, C[3]; Philip, S[4], Chilcott, C[5]

[1]CSIRO Agriculture and Food, Ian.Watson@csiro.au, [2]CSIRO Environment, Cuan.Petheram@csiro.au, [3]CSIRO Environment, Caroline.Bruce@csiro.au, [4]CSIRO Environment, Seonaid.Philip@csiro.au, [5]CSIRO Environment, Chris.Chilcott@csiro.au

Key words: Intensification; irrigation; Indigenous values and rights; ecological assets; development impacts and risks

Abstract

Sustainable regional development is a priority for all governments which have jurisdiction in northern Australia. The land and water resources of most of northern Australia's rangelands have not been mapped in sufficient detail to provide for reliable resource allocation, mitigate investment or environmental risks, or build policy settings that can support decisions about development.

Since 2012 CSIRO has led large multi-disciplinary assessments across about 620,000 km^2 of northern Australia. These assessments have considered; Indigenous rights, values, interests and development aspirations; climate drivers; surface water hyrdology; groundwater hydrology; ecological assets and impacts; soils and land suitability; surface water storage; and agricultural and socio-economic considerations. The assessments have included a combination of field data collection, desktop studies and modelling to provide a comprehensive analysis of the kinds of intensified water resource development which might be possible and the risks which would accompany those developments.

The catchments studied are largely 'greenfield', i.e. potential development would occur on land which is not already within a matrix of existing water resource development or intensified agricultural production. The majority of the land is Indigenous held and/or is used for extensive beef cattle grazing on native pastures.

The work has shown that there are considerable soil and water resources which could be developed, however these resources are not always found together and intensified production would only be economically viable under certain, often difficult to meet, conditions. Beyond financial considerations, there are many other issues which influence the extent to which development might occur. These relate to the social licence to develop water resources, to grow certain crops such as cotton, and to clear native vegetation - as well as regulatory and legislative conditions which reflect this social licence.

Introduction

Northern Australia is remote and sparsely populated and decisions made about development need to be based on the best available data and information, provided in a manner which the public can access and digest. We used a multidisciplinary approach to examine the resources in eight study areas (14 catchments) in the rangelands of northern Australia and then investigated how these might be used to support increased economic activity. We also considered the risks (social, cultural, environmental and financial) which might accompany this activity.

Methods

A wide range (and large number) of quantitative and qualitative methods were used. Topics covered are shown in Figure 1. The approach was to provide a number of detailed technical reports, typically more than 10 reports for each catchment, a synthesis of which was provided in Catchment Reports, then pared back into much shorter Summary Reports. Data layers were made available through CSIRO's Data Access Portal. Several web-based tools were developed along with short videos. The full set of more than 110 reports is provided at https://www.csiro.au/en/research/natural-environment/water/water-resource-assessment

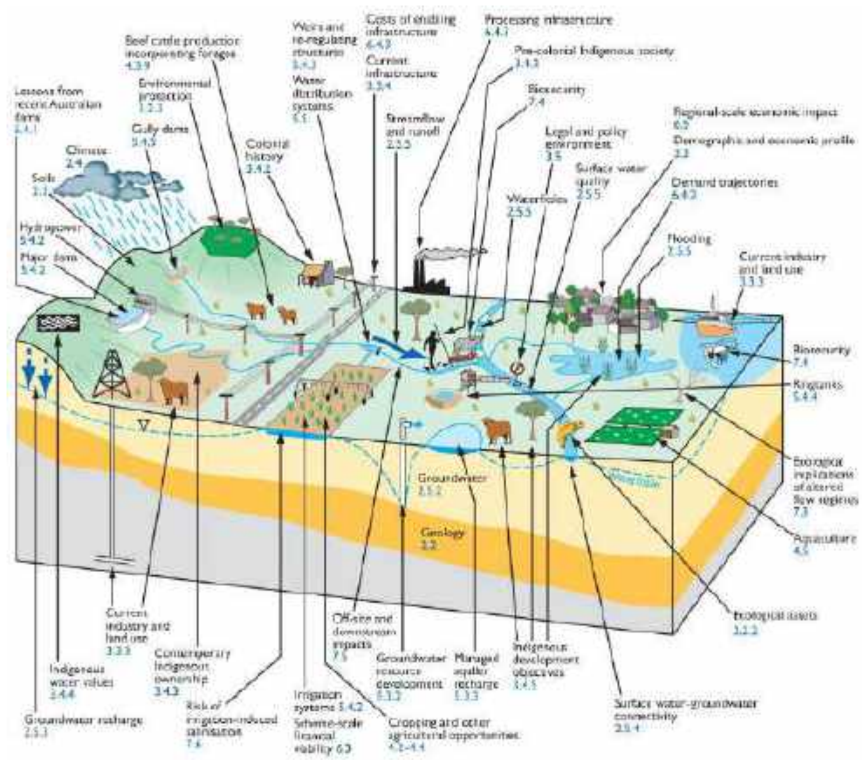

Figure 1. Schematic diagram of key components and concepts considered in the Assessments. Section numbers are from Petheram et al., (2024).

Results

Streamflow is highly variable both within years (due to the wet-dry climate) and between years. For example, the mean annual streamflow is 34% higher than the median annual streamflow in the Fitzroy River and more than double in the Flinders River. Streamflow is more variable than for catchments found in similar environments elsewhere in the world. The catchments are largely unregulated, being free of dams or weirs except in a few cases. Modelled median annual streamflow is shown in Figure 2.

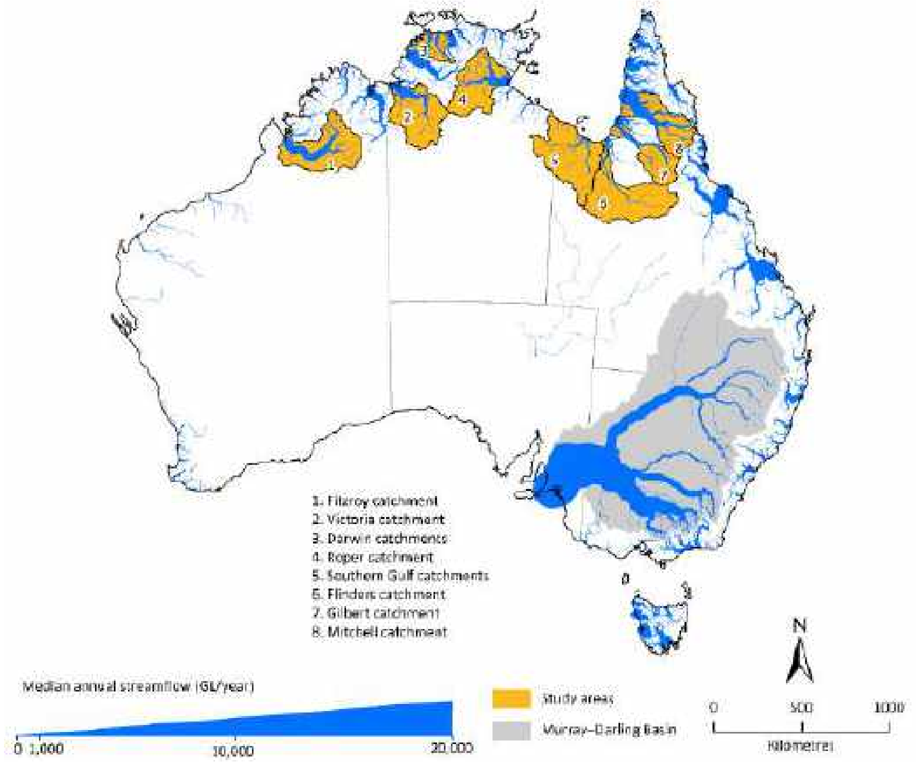

Figure 2. Schematic showing modelled median annual streamflow of Australian catchments (prior to European settlement and development). Study areas shown in orange.

Only one assessment (Darwin catchments) contained a population centre in excess of 20,000. The population density is very low (Table 1) and in all catchments the proportion of the population which is Indigenous exceeds the Australian average of 3.2%. The level of socio-economic disadvantage is high.

Soils mapping and consequent land suitability assessment suggested that between 35% and 76% of each catchment was suitable for growing irrigated Rhodes grass using spray irrigation (Table 1) such as might be fed to cattle on-farm. Note that land suitability does not consider risk of flooding, secondary salinisation, water availability or other factors, it is an upper bound.

The dominant agricultural land use was extensive beef cattle grazing, which occupied between 37% and 95% of the catchments. Almost all cattle grazing occurred on pastoral leasehold land, owned by the Crown. Indigenous-owned freehold land makes up nearly one half of the Northern Territory. In the Victoria and Roper catchments Indigenous freehold was 31% and 45% respectively. While freehold, these lands are held in communal ownership and unlikely to be intensively developed beyond very small scale activities. From a regulatory and legal basis, the extent to which pastoral leasehold land can be intensively developed for cropping is disputed. While diversification is sometimes permitted, the extent to which pastoral land can be used for cropping depends on the jurisdiction and is the subject of recent court cases.

Table 1: Key characteristics of each study area. 'Suitable land' is percentage area for Rhodes grass under spray irrigation (first number) and for cotton under furrow irrigation in the dry season (second number), noting that suitability includes various limitations. References for all study areas are provided below.

Study area, jurisdiction & year released	Area (km^2)	Median annual streamflow (GL/yr)	Population (Indigenous)	Grazing land	Suitable land
Flinders, Qld, 2013	109,000	*1,241	8,952 (19%)	96%	76%, 71%
Gilbert, Qld, 2013	46,000	*2,647	2,948 (37%)	84%	43%, 19%
Fitzroy, WA, 2018	94,000	4,925	7,533 (65%)	95%	58%, 6%
Darwin, NT, 2018	30,000	10,188	139,052 (9%)	37%	43%, 2%
Mitchell, Qld. 2018	72,000	14,237	6,365 (26%)	95%	46%, 18%
Roper, NT, 2024	77,400	4,341	2,500 (73%)	46%	51%, 4%

* Modelled for the most downstream gauging station. All others modelled for end of system.

The amount of water made available for uses such as irrigated agriculture is a matter for legislation and regulation under the Western Australian, Northern Territory and Queensland governments. Ideally, this is laid out in water resource, or water management plans, but not all catchments are the subject of such plans. Typically, water extraction rules are conservative. Released in February 2024, the NT's 'Surface water take – wet season flow policy' states '*The volume of water available from wet season water flows to consumptive uses will be five per cent of the 25th percentile of total flows for the three highest flow months of the year based on the previous 50 years flow or modelled rainfall data of the river basin …*'. Note that a greater volume of water than this could be made available if it was established in a water allocation plan. In the absence of a water allocation plan, the policy would restrict surface water take in the Victoria catchment to about 2.5% of median annual flow.

Indigenous Traditional Owners were not necessarily averse to water resource development, however they have strong views, consistent across northern Australia, about the nature of that development. Traditional Owners were not in favour of large in-stream dams but could see benefit in small scale surface water capture or use of groundwater to irrigate such things as forages for cattle, or fruit and vegetables for local markets. Typically, they want to be owners, partners, investors and stakeholders in any future development. This reflects their status as the longest-term residents (tens of thousands of years) with deep inter-generational ties to the catchment. In at least one catchment, the Martuwarra (Fitzroy) Elders from independent First Nations groups have formed an alliance to limit the influence of 'extractive industries' (including water resource development) to 'forever economies' (https://martuwarra.org/protect_martuwarra).

While these catchments are not pristine, their low human density and minimal (in global terms) level of development has meant they retain high-value (often iconic) ecological processes, habitats and species. Examples include monsoon vine forest, large numbers of groundwater dependent ecosystems, nationally important wetlands, seagrass habitats, the freshwater sawfish (*Pristis pristis*) the northern river shark (*Glyphis garricki*) and the Rosewood keeled snail (*Ordtrachia septentrionalis*) as well as a number of migratory shorebirds.

Irrigated agriculture was found to be financially viable only if there was an alignment of good prices for high-value produce and market advantages. Other factors include availability of suitable markets for the products, investment in fundamental infrastructure such as all-weather roads, bridges and processing facilities, and land tenure arrangements that support development. Rainfed cropping was determined to be largely opportunistic and depend upon farmers' appetite for risk and the extent to which it could be an adjunct to an irrigation enterprise. Growing forages or hay to feed cattle to be turned off at a younger age was determined unlikely to be financially viable. Feeding irrigated forages or hay increases beef production and total income, but increased costs mean that gross margins would be less than baseline cattle operations, and the high capital outlay would in most cases be prohibitive.

Discussion

The catchments assessed were not homogenous. Each had different characteristics which provided a range of opportunities and risks. The coincidence of soil and water (within the context of bio-physical and regulatory constraints) could result in irrigated development of less than 2% of the land area across all catchments. That is, the essential rangeland characteristics of these areas would remain into the future, that being; Indigenous held land, land set aside for nature conservation, and land used for extensive beef cattle grazing.

Acknowledgements

The three most recent assessments were funded through the National Water Grid's Science Program, which sits within the Australian Government's Department of Climate Change, Energy, the Environment and Water. Funding for the other five assessments also came from the Australian Government. We thank Justin Hughes and Mat Gibbs for reviewing a draft. We also thank the more than 200 people (internal and external to CSIRO) who have contributed to these assessments since 2012.

Green energy and grazing in the rangelands: a just transition?

Waters-Bayer, A[1]; Wario, HT[2]; Ulambayar, T[3]; Upton C[4]

Key words: energy justice; land alienation; pastoralism; renewable energy

Abstract

Growing global awareness of the climate crisis and the need to switch from fossil to renewable energy (RE) has led to growing interest in acquiring land to generate it. Tropical and subtropical rangelands are prime targets for producing RE. Investors, governments and project planners often regard rangelands as "empty", yet pastoralists, hunter-gatherers and cultivators have long used these areas as a common pool resource, through multipurpose use of the land, for their livelihoods.

Globally, large-scale land acquisition for RE projects often displaces local people from their land, contrary to their traditional rights, disadvantaging especially pastoralists by blocking access to and fragmenting pastures. This reduces pastoralists' ability to use herd mobility to deal with climatic variability and change and to support their livelihoods. Moreover, project planners rarely manage to obtain locally meaningful free, prior and informed consent (FPIC) for using pastureland to produce renewable energy. Even where communities have a chance to negotiate placement of energy installations, they typically enjoy little bargaining power or subsequent benefits, not least because governments and developers may greatly underestimate the value of pastoralism in terms of food production, economic value and ecosystem services and therefore afford low value to rangelands.

We analyse the impact of land acquisition in rangelands for RE in Kenya and Mongolia, especially in relation to considerations of climate and energy justice. We explore possibilities of multifunctional land use as part of a 'just transition' that combines pastoralism with generating RE. We identify the type of research needed to help local people gain evidence about the value of their production systems and their contribution to ecosystem services, putting them in a better position to negotiate sharing of land for and benefits from RE generation.

Introduction

Confronted by the climate crisis, countries are striving to meet the Sustainable Development Goals (SDGs) and to deliver on their zero-carbon pledges at the UN Climate Change Conferences by transitioning from fossil to renewable energy for their industries and citizens. This has led to rapid expansion of large-scale renewable energy (RE) projects, particularly in sparsely populated regions or on land regarded by governments as "unproductive". Investors from more industrialised countries are making agreements especially with governments of less industrialised countries to use their land to produce solar, wind or hydropower. They frequently draw on discourses of “empty”, “underutilised” or “degraded” wastelands – discourses that have historically underpinned injustices to local land users, particularly pastoralists, in the name of development since colonial times (Lind et al. 2020).

In many of these areas now coveted for generating RE, pastoralists have been grazing their herds in mobile systems of production on land used in common with other herders, smallholder farmers and hunter-gatherers. The large-scale RE projects could have adverse impacts on pastoral production systems, which rely on flexible and highly mobile use of large expanses of diverse types of land at different times of the year in order to produce food (milk and meat) for themselves and other consumers. These production systems typically use few or no fossil-fuel-based inputs.

We therefore conducted research into the impact of large-scale RE projects on pastoralists in the drylands with a view to i) helping policymakers and civil society shape the expansion of producing RE so that, at minimum, it does no harm, and ii) helping pastoralists become better prepared to deal with the expansion of RE projects and possibly even benefit from them.

Methods

We made a desk-based study of literature on pastoralists’ experiences with RE projects worldwide, searching in SCOPUS and Web of Science on terms around pertinent livelihood strategies and environments (e.g. pastoralism, agropastoralism, rangelands, drylands); RE; just transition; and consultation and consent. We delved deeper into cases in Kenya and Mongolia, countries in which we had prior experience, by seeking “grey literature” (policy documents, reports and media sources), conducting interviews with affected community members, RE developers and government staff, and visiting some wind and solar power sites in the two countries.

On the basis of these information sources, we analysed how land acquisition processes in the name of the energy transition affected mobile pastoralists, the role of Free, Prior and Informed Consent (FPIC), whether the land was used for both RE and pastoralism rather than as mutually exclusive alternatives, pastoralists’ responses to displacement and the extent to which energy justice was achieved. Sovacool et al. (2017) define “energy justice” as an “energy system that fairly distributes both the benefits and burdens of energy services, and … contributes to more representative and inclusive energy decision-making”. It forms part of the concept of “just transition”, connecting social justice with environmental, climate, resource and energy reasons for the transition (Upham et al. 2022).

Results

The desk study revealed that, globally, governments and investors largely ignored or downplayed the impact of their RE projects on pastoralist communities. Large-scale land acquisition for RE in the drylands has been dispossessing pastoralists of their traditional grazing areas, reducing the mobility of herds over diverse landscapes that is essential for sustainable use of the drylands, and blocking access to key seasonal resources for pastoralism. This is making the pastoral production systems less viable.

Furthermore, pastoralists were usually excluded from access to the power generated by large-scale RE on their land and also lost access to natural sources of energy (e.g. firewood) on that land. Pastoralists thus became victims of not only “land grabbing” but also “energy grabbing”.

Most governments and investors showed little understanding of pastoral production systems and their value, and – even if, on paper, governments legally recognised the communal land systems needed for flexible and mobile pastoral systems to function effectively – did not respect these when implementing their RE projects. Expansion of RE generation was typically justified by “climate emergency narratives” (Borras et al. 2022). Project implementers often saw no need to seek FPIC, which would require that the current land users be fully informed about possible impacts of the project on their lives. Key international agreements such as the African Commission’s Africa Charter for Human and Peoples’ Rights and the United Nations Declaration on the Rights of Indigenous

Peoples (UNDRIP) uphold the principle of FPIC and do not limit it to indigenous peoples. However, most governments, although having formally endorsed these agreements, did not adhere to them when dealing with local communities in areas foreseen for RE projects. These communities were often unaware of their rights and of ways in which they could legally oppose RE projects or negotiate benefits for local people.

In the less industrialised countries, governments and investors rarely considered possibilities of shared use of the land for pastoralism and RE – and shared benefits from the energy generated. Most pastoralist communities in these countries did not consider these possibilities themselves and were, in any case, in a weak position to negotiate a fair deal.

Kenya case study

In Kenya, investments in geothermal, solar and wind energy have been mainly in the drylands (Hughes & Rogei 2020). They have given little or no attention to impacts on traditional dryland production systems and reflect a continuation of the historical lack of recognition of mobile pastoralism as a meaningful form of livelihood that generates economic value (Lind et al. 2020).

North Kenya hosts the largest wind-power plant in Africa: Lake Turkana Wind Power (LTWP) near Marsabit, completed in 2019. This generates over 300MW of electricity on 60,700 ha of rangeland leased from the Government in 2009. According to Achiba (2019), because developers regarded the land as uninhabited, they did not consult the Turkana, Samburu, Rendille and El Molo herders who used the land seasonally. The Government of Kenya's refusal to endorse UNDRIP was a factor in investors' disregard for FPIC principles (Cormack & Kurewa 2018). The developers allegedly exploited pre-existing ethnic conflicts over natural resources to de-emphasise some "indigenous" claims over others (Renkens 2019). These intercommunity tensions constrained emergence of a united grassroots resistance (Achiba 2019). Instead, LTWP presence and actions created greater divisions among the local land users, as stated by a Turkana elder in our 2022 interviews: *"this has affected the social relations, intercommunity dialogue, peace and social cohesion between these communities"*.

Construction of the turbines began in 2014. LTWP (2011) stated that herders could continue grazing animals between the turbines but the process of land acquisition without consultation or compensation nonetheless made the herders feel robbed. As a Rendille elder said in 2022: *"even if the communities are allowed to graze the animals, they are not happy to settle or move freely within the project area because the land does not belong to them anymore"*. Moreover, herders stated that noise and frequent vehicle movements made the land unusable for grazing. Thus, the capture of resources and authority by LTWP disrupted traditional patterns of land use and decreased the resilience of pastoralists to adapt their land-management and grazing systems in the face of climate change.

The benefits for local people have thus far been very limited: they have no direct access to the power produced by LTWP on their land; jobs on the project are few and LTWP does not share the RE revenues with the local communities, which therefore feel excluded and unfairly treated.

In 2014, the pastoralist groups managed to overcome intercommunity tensions and organise themselves to resist this energy injustice. They formed the Sarima Indigenous Peoples' Land Forum and took the case to district court, which ruled in 2021 that the process of transferring communal land to investors had been illegal. The Kenyan High Court upheld this ruling in 2023. However, the wind park was by then in full operation. The LTWP will either have to return land to the pastoralist communities or find some way to compensate them.

Mongolia case study

Mongolia aims to meet all its energy demands by domestic production and become an energy exporter by 2040 (State Great Khural 2020). As of 2023, its RE energy is derived from seven small hydropower plants (HPPs), three wind farms (WFs) and nine solar-power plants (SPPs) (Dimovska 2024).

Pastoralists have *de facto* customary rights to pasture, which is officially state property; they thus have little defence against land alienation. Thus far, RE projects claim to have no negative impacts on pastoralism, and the few accessible publications on RE largely concur. All RE projects in Mongolia are officially classified as having no impact on indigenous peoples; the herders do not self-identify in this way and the associated safeguards are therefore deemed inapplicable (Waters-Bayer & Wario 2022). However, Environmental and Social Impact Assessment reports indicate that herders' consent was obtained. Those we interviewed reported that their initial reactions were negative, but their views changed after they received more information and saw that the impacts on grazing were minimal. The herder families' perceptions of energy justice were also influenced by their own access to household solar energy through Mongolia's 100,000 Solar Ger Electrification Programme and the fact that their extended families in nearby settlements had access to the energy generated through the RE projects.

Very few herders at case-study sites reported significant loss of pasture access: *"We are not adversely affected. The pasture, water and salt are all in good condition. We got used to living with this solar station. … The station does not affect grazing and migration"* (herder, Khushig Khundii SPP, 2022).

To date, the RE projects in Mongolia have been on a smaller scale than in Kenya. However, larger projects are now planned, e.g. the 28,000 ha Chinese-backed Erdeneburen HPP project in western Mongolia will impact some 270 herding households. Some affected herders protested publicly in the capital, Ulaanbaatar, against this project, mobilising resistance around potential impacts on herders' livelihoods and land rights and on biodiversity, e.g. in the nearby wetlands (Dugersuren 2022).

Discussion and conclusion

Large-scale RE projects as responses to governments' net-zero commitments and the "climate emergency" intersect with land issues and livelihoods. Specificities of the pastoral mode of production and rangelands, e.g. herd mobility and use of common land, render them especially vulnerable to acquisition for large-scale RE. Exclusion from meaningful participation in decision-making and from opportunities to give informed consent have often led to energy injustice – rooted primarily in lack of due process and transparency. Especially where the pastoralist communities do not have access to the RE being generated on their land, they experience a sense of land alienation and encroachment on their rights because of restrictions on access to resources essential for their livelihoods. However, availability of sufficient information and accessibility to household energy can moderate herders' perception of (in)justice when rangeland is taken to generate RE.

What are the prospects for energy justice for pastoralists faced with large-scale RE projects in the future? Inclusive participatory design of energy projects together with pastoralist communities could lead to forms of multipurpose land use for energy and pastoralism, as well as for biodiversity and equitable economic benefits. This has clear implications for developers' approaches to impact assessments and FPIC and requires, above all, considerable time to develop relationships with and to adequately inform all the pastoralist groups in the project area.

RE investors would be well advised to provide the resources and time for researchers to engage with affected pastoralist communities in transdisciplinary research to co-develop a place-based understanding of the heterogeneous local communities and opportunities for sharing the land and the benefits from RE production. This type of research would reveal the local people's values around land and the way that they use it, strengthen pastoralists' capacities to know and defend their land rights, and strengthen their ability to negotiate for fairer treatment in the energy transition.

A just transition to RE can be made only if governments manage the transition in open and inclusive discussion with well-informed pastoralists and seek synergies between producing energy and producing food to sustain local livelihoods.

Key words: ACCU Scheme; Paris Agreement; Australia; Bioeconomic Assessment

Abstract

Adoption of the Paris Climate Agreement has expanded Kyoto Protocol rules for carbon abatement actions from forest vegetation to include all land management actions. This change has the potential to significantly increase the area eligible for vegetation-based carbon sequestration actions and will allow countries to include these actions across extensive areas of low-biomass within national carbon abatement plans. Using the Australian rangelands as a case study, an area comprising approximately 5.55 million km^2, we assess the latent terrestrial carbon abatement potential under two eligibility scenarios. Firstly, areas of the Australian rangelands that meet the Kyoto Protocol minimum 20% tree canopy cover potential (forest) and secondly the large, previously unaccounted for part of the Australian rangelands where dominant cover potential is less than the Kyoto 20% requirement (sub-forest). We define areas eligible for assisted natural regeneration under the Australian national Emissions Reduction Fund ACCU Scheme using national scale land use, forest and vegetation spatial datasets and model carbon abatement potential across these areas using the Full Carbon Accounting Model (FullCAM 2.0). Results show up to 512,089 km^2 and 354,770 km^2 of eligible land under the forest and sub-forest scenarios respectively providing a total abatement potential of 1,882.4 MtCO$_2$e and 866.4 MtCO$_2$e over a 25-year modelling period. In an economic assessment of this opportunity, we found most of this latent abatement potential was economically viable at current low carbon prices (between AUD 17 tCO$_2$e^{-1} and AUD 32 tCO$_2$e^{-1}) available within the Australian government and secondary markets. This is the first study that assesses latent carbon sequestration potential in Australian "sub-forest" ecosystems. We highlight the prospects for (particularly Indigenous) economic development in remote Australia.

Introduction

Regeneration using assisted natural regeneration (ANR) was included in the definition of afforestation and reforestation under the Kyoto Protocol and the UN Clean Development Mechanism if the vegetation met minimum thresholds for stand size (0.05-1.0 ha), canopy cover (10-30 per cent) and height (2-5 m) (Chazdon et al., 2016; Smith, 2002; UNFCCC, 1992). However, with the adoption of the Paris Agreement, eligible abatement actions have been expanded while removing specific reference to forests and the requirement that vegetation meet the threshold definition of forest cover for eligibility (Dooley, 2018).

Currently large areas of Australia's rangelands deemed capable of regenerating Kyoto compliant forests are home to carbon sequestration projects incentivized by Australia's national carbon policy, the ACCU Scheme. However, the Paris Agreement changes provide new impetus for Australia's carbon abatement plans to now include areas of sparse woody vegetation (what we term sub-forests) that were previously ineligible including recently modified rangeland areas, particularly across drier biomes. However, the size and economic viability of this opportunity is yet to be investigated.

This article presents a bioeconomic assessment of latent terrestrial carbon abatement potential across extensive marginal and low-biomass Australian Rangeland zones. We explore two vegetation canopy cover scenarios, firstly Kyoto compliant forest with a minimum canopy cover of 20% and sub-forest which does not meet this threshold, having canopy covers between zero and 20%. We estimated carbon sequestration potential in rangelands Australia for both forest types. We report the carbon prices required for land use change to be profitable under conventional investment criteria and discuss implications for economic development in remote communities.

Methods

This case study covers the extensive Australian Rangelands (Figure) and includes vast tracts of northern and central Australia and incorporates climates and biomes ranging from tropical grasslands, savanna and shrublands in the north to deserts and arid shrublands in the south (Department of Agriculture, 2021).

Suitable areas for the Forest and sub-forest scenarios ((Figure) were defined using a series of spatial datasets relating to forest cover, land use and vegetation type. Forest cover was defined using the Australian National Carbon Accounting System (NCAS) forest mapping dataset (DISER, 2021; Furby, 2002). Current land use was defined using the Australian Land Use and Management (ALUM) data (ABARES, 2016). Vegetation types were defined using the Australian National Vegetation Information System (NVIS) major vegetation groups (MVG) data (NVIS, 2017). Areas were included in the analysis as eligible for Forest carbon farming if they were defined as having non-forest or sparse woody vegetation in the NCAS data and having MVGs that can achieve forest cover (e.g. forest, closed woodlands, tall closed shrublands) in the NVIS data. In contrast, areas were included as eligible for Sub-Forest carbon farming if there was no forest or sparse woody vegetation present in the NCAS data and only MGVs that can achieve between zero to twenty per cent canopy cover (e.g., open woodland) in the NVIS data.

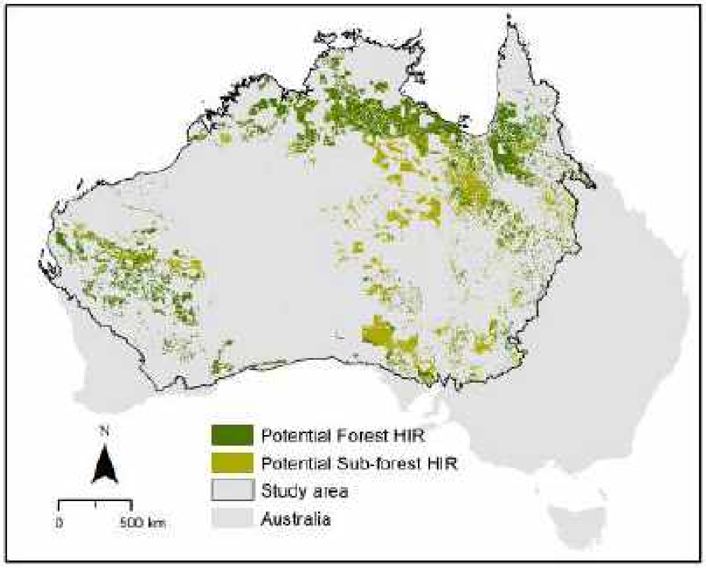

Figure 1: The Australian Rangelands study area and potential areas for regeneration under current forest and sub-forest suitability requirements.

Annual carbon sequestration estimates in tonnes of CO_2e per hectare were modelled using the ERF approved software Full Carbon Accounting Model (FullCAM) 2020 (DISER, 2020a). Carbon estimates were modelled on a 0.05-degree grid across all suitable areas and over a 25-year timeline starting in 2020. The same FullCAM settings were used for both the Forest and sub-forest scenarios. The difference between the two scenarios was based solely on location. All FullCAM modelling was carried out in line with the legislation (Commonwealth of Australia, 2013) and the FullCAM Guidelines for the Human Induced Regeneration method (DISER, 2020b)

Net present value (NPV) was used to evaluate the economic viability of land use change from the business-as-usual land use to carbon using the ACCU Scheme HIR methodology. The NPV of the Forest and sub-forest scenarios was calculated considering project establishment costs including the opportunity of lost agricultural revenue, fencing costs, brokerage/transactions costs and maintenance costs.

Functionally, the NPV_{ANRp} of changing from current agricultural land use to carbon land use ANR at carbon credit price p can be expressed as:

$$NPV_{hir} = PVR_{ANRp} - PVC_{ANR} \tag{1}$$

In equation 1, PVR_{ANRp} is the present value of returns to ANR at price p was calculated as:

$$PVR_{ANRp} = \sum_{t=0}^{T} \frac{p \times Cseq_{ANR}}{(1+r)^t} \tag{2}$$

Where $Cseq_{ANR}$ described sequestered carbon in each year t. Spatially differentiated estimates of $Cseq_{ANR}$ annual incremental and cumulative values over a 25-year and 100-year horizon were estimated across relevant areas for ANR using the FullCAM model.

The term r is the discount rate applied in discounting future costs and returns and T is the time horizon in our case 25 years and 100 years. We assumed a real rate of 5.25%.

The term PVC_{ANR} in equation 1 is the present value of all costs for ANR: it is calculated as:

$$PVC_{ANR} = FC_{ANR} + \sum_{t=0}^{T} \frac{MC_{ANR} + BC_{ANR} + PFE_t}{(1+r)^t} \tag{3}$$

Four elements of cost are considered in equation 3: FC_{ANR} is the fencing costs assumed to be \$24 ha^{-1} for ANR. This value is not discounted as it occurs at project initiation. MC_{ANR} are the maintenance costs that occur in each year t over the investment horizon and assumed to be \$1 ha^{-1} over the first 5 years following establishment and \$0.5 ha^{-1} for every year thereafter (Cockfield et al., 2019). And brokerage costs BC_{ANR} (including measurement, compliance and auditing costs) assumed to be 20 percent of the total value of the carbon. This percentage was considered fixed with no spatial variation and were taken from Cockfield et al. (2019). The final term considered in calculating the present value of costs is the opportunity cost of forgoing previous agricultural land use returns. This is expressed as the profit at full equity (PFE_t) at time t. These spatially explicit layers of agricultural profit at full equity (PFE), produced by Marinoni et al. (2012), were updated following the method outlined in (Regan et al., 2020). Consistent with this approach, the input layers were updated with price and inflation indices from the Australian Bureau of Statistics (ABS) (ABS, 2017a, b) yield data from the ABS Agricultural Commodities 2015/16 dataset at SA2 resolution (ABS, 2016). It should be noted that arid areas, in particular have very low to negative returns for agriculture. In this analysis, we assumed all positive agricultural revenue was ceased (e.g. the areas is destocked) with implementation of an HIR project.

Results

Over the 25-year period total carbon abatement potential across all eligible areas was estimated to be 1,882.4 $MtCO_2e$ and 866.4 $MtCO_2e$ for the Forest and sub-forest scenarios respectively. Figure 2 shows the spatial distribution of total per hectare carbon abatement across the study area over the 25-year modelling period.

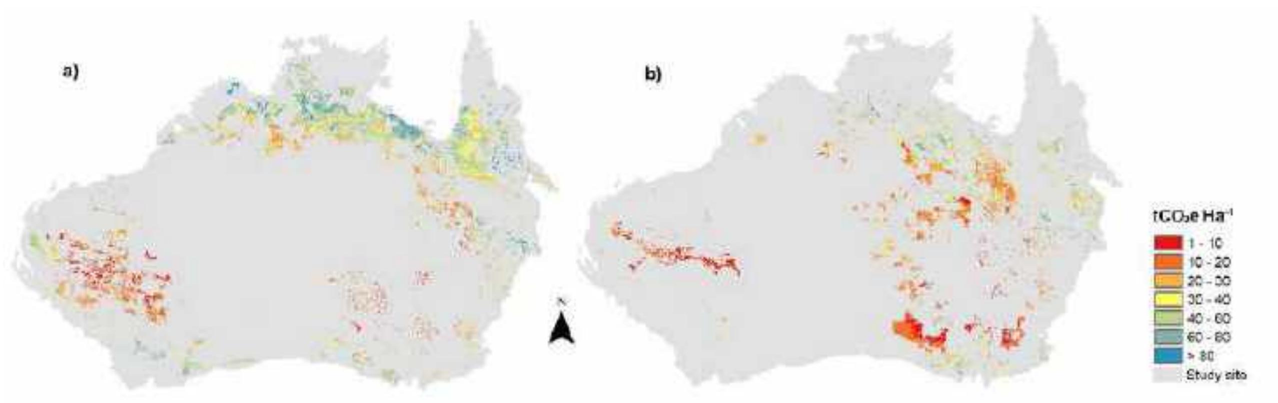

Figure 2: Estimated total carbon abatement (tCO_2e ha^{-1}) over 25 years for forest (a) and sub-forest (b) eligible areas.

Figure 3 shows the spatial distribution of the minimum carbon prices required for a project to be viable for the Forest (a) and sub-forest (b) scenarios.

Under the Forest scenario, economically viable carbon is available from AUD 2 tCO_2e^{-1} with 21.4 $MtCO_2e$ available at this price. At the low carbon price (AUD 17 tCO_2e^{-1}) there are 1569.0 $MtCO_2e$ available while at the high market price (AUD 32 tCO_2e^{-1}) 1855.5 $MtCO_2e$ is economically viable. These carbon sequestration amounts account for approximately 83% and 98% respectively of the total latent abatement potential under this scenario.

Under the sub-forest scenario limited carbon abatement potential is available at very low prices with just 2.4 $MtCO_2e$ available at AUD 2 tCO_2e^{-1}. At the low carbon price (AUD 17 tCO_2e^{-1}) there is 661.2 $MtCO_2e$ available while at the high carbon price (AUD 32 tCO_2e^{-1}) there is 834.4 $MtCO_2e$ available. This accounts for approximately 76% and 96% respectively of the total estimated carbon available under the sub-forest scenario across the modelling period.

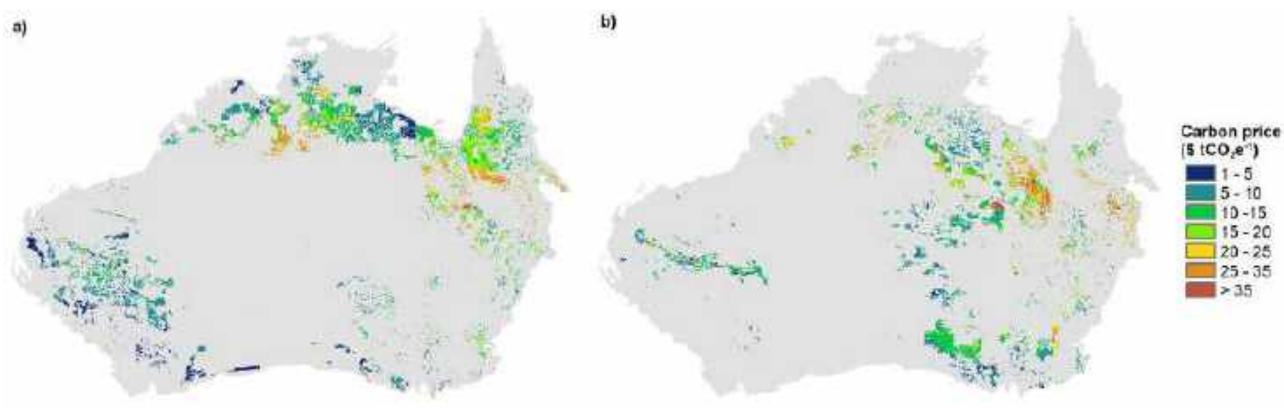

Figure 3: Estimated minimum carbon price ($ tCO_2e^{-1}) at which the carbon becomes economically viable for forest (a) and sub-forest (b) eligible areas.

Discussion [Conclusions/Implications]

Despite recognition in the Paris Agreement, no method currently exist in the Australian ACCU scheme that would include non-Kyoto compliant forest types like those found over much of the Australian rangelands. However, our results found that despite the low per hectare biomass productivity, significant abatement potential is available from this *sub-forest* category across the extensive rangeland areas of central and northern Australia. We found latent potential for economically viable carbon storage on over 350,000 km^2 using ANR for the sub-forest canopy cover scenario.

Relevant globally and in Australia is the potential for regeneration projects to produce significant co-benefits such as improved biodiversity and habitat provision, soil quality and fertility, water quality, reduced salinity and nutrient cycling (Baumber et al., 2020; Crossman et al., 2011; Lin et al., 2013; Muenzel and Martino, 2018; Tang et al., 2016). Consequently, revegetation projects over such a vast area have the potential to contribute simultaneously to Australia greenhouse gas mitigation and nature repair objectives.

In addition, evidence suggests carbon abatement actions can also promote a flow of positive economic benefits to participants including increases in landholder income, diversification of income sources and increased availability of capital for farm improvement (Baumber et al., 2020; Cowie et al., 2019). This may be particularly relevant for remote Indigenous communities where the income from carbon projects can offer transformative benefits for community well-being, economic and social development (Russell-Smith et al., 2015). Evidence from ACCU Scheme projects to date demonstrate that Indigenous environmental planting and fire management projects can deliver multiple benefits (Robinson et al., 2016; Russell-Smith et al., 2015; Sangha et al., 2021). Indeed, Sangha et al. (2021) estimated Indigenous well-being benefits from fire management activities in northern Australia to be in the order of USD 189 million $year^{-1}$. While connection to and interaction with 'Country', specifically the opportunity to care for Country, have been recognised as a key health determinant for Indigenous people (Garnett et al., 2009; Robinson et al., 2016).

The results suggest that developing a scientifically robust methods for inclusion of sub-forests in the ACCU Scheme, alongside revised HIR methods for Kyoto-compliant forests, could provide a significant economically viable additional carbon sink while catalysing remote community economic development and enhancement of ecosystem function and should be prioritised.

Key words: livestock production, soil classification, Uruguay, natural capital

Abstract

Soil organic carbon content is a central characteristic for sustaining the productive system and the provision of important ecosystem services, including carbon sequestration. Knowing the carbon stock in the soil is important in order to design and manage strategies for its conservation and capture. The main objective of this work is to characterize the carbon stock in livestock systems in Uruguay and explore estimation methods based on satellite information.

Twelve farms with extensive mixed livestock production (cattle and sheep) located on the basaltic slope geomorphological region of Uruguay were evaluated. Three categories of soil were defined (superficial, medium and deep) with an average depth of 9.0, 18.5 and more than 30 cm depth respectively. This classification of soils was done through the normalized vegetation index (NDVI) obtained for selected dates when low soil water content was evident. The ability to maintain green vegetation due to soil water content is strongly linked to depth. Ten sites were randomly selected for each soil category also considering the representativeness of the main soil cartographic units (CONEAT) where 20 soil core samples up to 30 cm deep were extracted with a drill and divided into four strata: 0 to 5, 5 to 10, 10 to 20 and 20 to 30 cm. A specific sampling was performed for determining bulk density. The organic carbon stock was calculated for each soil category. The sampling locations were geo-referenced and the soil carbon values and average NDVI for the last 5 or 10 years was calculated for determination of correlations. The determined carbon stocks we found varied between 16 Mg/ha in extremely superficial soils and 144 Mg/ha up to 30 cm deep in deep soils. Based on these results, we now propose to develop a reliable method for estimating carbon stocks across the basaltic slope region using models based on remote sensing variables.

Introduction

Soil organic carbon content is a central characteristic for sustaining a productive livestock system and the provision of important ecosystem services, including carbon sequestration. Knowing the carbon stock in the soil is important to manage and design strategies for its conservation and capture.

The heterogeneity of soils in the conditions of the native grasslands of Uruguay makes it essential to categorize them using remote sensing tools which are complementary to available cartography and carry out exhaustive sampling to determine the carbon contents. On the other hand, given the few studies carried out in the basaltic slope region of the country, this work seeks to provide a referential baseline and demonstrate the association of the soil carbon content with the physicochemical characteristics of the soils.

The objective of this study was to characterize soil carbon stocks in livestock systems in this region, analyzing the relationships with other soil physical variables and the possible influences of livestock management.

Methods

Study sites and sampling design

Twelve farms located on the basaltic slope geomorphological region in the north of Uruguay, corresponding to extensive mixed livestock farming (cattle and sheep), were evaluated.

For the field sampling design, a classification of soils was carried out according to soil depth based on the normalized vegetation index (NDVI) obtained from Sentinel images. These images are selected on dates with marked water deficit, which allows us to differentiate the water retention capacity and therefore maintain green vegetation, where higher NDVI values indicate deeper soils. Three categories of soil were defined: superficial. medium and deep. In each of these categories, 10 sampling sites were randomly selected and identified on the map. Moreover, a national cartography of soils -CONEAT- (MGAP, 2024) was overlapped to assure equitable representation of soil type classification in the sampling design (Fig 1).

Field sampling

Soil sampling was carried out by extracting columns 30 cm deep with a drill, which were then divided into strata from 0 to 5, 5 to 10, 10 to 20 and 20 to 30 cm. In each sampling unit, samples were composed of sub-samples (30 in average) taken from a virtual circle of 15 m radius. For soil categories that did not reach 30 cm in depth, the depth of soil until contact with the rock in each subsample was determined, thus obtaining an average depth for each site. Additionally, with the same stratification, samples were taken in metal cylinders of 5 cm deep and 5 cm diameter to determine the bulk density.

In the laboratory, the first step is the drying of samples for grinding and the removal of roots, rocks and remove any fraction that exceeds 2 mm. In the sieved samples, organic carbon in soil was determined by dry combustion of the sample and subsequent detection of CO2 by infrared. Determinations of organic carbon was done in INIA´s soil laboratory, using a Leco CN-2000 dry combustion analyzer, with a test method conforming to Wright and Bailey (2001). Additionally, soil texture analysis was performed at each sampling site.

Stock calculation

In the last stage. the calculation of the soil organic carbon stock was carried out for each depth, multiplying the value obtained in the laboratory by the bulk density and depth of the stratum. By adding the different strata, the quantity in the profile for a unit of area was obtained, providing the stock in Mg C/ha. The final SOC stock for each soil category was obtained by multiplying the total surface area of each soil category by the soil carbon stock

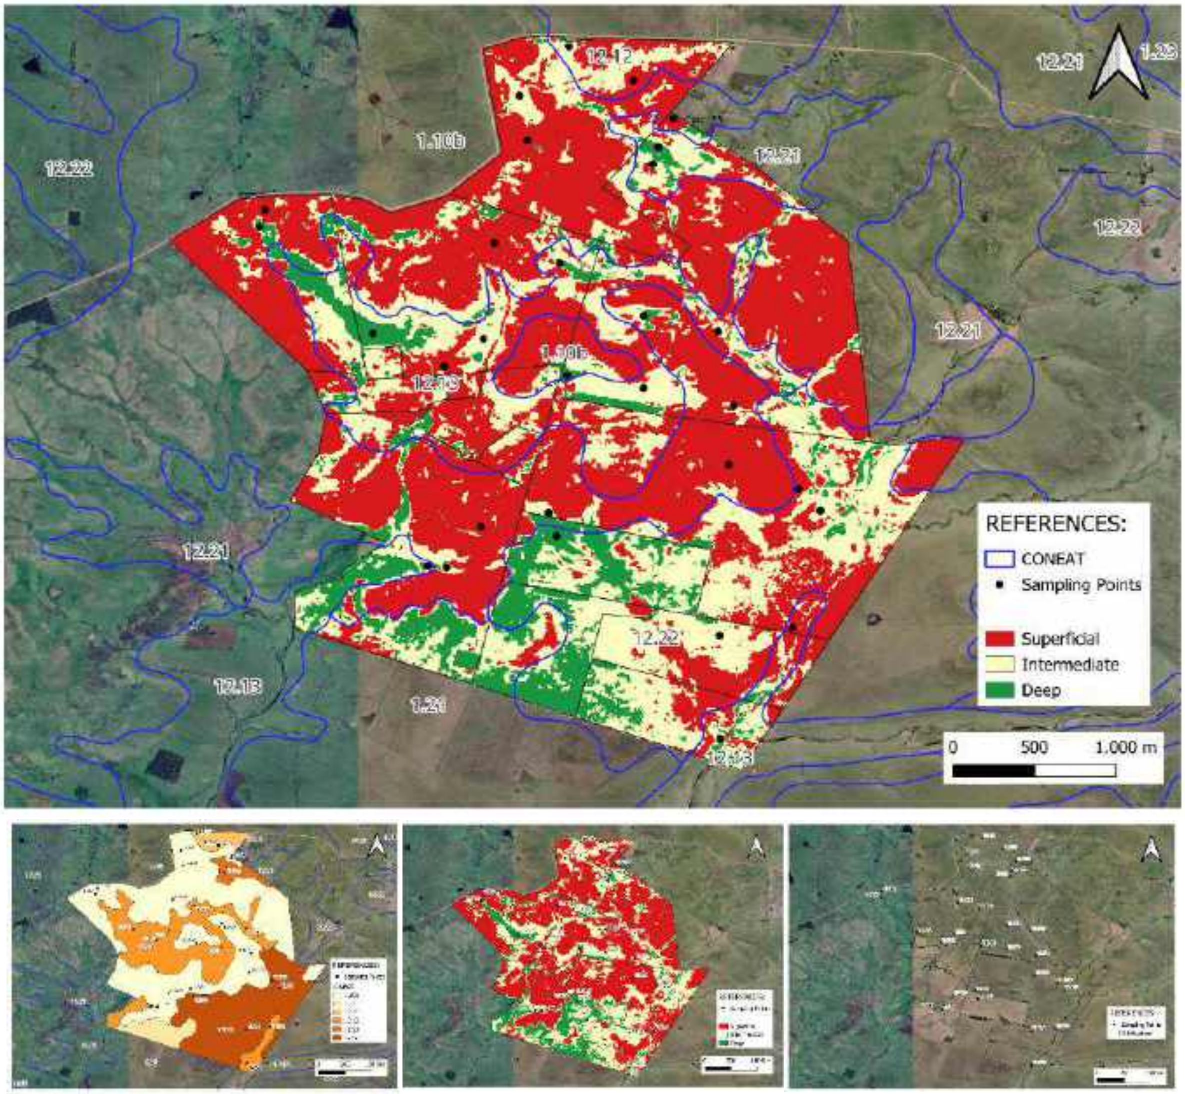

Fig 1- Example of sampling design considering the three categories of soil determined by NDVI (superficial. intermediate and deep) and the representation of the CONEAT cartogtaphy.

.

Results

Physical-chemical variables

The result of analysis showed a tendency for reduced carbon contents and increased bulk density in deeper strata. Within each depth strata, no differences were detected for different soil depth categories or CONEAT soil categories. Table 1 shows the average values of the variables determined in the soil samples.

Table 1 – Results of physical-chemical analysis of soil

Depth strata (cm)	Organic carbon (%)	Sand (%)	Silt (%)	Clay (%)	Bulk density (g/cm^3)	pH	Org. carbon Mg/ha
0-5	5.32 ±1.45a	20.3±14.2a	32.6±12.0a	47.1±11.6a	0.92±0.17c	5.8±0.5d	22.9±5.6b
5-10	3.68 ±0.87b	17.8±17.8ab	30.3±12.4ab	51.9±13.9ab	1.06±0.14b	6.0±0.5c	17.2±5.4c
10-20	3.30±0.75c	14.7±11.5ab	28.3±12.1ab	57.0±13.2bc	1.11±0.16a	6.3±0.6b	29.2±11.1a
20-30	2.85±0.61d	13.2±10.4b	26.7±10.1b	60.2±12.4c	1.12±0.13a	6.5±0.6a	24.0±11.5b

Table 2 shows the average depth of each soil category, the proportion of area for the different categories in the farms and the total carbon stock by hectare are presented.

Table 2- Contents of organic carbon, depth and proportion occupied in farms for each soil class.

Soil class	**Depth cm (mean ± SD)**	**Proportion (%)**	**Org. C stock Mg/ha (mean ± SD)**
Deep	30.00±0.00	46.3±18.9	118.4±17.3
Intermediate	18.50±7.71	36.0±12.5	60.7±25.6
Superficial	8.95±6.99	17.7±12.8	26.9±11.4
Farm average			82.0±10.6

Within each strata correlations between organic carbon content and texture were intermediate, ranging from 0.43 and 0.57 with clay content and -0.9 and -43 with sand content. The strongest correlation was obtained for bulk density ranging from -0.59 and -0.74.

In the exploratory analysis, no significant correlations were found between soil carbon content at each sampling point and the NDVI average of the last 5 and 10 years.

Discussion

The results show a large stock of carbon in the soil, with an average of 82 tons per hectare, even when about 54% of the area did not reach a 20 cm of soil depth. Shallow soil depth creates a real challenge to increase soil carbon stocks and sequester carbon, although some studies predict a potential (Dondini et al, 2023). However, it emphases the importance of grazing land use to maintain large amounts of carbon in the soil.

As expected, the carbon content decreases with soil depth, which is probably partly explained by the heavy textural horizon of these types of soil that prevents a massive penetration of roots deeper in the soil profile.

Considering the different types of soil according to CONEAT cartography or the three depth categories, no differences were found in the soil carbon contents within the same depth strata. This indicates that any variations found between different farmers and points within the same farm should be explained by other variables. We consider that one of these variables may be the management history of the farm or paddock within a farm, which could have led to change in vegetation biomass and consequently change in soil carbon stock over time. This possibility is impossible to verify given the absence of this information, but it indicates that conditions unrelated to the texture or type of soil may explain any changes in carbon stocks.

The NDVI extracted from Sentinel has not allowed us to detect differences in soil carbon content between different points in basaltic soils, perhaps because of the very small variations in the carbon stock found in this study. Future work to predict carbon stocks using models should be based on other remote sensing variables, such as radar images or combinations of multispectral measures. Use of models supported by remote sensing variables would undoubtedly be an important step forward in carrying out faster analyses, without consuming so much time and effort, and which could be extrapolated to large areas.

Carbon farming in rangelands: Policy lessons from Australia

Baumber, A

Transdisciplinary School, University of Technology Sydney, Australia alex.baumber@uts.edu.au

Key words: carbon, sequestration, incentives, co-benefits

Abstract

Australia was one of the world's earliest adopters of carbon farming incentives via its 2011 Carbon Farming Initiative, with rangelands at the forefront of project development. Since that time, policy incentives for rangeland carbon sequestration have been introduced from Canada to China and the European Union has embraced the language of carbon farming. So, what has Australia learnt in the past 15 years that could provide insights for other countries embarking on their rangeland carbon journey? This paper traces the history of Australian carbon policy and presents perspectives from diverse stakeholders based on interview data collected through five research projects undertaken between 2009 and 2025. This analysis maps the changing issues and attitudes amongst rangeland landholders, government agency staff, researchers and the carbon industry.

One notable trend apparent in the interview data is the way that concerns raised by landholders in earlier interviews, such as long commitment periods, taxation rules and inflexible trading rules were addressed through subsequent policy adaptation, only to be replaced by new concerns such as absenteeism, sequestration shortfalls or credit integrity. Whilst these concerns have evolved over time, the interviews also provide a record of carbon farming's progression from a potential income stream to a reality for many landholders, with reported benefits for economic resilience, sustainable land management and socio-cultural wellbeing. Amidst all this change, one factor that has been a constant throughout is the perception that carbon farming is a complex activity facing considerable uncertainty relating to biophysical outcomes, market conditions and policy shifts. These lessons may help other countries to anticipate issues that could emerge as their own carbon industries mature and design carbon farming policy proactively rather than reactively.

Introduction

Carbon farming is increasingly recognised as a significant strategy for climate change mitigation. Numerous jurisdictions, including the European Union, China, India and Canada have established frameworks for landholders to generate income by storing carbon in their soils and vegetation (Baumber et al., 2024). Australia established itself as an early pioneer of carbon farming policy with its 2011 Carbon Farming Initiative (CFI) and 2015 Emissions Reduction Fund (ERF). The ERF involved direct government purchases of carbon credits while also creating the policy infrastructure to support a private market in carbon offsets. Australia's early adoption of, and experimentation with, carbon farming may provide lessons for more recent developments in other jurisdictions, including the use of results-based payment schemes for carbon sequestration under the European Union's Green

Deal initiative (Bumbiere et al., 2022), the Alberta offset scheme in Canada (Government of Alberta, 2023) and the emergence of public-private partnerships focused on trading farm-based carbon credits in India (Jat et al., 2022).

In this paper, the term "carbon farming" is used to refer to practices aimed at maintaining or increasing carbon sinks in vegetation and soils, such as afforestation or reforestation to increase above-ground biomass and the alteration of grazing or cropping regimes to increase soil organic carbon. It should be noted that other research and policy literature employs a broader definition that covers all farm-level management of carbon pools, flows and greenhouse gas fluxes, including on-farm emissions from transport, livestock and fertilisers (EC, 2021).

Carbon farming in Australia received its first major policy boost via the creation of the Carbon Farming Initiative (CFI) in 2011. This created a set of prescribed methods that could be used to generate carbon credits through sequestration in vegetation and soils. The original plan to link the CFI to a comprehensive cap-and-trade scheme did not survive a change in government in 2013, but it did lay the foundation for the Emissions Reduction Fund (ERF), a AUD4.5 billion initiative that was established in 2015. The ERF utilised a reverse auction system to provide financial incentives for projects that reduce emissions or sequester carbon, with government funds directed to the lowest-cost abatement methods. This was a boon for vegetation projects in the rangelands (Figure 1), with the two key methods of Human-Induced Regeneration (HIR) and Avoided Deforestation (AD) making up almost half of all Australian Carbon Credit Units (ACCUs) issued by 2020 (Baumber et al., 2020).

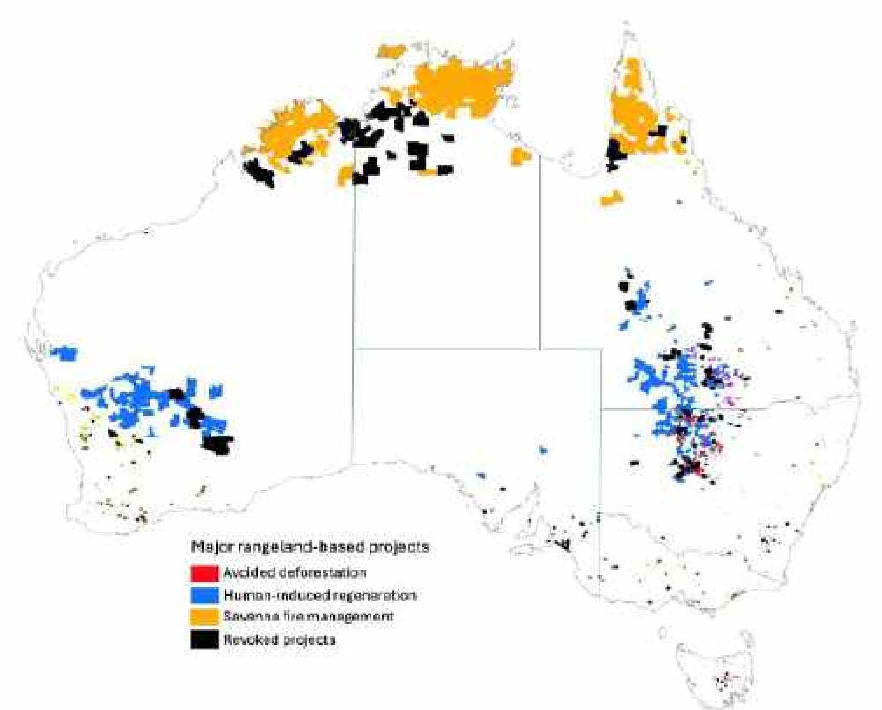

Figure 1: Australian ERF projects as of 2020 (adapted from Baumber et al., 2020). Note that savanna fire management involves emissions reduction rather than sequestration and is not covered in this paper.

The AD method involved a landholder agreeing not to clear trees they hold a legal right to clear, while the HIR method required a change in management to allow trees to regenerate (e.g. fencing out livestock). The rapid growth in these rangeland-based methods attracted some criticism, including "additionality" concerns around AD, given that some of the areas were unlikely to have ever been cleared, and concerns that HIR models were over-estimating the amount of carbon that was actually being sequestered through changes in land management (Macintosh et al., 2024). The independent "Chubb Review" recommended some changes in 2022 aimed at improving transparency around project reporting and method development and separating responsibilities for scheme regulation from government procurement of credits (Chubb et al., 2022). The AD method was revoked and HIR was allowed to expire, meaning no new projects could be registered after 2023. Other recent trends include a shift in policy terminology from "ERF" to "ACCU Scheme", an increased interest in soil-based sequestration in higher-rainfall areas and an expansion of the "Safeguard Mechanism", which has increased demand for carbon offsets amongst large emitters and shifts the carbon market in Australia away from its earlier reliance on government purchases of carbon credits (Baumber et al., 2024).

Overview of previous research projects

The policy lessons discussed in this paper are drawn from the following five research projects involving carbon farming across Australia, with a particular focus on the rangelands of New South Wales (NSW):

1. A 2009-11 study involving farmer interviews on woody crops for multiple purposes, including bioenergy, eucalyptus oil and carbon credits in western NSW (Baumber et al., 2011)
2. A 2017-18 study involving a technical workshop and online survey of landholders, researchers and agency staff linked to carbon farming in western NSW (Cowie et al., 2019)
3. A 2018-20 study involving an online survey, semi-structured interviews and focus groups with carbon farming stakeholders in western NSW (Baumber et al., 2022)
4. 2022-24 study on collaborative approaches to soil-based carbon farming with national key informant interviews and a western NSW case study (Baumber et al., 2024)
5. Ongoing 2023-26 study of landholder information sources and intended actions on carbon farming, involving ten interviews in NSW so far (unpublished)

The studies listed range from the period just prior to the introduction of the CFI, when federal carbon farming policy was being developed and debated, through the period of rapid growth in rangeland projects following the introduction of ERF payments (2015-2020), to the period of policy reform in 2022-2025. The research questions focused on in these studies cover perceived risks and benefits of carbon farming, perceptions of carbon farming versus other land use activities, carbon farming's potential contribution to socio-ecological resilience, social licence (i.e. community acceptance), information sources and adoption support, and the potential for collaboration between landholders.

Policy lessons

Lesson 1: The need for policy adaptation

One of the characteristics of Australia's global leadership on carbon farming has been a willingness to change rules and policy settings to increase adoption. A notable result in Study #1 on woody crops (Baumber et al., 2011) was that interviewed landholders preferred bioenergy over carbon due the perceived inflexibility of carbon farming, with comments including "It's inhibitive, it devalues the land" and "You lose control of your land for 99 years". A requirement to maintain sequestration for 100 years was incorporated into the CFI in 2011, but the introduction of the ERF in 2015 also provided a 25-year option. Farmers could commit to the shorter permanence period in exchange for a 20% discount on the credits they received (designed to cover the risk that sequestration may be reversed after that time).

The focus studies record the shift over time as carbon farming changed from a potential to a real income stream, with socio-economic benefits for landholders and surrounding communities. As income was generated, taxation emerged as another area in which policy adaptation was required to achieve fairness and increase incentives for adoption. Tax treatment was a common complaint amongst landholders in Study #2, including "Got 3.5 years' worth of carbon payments and lost a lot to tax" and "Why isn't it primary production?" (Baumber et al., 2022).

Taxation rules were later changed to allow concessional tax treatment for ACCUs generated by primary producers from 1 July 2022. Another example of a policy change that was designed to increase flexibility and the incentive to participate was the 2022 decision to allow carbon farmers to exit fixed delivery contracts they held with the government under the ERF in order to capitalise on higher prices available on the ACCU spot market (IEEFA, 2022).

Lesson 2: The need to overcome complexity and uncertainty

Landholder concerns about the complexity of carbon farming rules and uncertainty around future policy changes are a key theme running through each of the five focus studies – and other studies as well (e.g. Cotton and Witt, 2024). Landholders expressed these concerns in remarkably similar ways over the 15-year timeframe covered by the focus studies, including:

- "Carbon trading is very political… too susceptible to political change" (Study #1).
- "Where do you go to for info?" and "I have found that there is a lot of uncertainty in the future direction of carbon farming" (Study #3)
- "I think the main barriers are understanding it" and "I think the biggest prohibitor is the lack of education and the confusion around carbon farming" (Study #4)

While improvements in information provision and landholder support may help to address uncertainty, confusion and complexity, there is also a fundamental tension between Lesson 1 on the need for policy adaptation and Lesson 2 on the need to overcome uncertainty. This tension was highlighted in Study #2 on socio-ecological resilience (Cowie et al., 2019) and Study #3 on social licence (Baumber et al., 2022). Confidence in governance is a key determinant of social licence and continual policy changes can erode trust. However, the potential loss of trust and social capital from continual policy changes needs to be weighed against the benefits of increased flexibility and adaptability, which can improve the resilience of farming enterprises and rangeland communities more broadly (Baumber et al., 2020).

Lesson 3: The need for confidence and integrity

This lesson was most clearly highlighted by the Chubb Review in 2022, including some of the concerns and claims that surrounded it (Macintosh et al., 2024) and the review's recommendations to close down the AD method, suspend the HIR method, and separate scheme regulation from government credit procurement into different agencies. This review was highly topical during Study #4 and was linked to several statements of cynicism about the carbon farming industry from landholders and other stakeholders, including: "farmers are inherently suspicious of any government scheme", "cover for the fossil fuel industry to continue business as usual" and numerous references to "sharks" in the industry.

Study #3 considered the social licence to operate with regard to carbon farming and found that a lack of confidence in governance was one of the biggest barriers to obtaining a broad-based social licence in affected communities. A narrow focus on maximising carbon was also found to be problematic in cases where it clashed with local values, such as the preferred balance between grass and trees and a feeling that people should stay on the land rather than become "absentee" landholders producing carbon only. Recommendations for building and maintaining social licence include using trusted information sources to disseminate information (e.g. landholders, local agencies), considering norms and values when designing carbon farming policy (e.g. perceptions of what good land management is), closing the gap between global-scale policy frameworks and locally-relevant actions, valuing co-benefits such as biodiversity and soil health, and decreasing dependence on a single program (i.e. the ERF).

Lesson 4: The need to overcome barriers of cost and bureaucracy

The costs involved in becoming a carbon farmer were a prominent barrier in each of the focus studies. These include costs associated with obtaining information and advice, baselining current carbon levels in vegetation or soils, registering projects, entering into contracts, changing practices, measuring carbon sequestration and compliance and auditing of projects. These cost factors were a particular issue in Study #4, which looked at soil carbon and the potential for collaboration. While models exist to estimate above-ground carbon based on predicted tree growth, developing similar models for below-ground carbon has been challenging. Without reliable models, the costs involved with baselining carbon levels and measuring sequestration levels in subsequent years can be prohibitive, for example: "how much would it probably cost me… maybe 30, 50 grand to do the baselining…that's a fair bit of money then I'd have to recoup that in a sale." (Baumber et al., 2024).

As with Lessons 1 and 2, there is also a trade-off required between Lesson 3 on the need for integrity and Lesson 4 on the need to reduce costs. Bringing down the costs of measurement and compliance has been identified as a critical goal for expanding the adoption of carbon farming and realising its potential in Australia. However, the experiences with the Chubb Review and the ongoing questioning of the models used to calculate carbon sequestration from HIR highlight the need to tread carefully when replacing on-ground measurements with modelling and assumptions.

Conclusion

Australia's experiences with policy innovation, experimentation and learning over the past 15 years not only places it in a strong position to continue Australia's global leadership on carbon farming, but also to help inform the policy decisions made in other jurisdictions. However, challenges remain around the barriers of complexity and cost, the need to increase confidence in the integrity of carbon farming schemes and the need to balance continual adaption with landholders' desires for certainty and clarity. The Australian Government has demonstrated an ability to respond to concerns raised by landholders, such as around long commitment periods, taxation and inflexible trading rules. As these concerns are replaced by newer ones, such as around credit integrity or absenteeism, further adaptation will be needed, while also keeping key actors informed and avoiding a sense of constantly changing rules. By drawing on Australia's policy lessons, other countries may be able to anticipate issues that could emerge around their own carbon industries and design carbon farming policy proactively rather than reactively.

This paper also demonstrates how ongoing social research with landholders, government agencies, industry players and other members of rangeland communities is essential for sustaining a successful and responsible carbon farming industry. Semi-structured interviews, focus groups and surveys can all provide valuable data for this purpose, as can a mix of national-scale and locally-specific case studies.

What lurks beneath the surface: Contribution of profile soil to total organic carbon pools in vertosols of central Queensland, Australia

Elledge, A[1]; Thornton, C[1]

[1] Department of the Environment, Tourism, Science and Innovation, PO Box 3130, Red Hill, Rockhampton, Queensland, 4701, Australia

Key words: carbon accounting; carbon sequestration; natural capital; soil carbon; subsoil.

Abstract

The standard practice for calculating carbon stocks in soil is tonnes per hectare (t/ha) to a depth of 0.3 m. Such calculations are influenced by the greater proportion of carbon in the 0.0 to 0.1 m depth, but sampling to 0.3 m provides additional information on the impact of management practices. Regardless, only sampling to a depth of 0.3 m neglects a substantial portion of carbon in profile soil. Intrigued by this conundrum, profile samples from the Brigalow Catchment Study were analysed for Walkley and Black soil organic carbon (SOC) for three land uses: remanent brigalow woodland, cropping and grazing. Samples were collected from Vertosol soils to a maximum depth of 4.4 m in 2018, 36 years after clearing of the two agricultural land uses. In agreement with earlier studies, there was less carbon under cropping than grazing or brigalow woodland. On average there was 42 t/ha of carbon in the top 0.3 m of soil under grazing and woodland which accounted for 56% of the SOC stock to 4.4 m, compared with only 28 t/ha under cropping which accounted for 48% of the SOC stock to 4.4 m. Carbon stocks were steady below 1.8 m for all three land uses, and carbon in the 0.3 to 1.8 m depths accounted for 30% of the total SOC stock to 4.4 m. Root biomass is the main input of organic carbon into soil, and land management practices that promote perennial pastures and native vegetation with deeper root systems increase the opportunity of profile soil to sequester carbon.

Introduction

Many studies focus on SOC in the top 0.3 m of soil due to its concentration at the surface and ease of sampling, but this depth has limited potential to sequester further carbon due to its high mineralisation rates and subsequently shorter residence times (Button *et al.* 2022; Hicks Pries *et al.* 2023). Globally, 68% of SOC is in the 0.3 to 2.0 m depth yet many studies still focus on carbon in the 0.0 to 0.3 m depth (Hicks Pries *et al.* 2023). Whether soil becomes a sink or source of atmospheric CO_2 depends on plant growth (carbon input into soil) and organic matter decomposition (carbon output to the atmosphere), and estimates under future climate warming scenarios indicate that SOC globally will become a source of carbon to the atmosphere but that losses would be proportionally lower from the subsoil (Wang *et al.* 2022). This indicates that subsoils have the potential to offset anthropogenic emissions by sequestering carbon into stabilised pools which decompose more slowly with turnover times of thousands of years (Button *et al.* 2022). However, it is possible that new plant inputs in profile soil may alternatively increase the decomposition rate of extant carbon due to priming (Hicks Pries *et al.* 2023). The present study demonstrates the substantial contribution of carbon in the 0.3 to 1.8 m depths under native vegetation with two agricultural systems to the total organic carbon (TOC) pool to 4.4 m and discusses opportunities to optimise carbon sequestration in the subsoil.

Methods

This study was conducted at the Brigalow Catchment Study located in central Queensland, Australia. The area has a semi-arid to subtropical climate, with a long-term (1965 to 2023) mean annual rainfall of 643 mm. Data was collected from three land uses: 1) virgin brigalow woodland representative of the pre-European landscape; 2) cropping, typically with annual wheat or sorghum; and 3) grazing on a perennial improved grass pasture. The three land uses are adjoining paddocks within an area of about 80 ha and have similar soil and landscape characteristics. The two agricultural systems were cleared and developed in the early 1980s with commencement of their respective land uses in 1983. The cropping system also had a ley pasture of butterfly pea planted in 2010 to improve soil fertility. Further details are provided in Elledge and Thornton (2022).

Samples were collected in 2018 from all three land uses, which was 36 years after the commencement of grazing and cropping in the two agriculture systems. Soil was sampled at 0.1 m increments to a depth of 2.0 m and then 0.3 m increments until either bedrock or a maximum depth of 5 m. However, only data for key depths is presented in this paper: 0.0 to 0.1, 0.1 to 0.2, 0.2 to 0.3, 0.5 to 0.6, 0.8 to 0.9, 1.1 to 1.2, 1.4 to 1.5, 1.7 to 1.8, 2.0 to 2.3, 2.6 to 2.9, 3.2 to 3.5, and 4.1 to 4.4 m. There were two Vertosol sites within each of the three land uses. Five cores per site were bulked by sampling depth, and then analysed for Walkley and Black organic carbon (method 6A1, Rayment and Lyons 2010). Organic carbon concentrations (%) were converted to total carbon pools (t/ha) using bulk density for each of the key depths with values standardised to a 0.1 m increment for the 0.3 m cores. Bulk density was determined by weighing individual cores after air drying, oven drying a subsample of each core, and then correcting the sample mass to the equivalent oven dry soil mass (Thornton and Shrestha 2021). Averages are presented for the two Vertosol soils, with values graphed using the sample mid-point depth.

Results

TOC to 4.4 m was 80 t/ha under grazing, 71 t/ha under brigalow woodland, and 59 t/ha under cropping. Unsurprisingly, most of the carbon was in the 0.0 to 0.3 m soil depths. However, across all three land uses there was on average 30% of TOC in the 0.3 to 1.8 m depths and 17% in the 1.8 to 4.4 m depths (Table 1). Differences were observed in the 0.0 to 0.6 m soil depths with SOC lower under cropping than from brigalow woodland and grazing, which had similar TOC. Although carbon stock declined with depth for all three land uses, it tended to stabilise below 1.8 m (Figure 1).

***Table 1*:** Soil organic carbon under virgin brigalow woodland compared with two agricultural systems.

Total Organic Carbon	Woodland	Cropping	Grazing
t/ha in 0.0 to 0.3 m depth	42	28	43
t/ha in 0.3 to 1.8 m depth	19	19	24
t/ha in 1.8 to 4.4 m depth	10	12	13
% in 0.0 to 0.1 m depth	26	18	25
% in 0.1 to 0.2 m depth	16	16	16
% in 0.2 to 0.3 m depth	16	15	13
% in 0.0 to 0.3 m depth	59	48	54
% in 0.3 to 1.8 m depth	27	32	30
% in 1.8 to 4.4 m depth	14	20	16

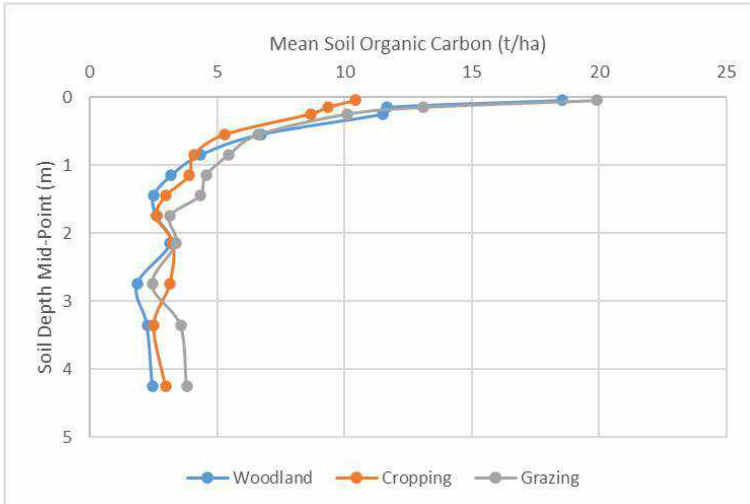

Figure 1: Soil organic carbon under virgin brigalow woodland compared with two agricultural systems.

Discussion

SOC under brigalow woodland and grazing were similar throughout the soil profile, but cropping typically had less, especially in the 0.0 to 0.6 m depths. This is logical given the considerably greater removal of carbon in the form of harvested grain from cropping compared to cattle live weight gains from grazing (Radford *et al.* 2007). A study by Dalal *et al.* (2021), also conducted at the Brigalow Catchment Study, reported an initial 12% decline in SOC when brigalow woodland was converted to grazing due to land development and pasture establishment (≤1.75 years). But particulate, humus and resistant fractions of carbon remained constant over the following 33 years in the 0.0 to 0.4 m depths due to ongoing inputs from root biomass. In contrast, conversion of brigalow woodland to cropping decreased SOC by 38% in the 0.0 to 0.3 m depths over 26 years (declines reported for all carbon fractions), but there was no statistical difference for the 0.3 to 0.4 m depth indicating that deeper carbon stock remains steady (Dalal *et al.* 2021). Furthermore, the planting of a ley pasture to improve soil fertility in this cropping system had arrested further decline (Dalal *et al.* 2021). These carbon trends between land uses are consistent with other studies (Murty *et al.* 2002).

It is important to note that although grazing appears to have greater TOC than brigalow in this study, which occurred 36 years after clearing and development for agriculture, this is not the case when the pasture catchment was compared to its original condition with multiple studies reporting a decline in TOC over time (Dalal *et al.* 2021; Thornton and Shrestha 2021). An earlier study by Dalal *et al.* (2013) at the study site also found that 62% of SOC under the two agriculture systems was derived from the original brigalow woodland. That is, 23 years after land use change, carbon incorporated into the soil (0.0 to 0.3 m) from either pasture or crops had replaced 41% and 36% of the carbon source, respectively. Although these results are from a long-term (decadal) study, the turnover of SOC at this site was reported to be 31 years in the 0.0 to 0.1 m depth which almost doubled to 60 years in the 0.1 to 0.2 m depth, where it then retained a similar age to the maximum sampled depth of 0.4 m (Dalal *et al.* 2011). However, SOC in the subsoil can have turnover times from 1,000 to more than 10,000 years which is where the potential for climate change mitigation via the sequestration of carbon occurs (Hicks Pries *et al.* 2023). This highlights the important contribution of carbon in profile soil below 0.3 m depth.

TOC in the three land uses of this study stabilised at about 1.8 m depth, which is logical given the known rooting depths of the different plants. That is, annual crops such as wheat and sorghum used in this study have a maximum rooting depth of 1.8 m, but with most of the root biomass in the top 0.3 m (Fan *et al.* 2016; GRDC 2017; Demissie *et al.* 2023). Cropping also involves the harvesting of above ground biomass and soil disturbance from machinery which leads to a decline in soil organic matter, which may have contributed to the apparent difference in SOC in the top 0.6 m depth in this study. This is aligned with a global meta-analysis that reported reforestation of croplands increased SOC to 0.6 m (Hicks Pries *et al.* 2023). The rooting depth of grass pasture on brigalow soils was also reported to be about 2 m (Shelton and Dalzell 2007), but with the added benefit of no disturbance to the soil surface. Considering that native vegetation in this region have rooting depths greater than 5 m (Shelton and Dalzell 2007) and that the original brigalow woodland contributed to most of the SOC under all three land uses (Dalal *et al.* 2013), this highlights the importance of adopting plants with deeper root systems for SOC sequestration. That is, the progression from annual crops to a perennial pasture and then to native vegetation not only increases the potential for carbon sequestration in the subsoil, but also improves drought tolerance under future climate warming scenarios by allowing for the enhanced use of water and nutrients at depth (Button *et al.* 2022).

Furthermore, a vegetation survey at the Brigalow Catchment Study in 2015 found that there was 10 times more live tree biomass (overstorey and understory) in brigalow woodland than the grazing system (56.8 t/ha vs 5.1 t/ha, respectively) (Elledge, pers. comment), and brigalow trees (*Acacia harpophylla*) at the site have been estimated to be about 100 to 150 years old (Brooks English 2024). This indicates that if agricultural land is converted back to native vegetation for the purposes of carbon sequestration, it may take more than a century to reach a stable state of carbon at depth.

Comparison of techniques for estimating soil bulk density in arid and semi-arid rangelands: implications for estimation of soil carbon stocks

England, JR[1]; Karunaratne, S[2]; McLachlan, G[2]; Piper, M[3]; Armstrong, J[3]; Vernon, J[2]

[1] CSIRO Environment, Private Bag 10, Clayton South, VIC 3169, Australia; [2] CSIRO Agriculture and Food, GPO Box 1700, ACT 2601, Australia; [3] CSIRO Environment, GPO Box 1700, ACT 2601, Australia.

Key words: soil bulk density; method comparison; carbon stock estimation

Abstract

In Australia, arid and semi-arid rangelands cover vast areas, and contribute to the livestock industry, carbon market, and provision of other ecosystem services. Because of their extent, even minor changes in rangeland soil organic carbon (SOC) stocks on a per-area basis may significantly impact the terrestrial carbon budget. Estimation of SOC stocks from soil C concentrations requires estimates of gravel content, sampling thickness and soil bulk density (*BD*). However, *BD* is a major source of uncertainty, and determination of SOC stocks is often limited by challenges in *BD* estimation. In the absence of measured *BD* values, alternatives such as digitally mapped spatial layers are used to derive *BD* but these values are at relatively low resolution, are static and have relatively high uncertainty. Due to inherently low SOC stocks in rangeland ecosystems, accurate estimation of *BD* is important to detect temporal change.

The most effective method for measuring *BD* will depend on factors such as soil type and moisture conditions at sampling. Here we compared estimates of *BD* to 50 cm sampling depth across several rangeland sites derived from different field methods including: i) the mass of whole soil and volume of carbon concentration cores, corrected for oven-dry moisture content; ii) the mass of whole soil and volume of brass rings collected from soil pits corrected for oven-dry moisture content; and iii) *in situ* gamma-neutron gauge measurements of dry density adjacent to a subset of the cores. Under relatively dry soil conditions, the soil core method gave inconsistent and sometimes spurious results. By comparison, the other methods gave more consistent results. These differences have significant implications for the subsequent estimation of SOC stocks. Our results inform optimal pathways for estimating *BD* in arid and semi-arid rangelands to allow more accurate calculation of stocks and change detection over time.

Introduction

Arid and semi-arid rangelands cover vast areas of Australia and contribute to the livestock industry, carbon market, and provision of other ecosystem services (Department of the Environment 2014; NRMMC 2010; Woinarski et al. 2007). Because of their extent, even minor changes in rangeland soil carbon stocks on a per-area basis may significantly impact the terrestrial carbon budget (Conant et al. 2017).

Estimation of SOC stocks (Mg C ha^{-1}) from soil C concentrations requires estimates of gravel content and soil bulk density:

$$C_s = C_m \times BD \times D \times (1\text{-}G/100) \qquad \text{(Eqn 1)}$$

where C_m is the mass of soil organic C in the soil (%), *BD* is the soil bulk density (g cm^{-3}), *G* is the gravel content (%), and *D* is the thickness of the layer (cm). *BD* is a major source of uncertainty (e.g. Poeplau et al. 2017; Taalab et al. 2013), and determination of SOC stocks in arid and semi-arid rangelands is often limited by challenges in *BD* estimation.

BD can be estimated from 'direct' methods, such as core, clod, and excavation sampling, or 'indirect' methods including radiation and regression approaches such as pedo-transfer functions (Al-Shammary et al. 2018). Digital soil maps can also be used to derive BD but are typically of relatively low resolution, are static and have relatively high uncertainty. The most effective method for measuring *BD* will likely depend on the soil type and moisture conditions at the time of sampling. For example, if soils are dry and crumbly, cores may not be fully intact, resulting in large variation between cores, potentially resulting in spurious estimates. Using rings collected from soil pits largely removes the issue of crumbling cores, but typically lacks spatial coverage. Spatial representation could be addressed through excavating multiple pits, but this is time consuming and expensive. Indirect methods such as using gamma-radiation attenuation may be useful for increasing spatial representation in a more time- and cost-effective way, but accuracy is influenced by soil depth (Alam et al. 2001). Therefore, the aim of this study was to compare and assess the utility of three alternative methods for estimating *BD* and subsequent estimation of SOC stocks to inform future sampling strategies in arid and semi-arid rangelands.

Methods

Field sampling and measurement

The study sites included six long-term experimental trials in Australian rangelands (Table 1). Sampling was undertaken between September 2023 and August 2024 to compare three methods for determining soil bulk density (*BD*):

i. Soil was sampled from 12-30 random locations per plot depending on plot size using a corer (internal diam. 43 mm) to 50 cm depth, with three depth intervals 0-10, 10-30 and 30-50 cm;

ii. Soil was sampled from a single excavated pit per plot, with pit ledges at 0, 10 and 30 cm. Where soils were dry and crumbly, pits were irrigated overnight to 'wet up' the soils prior to sampling. Three brass rings (internal diam. 98.5 mm) were collected from each of three depth intervals 0-10, 10-30, 30-50 cm per plot;

iii. *In situ* measurements of BD were taken using a surface gamma-neutron gauge (Troxler Model 3440+, Troxler Electronics Laboratories, Inc, NC, USA) at 4-12 locations per plot depending on plot size adjacent to a random subset of cores from method i., at three depths (10, 20 and 30 cm). Deeper measurements were also made on each of the pit ledges from method ii), corresponding to depths of 10, 20 and 30 cm, 20, 30 and 40 cm and 40, 50 and 60 cm for the pit ledges at 0, 10 and 30 cm, respectively.

Sample processing and BD estimation

For i., soil samples were air-dried (40°C oven until constant weight) and bulked into 4-5 composite samples per depth per plot. For each bulked sample, peds were crushed using a mortar and pestle, and sieved to <2 mm to remove gravel and large organic matter (e.g. woody roots). The moisture content in the <2 mm soil samples after air drying was quantified gravimetrically by oven drying a 20-30 g subsample at 105°C for 48 hours. For each >2 mm sample, gravel was separated from organic matter and the weight recorded. Gravel content (*G*, %) was calculated as:

$$G = G_m / W_m \times 100 \qquad \text{(Eqn 2)}$$

Where G_m is the mass of the gravel in the >2 mm sample and W_m is the oven-dry corrected mass of the whole (>2 mm + <2 mm) soil sample.

For ii., the fresh weight of each sample was recorded before drying at 105°C to constant mass. For iii., the gauge measures BD by gamma source and moisture by neutron source, correcting wet BD to dry BD.

Using these data, we estimated *BD* (g cm^{-3}) of each depth interval in three ways:

i. *Core BD*. From the mass of the whole soil (fine and gravel fractions) and volume of the cores, corrected for oven-dry moisture content, as recommended in the Guidelines for the Soil Carbon Measurement Methodology (Australian Government 2021);

ii. *Pit BD*. From the mass of the whole soil (fine and gravel fractions) and volume of the rings collected from a single soil pit per plot corrected for oven-dry moisture content;

iii. *Gauge BD*. From *in situ* gamma-neutron gauge measurements of dry density.

To provide a preliminary test of the implications of differing *BD* estimates in the estimation of SOC stocks, alternative estimates of carbon stocks were derived (Eqn 1) using a consistent total carbon concentration for each of the 0-10, 10-30 and 30-50 cm depths layer as 4, 3 and 2 mg g^{-1}, respectively. Two contrasting sites – one with dry soils at the time of sampling (Wapweelah), and another with relatively moist soils at the time of sampling (Boatman) were compared.

Data analysis

Bland-Altman analysis (Bland and Altman 1999) measures the agreement, and quantifies the difference, between two methods compared with correlation and regression analyses where only the association between two methods is assessed. Here, Bland-Altman plots (also called Tukey mean-difference plots) of the differences against the averages of the alternative methods for the plot-level data were used to evaluate bias between the mean differences, and to estimate an agreement interval, within which 95% of the differences of the second method, compared to the first one, fall. The 95% limits of agreement were estimated by mean difference ±1.96 standard deviation of the differences. Because three measurement methods were compared here, plots were compared for each pairwise combination (Core vs. Pit, Core vs. Gamma, and Pit vs. Gamma). Data were checked for the assumption of normality. All analyses were performed using R statistical software (R 4.4.1) (R Core Team 2024).

Results

BD obtained from individual cores gave inconsistent and sometimes spurious results, with values ranging from 0.49-3.46 g cm^{-3} (Figure 1a). By comparison, *BD* obtained from individual rings (method ii) or individual gauge measurements (method iii) gave more consistent results in the range 1.21-1.88 g cm^{-3} (Figure 1b) and 1.09-1.86 g cm^{-3} (Figure 1c), respectively. Plot means for *BD* obtained from cores, pits and gauge measurements were 1.17-2.15 g cm^{-3}, 1.27-1.83 g cm^{-3} and 1.18-1.86 g cm^{-3}, respectively.

Bland-Altman analysis of the Pit BD and Gamma BD methods (Figure 2a) showed the mean difference was 0.10 and the 95% limits of agreement ranged from -0.10 to 0.31. There was no clear proportional bias, indicating that the difference between the two methods was consistent across the average bulk densities. By comparison, Bland-Altman analysis of the Core BD and Pit BD methods (Figure 2b) showed the mean difference was 0.01 and the 95% limits of agreement ranged from -0.37 to 0.39. Although the mean difference was close to zero, the plot indicated a proportional bias, with the difference between the two methods varying as the average soil bulk density increased. Analysis of the Core BD and Gamma BD methods (Figure 2c) showed the mean difference was 0.09

and the 95% limits of agreement ranged from -0.19 to 0.38. The Bland-Altman plot indicated a proportional bias, with the difference between the two methods varying as the average soil bulk density increased, although less steeply than for the Core and Pit BD comparison.

SOC stocks at 0-10, 10-30 and 30-50 cm depth estimated at a site where soils were dry at the time of sampling, were 15.1%, 9.5 and 0.1 % higher, respectively, using *BD* estimated from individual cores compared with the plot mean for the pit. By comparison, at a site where soils were relatively moist at the time of sampling, SOC stocks at 0-10, 10-30 and 30-50 cm depth were 18.8%, 8.8 and 16.3 % lower, respectively, using BD estimated from individual cores compared with the plot mean for the pit.

Table 1. Site characteristics, experimental designs and previous studies relating to the experiments used in this study.

Site name	**State**[1]	**Latitude**	**Longitude**	**Experiment type**	**No. of plots**[2]	**Year trial established**	**Vegetation type**
Oakvale	NSW	-30.95	146.46	Grazing exclosure	4	1975	*Eucalyptus* woodland
Wapweelah	NSW	-29.26	145.32	Grazing exclosure	4	1996	*Acacia* woodland
Croxdale	QLD	-26.46	146.13	Grazing exclosure	3	1981	*Acacia* woodland

Boatman	QLD	-27.24	146.98	Thinning trial	7	1963	*Acacia* woodland
Monamby	QLD	-26.64	145.38	Thinning trial	6	1965	*Acacia* woodland

[1] NSW = New South Wales, Qld = Queensland; [2] number of plots sampled for bulk density. May not represent all plots in the experiment.

Discussion

A key finding of this study was that *BD* obtained from individual cores (method i) gave inconsistent and sometimes spurious results, while *BD* obtained from individual rings (method ii) or individual gamma-neutron gauge measurements (method iii) gave more consistent values within the expected range for soils. Although the plot means derived for core *BD* were more reasonable, in some cases they were still erroneously high (>2 g cm^{-3}). Further, because SOC stocks are typically calculated based on individual cores (or several cores where samples are bulked), SOC stock estimates using *BD* estimates from cores are likely to be significantly affected. This was demonstrated by the differences between SOC stocks using *BD* estimated from cores versus pits, particularly in the surface 10 cm of soil. The Soil Carbon Measurement Methodology Guidelines (Australian Government 2021) specify estimation of *BD* volumetrically using cores. Our results suggest that, depending on the soil conditions at sampling, alternative methods should be considered for determining *BD* in rangeland soils.

Results here confirmed that *BD* samples from pits that were irrigated overnight to ‘wet up’ the soils prior to sampling removed the issue of crumbling cores in dry soils. However, pit sampling lacked spatial coverage across the plots, and sampling multiple pits would be time consuming and expensive. Here, data from the gamma-neutron gauge provided better spatial coverage and more consistent *BD* estimates than cores. Although *BD* estimates from pit rings were typically higher than those from the gamma-neutron gauge, Bland-Altman analysis indicated that bias was relatively constant. By comparison, Bland-Altman analysis of core and pit estimates of BD showed that although the mean difference was close to zero, bias was proportional, with the difference between the two methods varying as the average soil bulk density increased. Bland and Altman (1999) recommended that 95% of data points should fall within 2 standard deviations of the mean difference. The method only defines the intervals of agreements, and not whether those limits are acceptable or not, therefore acceptable limits must be defined a priori (Giavarina 2015).

The main outcome of this work has been to progress knowledge on the trade-offs between three approaches to measurement of soil bulk density in rangelands. Although not sampled in this study, vertosols are a relatively common soil type throughout parts of the Australian rangelands. Determining *BD* in vertosols has the additional challenge of periodic swelling and cracking of these soils in relation to moisture content (Yule 1981), and further work is required to test the utility of methods in vertosols.

It should be noted that in the Soil Carbon Measurement Methodology Guidelines (Australian Government 2021), stocks are expressed on an equivalent soil mass (ESM) basis rather than on a specific thickness basis. The next phase of this work will investigate whether the ESM approach can avoid these differences in stock estimates resulting from different *BD* measurement approaches.

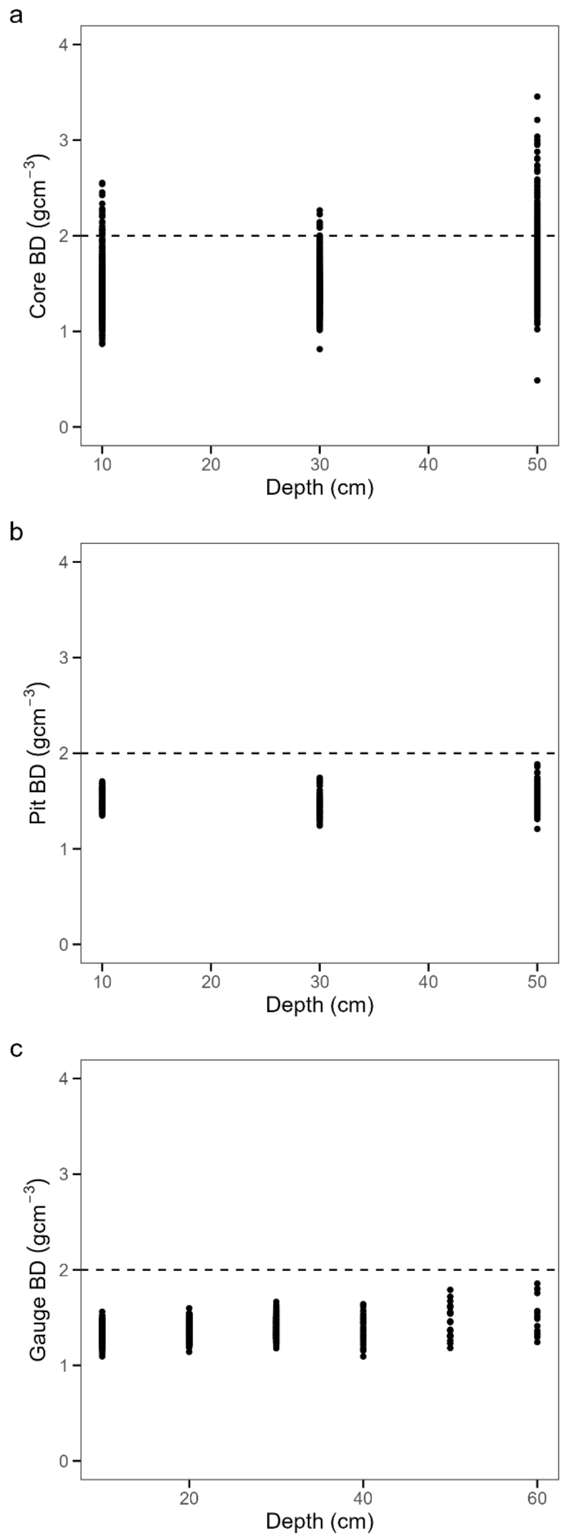

Figure 1 Scatterplots of individual soil bulk density (BD) estimates obtained from: a) individual cores (method i), b) individual gamma-neutron gauge measurements (method iii), and c) individual rings (method ii) by lower depth of sample (Depth). The dashed line indicates a value of 2 g cm^{-3}, the typical upper limit for soil.

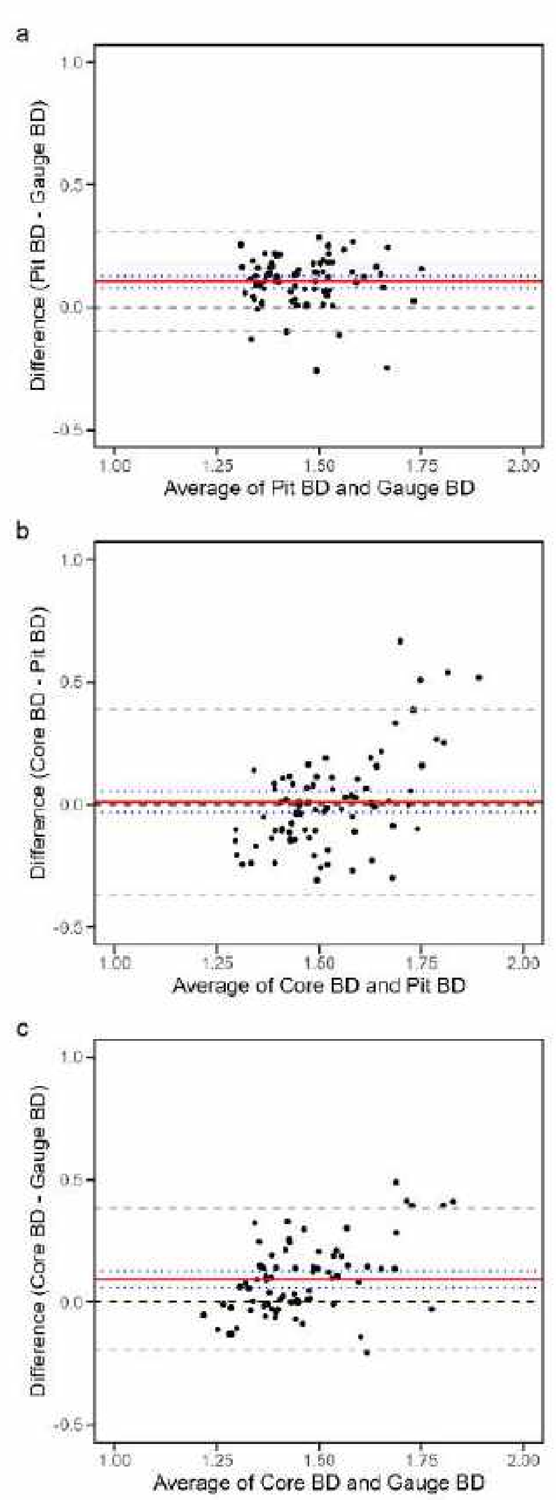

Figure 2 Bland-Altman plots showing the difference between pairs of bulk density (BD) methods plotted on the y-axis against the average of the methods on the x-axis for: a) Pit BD and Gauge BD, b) Core BD and Pit BD, and c) Core BD and Gauge BD. Solid red horizontal line shows the mean difference, dotted blue lines show the 95% confidence interval of the mean difference, dashed grey lines show limits of agreement (±1.96 standard deviation of the differences) and dashed black line shows the line of equality (zero difference). Difference and average values are calculated from three depth intervals (0-10, 10-30 and 30-50 cm) at each of the 27 plots across the six rangeland sites.

Oil, gas, and mineral industry role in rangeland restoration: a systematic review

Dhehibi, B[1]; Souissi, A[1]; Baker, D[2]; Flintan, F[3]; Wane, A[4]; Burkat, S[5]

[1] ICARDA-Tunisia, [2] Independent researcher - Australia, [3] ILRI-Addis Ababa-Ethiopia, [4]ILRI-Senegal, [5] Alliance - Cali, Colombia

Key words: Oil, gas, and mineral industry; rangeland restoration; investment.

Abstract

The rapid expansion of unconventional oil and gas development in the oil-gas-mineral (OGM) states has been controversial because of numerous environmental and social impacts. OGM industries have existed on rangelands for many years with various impacts depending upon the scope of operations and level of professional management (Walsh and Rose 2022; Allred et al. 2015; Chomphosy et al. 2021). In the last decades, energy production has become the largest user of rangelands in several parts of the OGM produced countries, occupying large areas and becoming the largest driver of land-use change (Kreuter et al. 2016). Although emerging energy resources, such as wind and solar, are growing rapidly due to the new advanced technologies, fossil fuel production continues and is predicted to expand in the future (Covert et al. 2016). This will have significant increases in damages to rangelands in terms of reduction of biodiversity, loses in vegetation, increase in carbon emissions, disruption on the natural ecological process, reduction and contamination of ground water, and decrease on the ecosystem services – the potential benefits that natural rangelands provide to humanity.

In the frame of STELARR (Sustainable Investments for Large-scale Rangeland Restoration) project, this paper aims to give a comprehensive overview on the role this industry could play on rangeland restoration in the West Asia and Middle East (WAME) region and what is expected from it in terms of sustainable business practices and what roles the OGM countries-governments are to play given that are currently confronted by overlapping rangeland-oriented demands from ecologists and industry.

Introduction

OGM industries have existed on rangelands for many years with various impacts depending on the scope of operations and level of professional management (Walsh and Rose 2022; Allred et al. 2015; Chomphosy et al. 2021). Advanced technology has stimulated growth in mineral, oil and gas development, not only in the number of wells, but also in the size of operations around the oil, gas and mining countries. In the last decades, energy production has become the largest user of rangelands in several parts of the oil and gas-producing countries, occupying large areas and becoming the largest driver of land-use change (Kreuter et al. 2016; Holechek et al. 2015; Moran et al. 2017; Covert et al. 2016; Hosseini and Shakouri 2016). Although emerging energy resources, such as wind and solar, are growing rapidly due to new advanced technologies, fossil fuel production continues and is predicted to expand (Covert et al. 2016; Hosseini and Shakouri 2016). This review aims to give a comprehensive overview on the industrial foundation of oil and gas and looks at what is expected from this industry in terms of sustainable business practices and focuses on how rangeland restoration can be an economic and environmentally friendly investment opportunity that the oil and gas sector should investigate.

Methods

The proposed method is a two-stage process analysis relying on quantitative and qualitative data. First, we used a quantitative framework developed by Derek (2024, *pers.comment*), to identify the potential value chains for potential investment in rangeland rehabilitation in the WAME region. The selection process was based on specific factors such as: (1) Availability of inputs and production capacity in the target regions/countries; (2) Existing market demand and growth potential; and (3) Diversification in the use of the final product. The results emerging from this framework regarding the oil, gas, and minerals value chain are displayed in Table 1.

Table 1. Oil, gas, and minerals value chain characteristics for rangeland products

Value Chain	**Oil, Gas, and Minerals (OGM)**
Main product and application	Minerals, oil, gas, oil by-products (i.e. derivates, etc.)
Location	Gulf Cooperation Council countries
WAME largest producer/target	Saudi Arabia

Source: Adapted from Derek (2024, pers.comment).

In the second step, we used qualitative data based on various published and unpublished sources. The data was analysed to provide an overview of the oil and gas industry including its main actors, the key challenges facing this industry and its impact on the environment. In addition, a comprehensive analysis on the potential rangeland restoration investment and support opportunities for the oil and gas industry was conducted.

Results

The oil and gas industry plays a central role in the global economy, constituting 3.8% of the world's Gross Domestic Product (GDP). The United States of America, Saudi Arabia and Russia are the largest producers and exporters of crude oil and gas worldwide. These three nations have a combined total of 43% of the market relative to the world figure in 2022, with production levels standing at 43.3 million barrels a day (MDD Forensic Accountants, 2023). Most rising economies such as the BRICS nations (Brazil, Russia, India, China and South Africa) have accelerated the escalating demand for oil and gas production. In 2022, BRICS members accounted for 25.8% of total world GDP, while the G7 nations held 51.9%. (Energy Information Administration 2023; IMF 2021). In 2023, the oil and gas industry employed over 41 million people worldwide (IEA 2022).

Numerous organizations play crucial roles in forming policies, standards and practices within the oil and gas sector. The International Energy Agency (IEA) delivers data, analysis and recommendations for reliable, affordable and clean energy to its member nations and beyond (Esu and Sindico 2016). OPEC, or the Organization of the Petroleum Exporting Countries, is committed to stabilizing prices by coordinating oil policies among member states (Heath-Brown 2015). Also known as API, the American Petroleum Institute is a standardization body for operational and environmental safety in both the oil and gas sectors (Miller 2014). The International Association of Oil and Gas Producers serves as a global voice for the upstream oil and gas industry, advocating for sound regulatory practices and sustainable operations, as stated on their website (iogp.org) (Threadgold 2018). The World Bank's Oil, Gas and Mining Policy Division offers economic and technical support to developing nations to help them develop their mineral, gas and oil industry in effective and sustainable ways (Toussaint 2023). These companies have made several commitments concerning the environment and society, aiming to reduce emissions and invest in renewable energy projects as well as supporting local development schemes (Al-Fattah 2013; Victor 2013). Sometimes, these efforts have been criticized by environmental activists and researchers as greenwashing and insufficient to mitigate the industry's substantial environmental and social impacts (Parafiniuk and Smith 2019).

Discussion

Possible rangeland restoration investment and support opportunities for the oil and gas industry

The oil and gas sector does not consider rangelands as raw material sources. Nonetheless, its accompanying activities influence local communities and ecosystems, especially in regions with delicate environments or native populations. It is imperative that responsible development practices, stakeholder engagement and environmental protection measures are employed in mitigating these impacts and ensuring social licence to industry officers (Elijah et al. 2021; Ruble 2019). Oil and gas firms invest in restoring land in several ways. Economic benefits of capping and remediating abandoned wells include eliminating pollution. In the past, all lands lying around shut-in wells in the Lower 48 states of America were rehabilitated for approximately US$7 billion. Research shows that reviving unused oil or gas land may have greater economic returns if there is enough crop yield from such areas, if we consider carbon-sequestration efforts and general improvement in environmental quality services. The industry could further evaluate these potential returns to justify investments in rangeland restoration (Moran and McClung 2021).

Mobilizing private sector funding for rangeland restoration: The STELARR project approach

The STELARR project (ILRI, 2024) is intended to reverse rangeland degradation and impact productivity through sustainable livestock value chains that benefit pastoralists and other land users globally. As the project engages with livestock value chain actors, particularly the private sector, it promotes sustainable practices and incentives for investment in rangeland restoration. The project encourages businesses to allocate a portion of their profits toward restoring degraded rangelands through a rangeland's stewardship scheme, which includes a certification standard that rewards sustainability efforts. Companies that meet the highest criteria for restoration investments receive Platinum-level recognition, providing a market-driven solution to rangeland degradation. A key component of STELARR is the development of a global rangelands monitoring system and data platform. This system consolidates datasets into an interactive platform, offering data on rangeland health, trends, and educational resources for policymakers, researchers, and pastoralists]. The platform ensures transparent monitoring and compliance, guiding decision-making and promoting sustainable management practices. It is designed to facilitate the adoption of globally recognized monitoring frameworks for rangeland stewardship and restoration. Capacity building is also central to STELARR's approach, providing support for value chain actors to implement monitoring systems and improve sustainability practices. By aligning its efforts with international initiatives such as the Land Degradation Neutrality targets and the UN Decade on Ecosystem Restoration, STELARR highlights the critical role of collaborative governance and private-sector engagement. It addresses the intricacies of rangeland governance and improves pastoral livelihoods. It will serve as a good example for all future interventions toward demonstrating how such sustainable value chains for livestock can steer economic development and ecological restoration to help in enhancing long-term resilience at the global scales of rangeland systems.

Conclusions and future directions

OGM development significantly impacts rangelands in the West Asia and Middle East (WAME), affecting pastoral livelihoods and ecosystems. The STELARR project explores investment opportunities for rangeland restoration to benefit pastoral communities and promoting sustainable rangeland management, including specific actions to mitigate OGM-related challenges and enhance the resilience of pastoral systems. The review provides some avenues on how rangeland restoration can be a viable investment for the oil and gas sector, aligning economic development with environmental sustainability and improved livelihoods for pastoralists. This initiative would potentially contribute sustain the transformed rangeland system, also raising the chances for successful environmental outcomes.

Key words: biodiversity; regenerative agriculture; native grasslands; greenhouse gases; life cycle assessment

Abstract

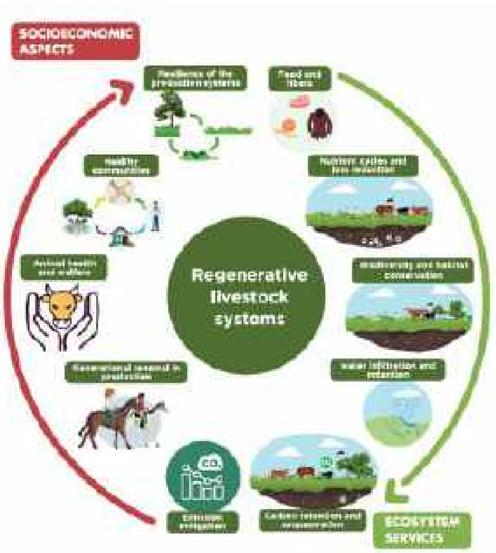
The conservation of native grasslands implies the safeguard from various threats, such as a change in land use. For achieving the objective native grassland conservation, it is necessary to strengthen extensive livestock systems by sustainability improving their performance and by increasing value of emerging products. We developed a regenerative livestock farming proposal based on research evaluating several environmental aspects of the livestock ecosystem functioning on Pampas biome and production technology developed over decades. The conceptual proposal consists of ten points that consider environmental and socioeconomical aspects. The baseline for environmental indicators includes: estimate of carbon footprint through life cycle assessment; organic carbon stock in the soil; assessment of the ecosystem integrity index (EII); the assemblages of wild birds' communities and the assessment of the genetic level of the flock. The latter is included based on its potential for reducing the greenhouse gases (GHG) emissions by improved genetics. We carried out a pilot project with 15 producers which led to the first "regenerative wool" exports from Uruguay to first world-class fashion brands. The results of the study were: a carbon footprint of 60 kg CO_2 equivalent per kg of greasy wool, 83,5 Mg/ha of soil organic carbon stock, an EII value of 3.5, with a bird richness of 104 and 4.26 of Shannon-Weaver Index. The average potential reduction of GHG emission by genetic improvement ranged from 13 to 18% depending on selection criteria used (improving feed efficiency, increasing wool production or reducing methane emissions). In terms of biodiversity, both the IIE results and the richness and diversity of birds are considered very satisfactory. A new collaborative project between INIA and the wool-textile industry seeks to incorporate 110 farmers reaching a total of 200,000 hectares.

Introduction

The livestock sector in Uruguay is the primary user of native grasslands, which in turn are the dominant ecosystem in the country. The conservation of these ecosystems and the significant ecosystem services they provide depends on preventing their replacement by other land uses and ensuring proper management by farmers. On the other hand, livestock farmers face pressures to maintain the sustainability of their operations, both economically, to sustain or improve profitability and continue land use, and environmentally, to reduce negative environmental externalities. To reconcile both objectives—conservation and economically viable production—it is necessary to establish a foundational framework: environmental diagnostics based on scientifically robust, multidimensional indicators, in-depth productive diagnostics, a conceptual proposal that allows for the integration of environmental and economic objectives, the appropriate methodology for implementing this proposal in production systems, and mechanisms for the market to recognize the added environmental value and make production economically viable. Our proposal for regenerative livestock farming (Blumetto et al, 2024), was applied in a pilot project with 15 farms and is being applied in a scaling project. This new collaborative project between INIA and the wool-textile industry seeks to incorporate 110 farmers into this productive scheme through a co-innovation initiative that implies a productive and environmental diagnosis of the farms, expanding the influence of this management to 200.000. The conceptual basis and the environmental baseline of the pilot project with commercial stakeholders is described here.

Methods

Conceptual proposal



INIA's proposal, framed in research projects with a co-innovation approach, accompanies the transition towards regenerative livestock farming based on its environmental diagnosis of the farming systems and in agreement with farmers for the productive redesign of the systems. The main objective of the first stage is to implement process technologies and strategic use of inputs, with an adequate native grasslands management (Jaurena et al., 2021), adapting the recommendations for each case and measuring its response in productive and environmental terms. The proposal includes aspects related to soil care and restoration, the care and re-introduction of native tree species, the strategic use of sown pastures and off-farm inputs, and the adaptation of a technological package for animal production. Additionally, INIA carries out the genetic evaluations of sheep and beef, which allows, by using genomics, the identification of animals that are more efficient in feed conversion and with lower methane emissions.

Environmental indicators

A) Life Cycle Analysis (LCA) for greenhouse gases (GHG) emissions

A LCA is carried out to estimate the carbon footprint of the farm system and its supply chain using the methodology proposed by FAO (2017) and the software OpenLCA. In our case, the analysis is carried out from the "cradle" (origin of all inputs) to the gate of the farm (sale of animals or wool). As a result, we obtain emissions of GHG expressed as kg of CO_2 equivalent per kg of co-products and for hectare of production system. The period evaluated is a productive exercise (July 2022-june 2023).

B) Ecosystem Integrity Index (EII)

The index of ecosystem integrity (EII) was applied for each field within the farms (Blumetto et al.,2019). It combines different ecosystem traits assessed by trained operators. Its application involves an assessment of four components: vegetation structure, plant species, soil and watercourses (streams or rivers), obtaining after calculations a value in a scale from 0 to 5, where five is the best possible state (fig 1).

$$IEI = \sum_{n=1}^{n} \frac{(VE_i + SPp_i + S_i + RZ_i)APi}{4RA}$$

Fig 1. Where, VEi = vegetation structure score for paddock i, SPpi = species presence score for paddock i, Si = soil score for paddock i, RZi = riparian zone score for paddock i, APi = area of paddock, and RA = total ranch area, adapted from (Blumetto et al, 2019).

The EII reflects the distance of the current state of the agroecosystem in relation to the best potential state of the ecosystem in that ecoregion (level 5 of the qualification). The results are calculated globally (the whole farm) but also by paddock or any spatial management unit.

C) Soil carbon stocks

Soil categorization and calculation of organic carbon stock is carried out throw a four steps methodology classification of soils using satellite image classification, field sampling in 30 sites determining bulk density and sending to laboratory for soil organic carbon (SOC) assessment up to a maximum depth of 30 cm, and finally the calculation of the total carbon stock.

D) Associated wild biodiversity

An evaluation of avian assemblage (Gibbons and Gregory, 2006) is carried out, estimating species richness, diversity and priority species for conservation (Soutullo et al., 2013). The study involves bird specialists using the MacKinnon lists methodology (MacKinnon and Phillips, 1993). Although there are numerous groups of wild organisms affected by productive activity, the flora is included within the EII and therefore a fauna indicator is added. The birds were selected for a series of practical advantages: they use all the ecosystems present in the country, they are mainly diurnal and it is possible to identify vocalizations, there are enough specialists to be able to scale the use of the indicator and there is more information available to interpret the results.

E) Productive and environmental genetic level of cattle and sheep

The most relevant rams from each flock (n=10-20) are genotyped, and their genetic value for relevant traits (feed efficiency, wool production, methane emissions, resistance again parasites) is estimated based on predictive genomics. This approach informs farmers about their flock's genetic level and the best options (evaluated rams) to achieve their productive and environmental goals (Vera et al, 2022). To calculate the potential for genetic improvement, a theoretical scenario was proposed where the entire flock of each farmer is replaced by the top 25% of the genetic evaluation. For this, variables that affect emissions were used separately: dry matter intake, metabolizable energy intake and daily methane emission.

Results

Results present the base line including the five indicators for the 15 farms involved in the pilot project.

Greenhouse gases emissions were estimated for a period of one year-round resulting in an average of 2192 ± 351 kg CO_2 eq /ha and the emission intensity for the co-products was 19 ± 6, 13 ± 3 and 60 ± 13 kg CO2 eq /kg of product for bovine meat, ovine meat and greasy wool respectively.

For sheeps, a simulated scenario were the whole flock of every farmer was substituted by the fenotipically top 25% of animals of the genetic evaluation, produced a reduction of CO_2 eq. emission of 12,8, 17,9 and 13,9 %

considering as the evaluated trait dry matter intake, metabolizable energy intake and daily methane emission, respectively.

The average of global EII for all farms was 3,5 ± 0,2. However, analyzing the variability of the values by single paddocks, it increased the SD to 0,6 which implies that exists an heterogenity in the results considering individual paddocks at each farm. An example for a single farm of geografic representation of IIE and the breakdown of the values obtained for each individual paddock and its components is presented in the fig 2.

Figure 2 – Example for a farm of spatial representation of EII and the breakdown of the values obtained for each individual paddock and its components (left) and soil categories and soil sampling points (right).

Average soil carbon stock for the involved farms was 83,7 ± 10,6 Mg per hectare, ranging between 67 and 94 Mg/ha. The variability is mainly explained by type and depths of soil, mainly in those farms located on the basaltic slope region, which have a high proportion of soils that do not reach 30 cm deep.

In terms of associated wild biodiversity, birds assemblages records results in an average richness of 111 ± 25 and the average Shannon Index was 4.2 ± 0.3. Aditionally 30 species are considered conservation priority for the Uruguayan Environmental Ministry (Soutullo et al., 2014).

Discussion

The environmental results obtained when quantifying the environmental baseline were considered good considering the published references for EII and birds' diversity (De Santiago *et al*, 2022; Aldabe *et al*,2023) and recently evaluations of 110 CREA federation farmers a of multiple production systems distributed throughout the country (2024, unpublished data). Therefore, it is challenging to propose improvements in these systems. However, there are opportunities for improvement in some aspects. This is only possible with an exhaustive planning such as the one proposed by co-innovation processes. In terms of reducing methane emission intensity, the main strategy is using genetic improvement. Nevertheless, there are improvement opportunities, in some cases, by improving pasture utilization and management, based on increasing forage allowance, allowing food selectivity and therefore improving nutrients acquisition by animals. Carbon stocks are high, near the reported stocking potential (Dondini et al, 2023). For this reason, the main objective is to maintain this status, although Piñeiro et al. (2024) reported a potential of sequestration of 187 kg of C/year by increasing the net primary production.

EEI presented good values in average (de Santiago et al, 2022; CREA 2024, unpublished data), but the variability obtained for the different paddocks inside each farm show opportunities of improving through management strategies, specially by improving vegetation structure, reducing erosion predisposing factors and by the protection of riparian zones. This last objective has specific actions through special temporary exclusion of grazing in some streams and riparian zones. The high richness and diversity of bird species make the main objective the preservation of this diversity. Parallelly, special management (e.g. pasture mass, conservation of native trees, streams, rivers and wetlands) will be performed in some areas for improving the habitat for priority conservation species.

The co-innovation process will assure the applicability of environmental measures without compromising the productive results or improving productive and economic outcome. This strategy, based on robust indicators and a medium-term action plan, will allow farmers and industrial processors to access high-value markets for superfine wool.

Acknowledgements
We want to thank all the farmers involved in the project, as well as the textile companies Chargeurs Luxury Fibers and Lanas Trinidad SA with which the cooperative project is developed.

Abstract

The provisioning of ecosystem services (Food & Fiber, Water, Carbon, Biodiversity, Wildlife) by rangelands used for livestock production is critical for social and ecological sustainability globally. Adaptive management through adjustments to grazing intensity, timing, and duration are of increasing interest to optimize multiple ecosystem services with increasing pressures from climate change and other environmental stressors. Yet, there is a need for more empirical grazing research at ranch-scales that quantifies management impacts on the suite of ecosystem services. In 2023, we established a ranch-scale experiment (943 ha) in a semi-arid sagebrush steppe rangeland in Wyoming, USA with grazing treatments stratified by ecological sites. Specifically, we established pairs of pastures (ranging in size from 39 to 149 ha) on five soil types: Saline Loamy, Clayey, Loamy, Sandy, and Shallow Loamy soils. Grazing was in the summer. Treatments included 5 Prescriptive (PR) herds grazed continuously for 11 weeks (ranging in size from 10 to 31 cow-calf pairs depending on pasture size; 100 cow-calf pairs total) and 1 Adaptive (AD) herd (100 cow-calf pairs) rotating through 5 pastures every 0.5 to 3 weeks based on adaptive decision making relative to animal behaviour, forage utilization, and weather. Grazing treatments had the same planned system-level stocking rate (meaning a similar number of cow-calf pairs for similar total treatment areas) but were managed with a different stock density -- with the higher density in the AD treatment with potentially different duration. We concurrently sampled multiple ecosystem services at the pasture scale including soil moisture and carbon, forage biomass and quality, wildlife habitat and populations (native rodents, predators, ungulates, and birds), cattle (movement and productivity), and CO_2 fluxes. We present data from the 2023 and 2024 seasons for the suite of ecosystem services with implications for the refinement of adaptive grazing management and intensification in semi-arid sagebrush steppe.

Introduction

Rangelands have the ability to provision a suite of ecosystem services simultaneously, broadly including food & fiber, water, carbon, biodiversity, and wildlife (Goodwin and Porensky 2023). From a multifunctional landscape perspective, rangelands sustainably managed may accomplish this provisioning of multiple ecosystem services through supporting livestock production which is critical for social and ecological sustainability globally (Godde et al. 2020; Monlezun et al. 2024). Yet, quantifying the full suite of ecosystem services presents a challenge in terms of sampling, instrumentation, cost, and infrastructure. Moreover, empirical approaches to understanding how manager decision making influences multiple ecosystem services simultaneously, and relevant tradeoffs, returns on investment (ROI), and temporal trajectories for improvement, remain limited. Given the threats of climate change, urbanization, desertification, and other threats to the people, flora, and fauna on rangelands, enhanced sampling is a critical and emerging need. Concurrent with the need to enhance broad sampling of rangeland ecosystem services has been the emergence in the interest about adaptive grazing management. Adaptive management through adjustments to grazing intensity, timing, and duration are of increasing interest to optimize multiple ecosystem services with increasing pressures from climate change and other environmental stressors. There have been variable claims about the singular benefits of such adaptive grazing management (Briske et al. 2008; Mosier et al. 2021; Jorns et al. 2024); therefore there is a need for more empirical grazing research at ranch-scales that quantifies impacts of adaptive management on multiple ecosystem services. Here we describe a new experiment quantifying multiple ecosystem service responses to adaptive multi-paddock grazing management in a North American semi-arid sagebrush steppe ranch experiment which will have implications for western North America but also arid and semi-arid rangelands globally.

Methods

The study site is managed by the University of Wyoming's (UW) Agricultural Experiment Station (AES) – Laramie Research and Extension Center (LREC) and is known as the McGuire Ranch (latitude 41° 41' 11.54" N, longitude 105° 33' 24.09" W). The ranch is located in Albany County, Wyoming, USA on the west side of the Laramie mountain range and on the east side of the Snowy Mountain Range and is in the Deserts and Xeric Shrublands Ecoregion according to the The Nature Conservancy classification and more specifically, is in the Wyoming Basin (18) Level III Environmental Protection Agency (EPA) Ecoregion which is a broad arid intermontane basin characterized by grasslands and shrublands. The climate is an arid cold steppe (BSk according to the Köppen classification) due to it being temperate, continental, with winter snow, and having a broad thermal gradient. The cold climate is, in part, associated with the high altitudinal position which is 2,190 m above sea level. Annual rainfall averages from 230 to 467 mm yr^{-1} with an average of 353 ± 14 (SE) mm yr^{-1} since 2000. Average annual air temperature since 2000 was 5.4 °C. Average air temperature ranges from -5.5 °C (winter) to 17.2 °C (summer), with mean minimum and maximum temperature of -1.3 °C and 12.2 °C, respectively. The McGuire Ranch is an area of 2,246 ha that is dominated by cool-season perennial grasses and sagebrush (*Artemisia* species) shrubs. The ranch was acquired by UW in 1992 and has been managed in a 3 or 4 pasture system since then for summer seasonal grazing (June through October) of cow-calf pairs. In 2022, 19 km of new internal fence [4-strand wildlife friendly for pronghorn (*Antilocapra americana*) and mule deer (*Odocoileus hemionus*)] and 3 new water tanks (1 – 9 m diameter tank providing water to 4 pastures and 2 – 15' diameter tanks providing water to 2 pastures each) taking the ranch to 14 pastures. This ranch is considered a semi-arid sagebrush steppe ecosystem and is a predominantly native rangeland co-dominated by grasses and shrubs with no trees. The dominant native cool-season grass species include muttongrass (*Poa fendleriana* (Steud.) Vasey), prairie Junegrass (*Koeleria macrantha* (Ledeb.) Schult.), and western wheatgrass (*Pascopyrum smithii* (Rydb.) Á. Löve). In a few study pastures (n = 4) with a history of tillage there are a few non-native cool-season grass species including crested wheatgrass (*Agropyron cristatum* (L.) Gaertn.), meadow brome (*Bromus biebersteinii* Roem. & Schult.), and Russian wildrye (*Psathyrostachys juncea* (Fisch.) Nevski). The dominant shrub species include Wyoming big sagebrush (*Artemisia tridentata* Nutt. ssp. wyomingensis Beetle & Young) and yellow rabbitbrush (*Chrysothamnus viscidiflorus* (Hook.) Nutt.). We established a ranch-scale experiment using approximately 42% of the ranch (943 ha) with grazing treatments stratified by ecological sites in 2023. In order to understand the role of soil texture and ecological site responses to management, we established pairs of pastures (ranging in size from 39 to 149 ha) on five ecological sites with variable soils including saline loamy, clayey, loamy, sandy, and shallow loamy soils. We applied grazing in the growing season due to the severe winters in this area which renders winter grazing practically impossible.

Grazing treatments included 5 Prescriptive (PR) herds grazed continuously for 11 weeks (ranging in size from 10 to 31 cow-calf pairs depending on pasture size; 100 cow-calf pairs total) and 1 Adaptive (AD) herd (100 cow-calf pairs) rotating through 5 pastures every 0.5 to 3 weeks based on adaptive decision making relative to animal behaviour, forage utilization (50% target based on Wyoming Rangeland Monitoring Guide using the Landscape Appearance method) , and weather (Figure 1). Grazing treatments had the same planned system-level stocking rate (meaning a similar number of cow-calf pairs for similar total treatment areas) but were managed with a different stock density -- with the higher density in the AD treatment with potentially different duration.

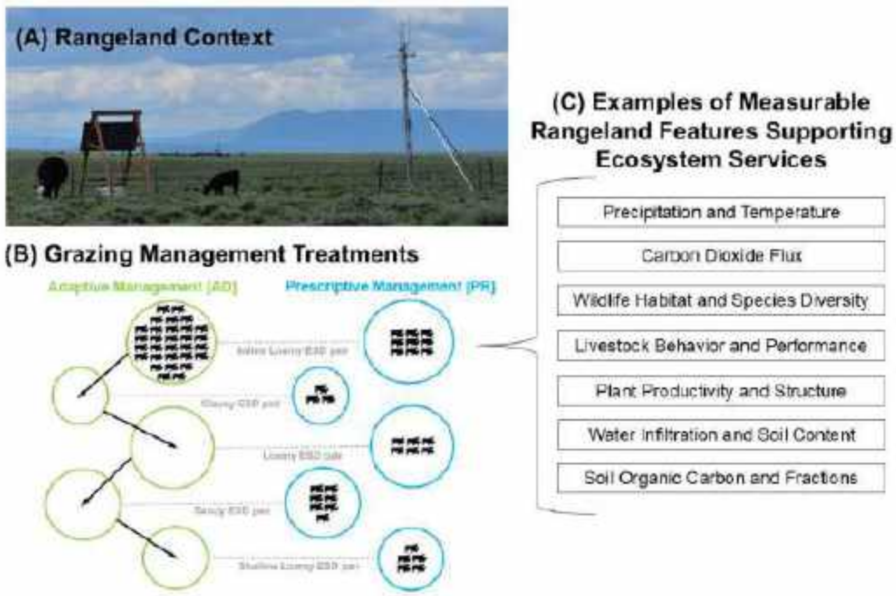

Figure 1. (A) Rangeland context, (B) Grazing management treatments with pastures represented by circles and treatments stratified by soils and ecological site descriptions (ESDs), and (C) measured rangeland features supporting a suite of ecosystem services on the McGuire Ranch in southeastern Wyoming, USA.

We implemented a suite of sampling at the pasture scale. Soils are sampled in each pasture using 12 triangles using a truck-mounted Giddings probe down to 1 m (if possible) with cores cut and sub-sampled at 4 depths: 0-15 cm, 15-30 cm, 30-50 cm, and 50-100 cm. Soil samples were cooled and sent to the laboratory for measurement of SOC/N, isotopes, SOC fractions (chAOM, lPOM, MAOM), BD, pH, texture, IC, and WSA. Soil moisture is being measured using SATURO infiltrometers with three samples per pasture with 10 cm rings to 10 cm depth to assess saturated hydraulic conductivity. In addition, in each pasture volumetric soil water content is being measured at three locations at 10 cm, 20 cm, and 30 cm depths using TEROS 10 (METER Group) capacitance sensor. Weather and greenhouse gas flux, specifically CO_2, is measured with solar powered flux towers that include a 3D sonic anemometer, a four component net radiometer, an ambient air temperature/humidity/pressure and rain sensor and an enclosure for trace gas measurements, soil heat flux plate, and soil temperature/moisture sensor (at 10 to 15 cm depth) provided by Quanterra Systems. Importantly, flux towers enable calculation of Fc, LE, H, based on EC technique. Forage biomass is sampled every 28 days during the growing season months of May, June, July, and August using 3 – 100 m transects with 2 – 0.5 m^2 quadrats clipped to ground level per transect. In addition, standing biomass is also measured every 10 m on the same transects using the non-destructive visual obstruction reading (VOR) technique modified but generally following Robel et al. (1970) where an observer observes a pole with 1 cm increment markings from a height of 1m and a distance of 4 m and records the plant species obstructing the lowest interval on the pole not completely obstructed as well as the highest interval where there was any obstruction. Forage samples will be assessed for forage quality metrics such as crude protein, energy, and digestibility. We are also using Ecological Outcome Verification (EOV) methods to assess water cycling, mineral cycling, energy flow, and community dynamics (Savory Institute 2024). Livestock variables measured included foraging behaviour using standardized observation techniques, animal movement using GPS-ear tags, and performance using calf weaning weights (to be initiated in 2025). In addition, grazing management data such as animal days per acre are also calculated. Wildlife are being measured using a network of infrared game cameras with a particular interest for large ungulates and carnivores. Bird communities are being measured using point count methods and in 2024 nest survival was being measured with nest searching techniques – and both techniques included additional habitat metrics being measured.

Results

Grazing treatments have been applied in 2023 and 2024 which were very different in terms of weather with 2023 being wetter through the growing season and 2024 drier early with late summer rains. The implementation of such a sampling system has been challenging the least. Cow days per acre have been higher in the AD treatment than the PR treatment both years (17% and 27% respectively) suggesting the realization of grazing management treatment different. We are in the process of integrating and summarizing our ecosystem service related data. Additional results at this point include lessons learned for establishing such networks in working rangeland landscapes. First, a diverse team of experts is required, and in our case, includes more than 40 individuals. Second, installation of such instrumentation takes time and financial resources that has to include trouble shooting and repair. Third, the streams of data will require dedicated personnel to build platforms that integrate and scaffold data into a useable interface. Fourth, measuring the response of the suite of ecosystem service responses will take time and likely 3 to 5 years.

Discussion

We are concurrently sampling multiple ecosystem services at the pasture scale including soil moisture and carbon, forage biomass and quality, wildlife habitat and populations (native rodents, predators, ungulates, and birds), cattle (movement and productivity), and CO_2 fluxes in a project that is the first of its kind in terms of scope. This adaptive multi-paddock grazing management in a North American semi-arid sagebrush steppe ranch experiment will have implications for western North America but also arid and semi-arid rangelands globally.

Key words: arid ecosystems, extinction, conservation, invasive species, grazing, predation

Abstract

Australia's arid rangelands have suffered record losses in biodiversity since European colonisation, especially for mammalian fauna, principally driven by invasive species. The scale of the challenge to restore biodiversity requires long-term multi-stakeholder partnerships. Arid Recovery is an independent NGO in the dry rangelands of South Australia, and a unique partnership between the mining industry, government, Indigenous groups, rangeland communities and pastoralists. Work centres around a large predator-proof fenced reserve (12,300 ha) where rabbits, cats and foxes have been removed and six threatened native species have been reintroduced. The reserve supports a robust conservation science program that includes developing tools for management of introduced species, reintroduction of threatened species, and approaches to restore biodiversity at scale. We share lessons from 28 years of rangeland ecosystem restoration and research.

Introduction

While arid and semi-arid ecosystems have had less vegetation clearance than other habitats in Australia since European colonisation, the arid and semi-arid rangelands have suffered record losses in biodiversity due largely to invasive species (Dickman and Pavey 2023). The introduction of rabbits (Oryctolagus cuniculus), cats (Felis catus) and foxes (Vulpes vulpes) has transformed rangeland ecosystems. The spread of rabbits has caused long-term damage to rangeland vegetation (Finlayson et al. 2022), exacerbated by livestock grazing and feral herbivores (Silcock and Fensham 2013). Rabbit populations support the persistence of invasive predators (Read and Bowen 2001), which in turn are the primary cause of the loss of two thirds of the mammal fauna in the rangelands (Woinarski et al. 2019). Of these losses, around half the affected mammal species are now extinct, while another half suffered dramatic range contractions, many of them only surviving on islands free of cats and foxes (Legge et al. 2018). There have also been impacts to other fauna and flora, with some bird and reptile species made locally extinct or rare and vegetation communities altered by grazing (McLellan and Watson 2022; Read and Cunningham 2010). Here we report on a long-term collaboration by diverse land users, institutions and communities to restore biodiversity in Australia's arid rangelands. We highlight some of the challenges faced and knowledge generated over 28 years of applied research.

Methods

Arid Recovery is an independent partnership between the mining industry, government, academia and the conservation sector, in collaboration with Indigenous groups, pastoralists and rangeland communities. The initiative started in 1997 when co-founders sought to take advantage of the transformational reduction in rabbits, cats and foxes numbers caused by rabbit haemorrhagic disease (Pedler et al. 2016) to permanently exclude rabbits from an area of outback South Australia to allow native vegetation to recover, while also excluding cats and foxes to enable the return of vulnerable native animals (Moseby et al. 2018). A cost-effective exclusion fence was designed and tested (Moseby and Read 2006). The reserve grew to six paddocks over 12,300 hectares. Foxes are excluded from all, rabbits have been removed from four paddocks (6,000 ha) and cats have been removed from five (8,600 ha) but allowed to remain in the sixth for experimental purposes. Five locally extinct threatened native species have been successfully reintroduced: burrowing bettongs *Bettongia lesueur*, greater bilbies *Macrotis lagotis*, Shark Bay bandicoots *Perameles bougainville*, western quolls *Dasyurus geoffroii* and kowaris *Dasyuroides byrnei*. A further three threatened species reintroductions were trialled but one failed (greater stick-nest rat *Leporillus conditor*) and two did not progress to full translocations due to predation by native predators (numbat *Myrmecobius fasciatus* and woma python *Aspidites ramsayi*). Two locally rare threatened species colonised the reserve and have sustained populations since: plains mice *Pseudomys australis* and thick-billed grasswrens *Amytornis modestus*. The reserve layout provides experimental power with different experimental treatments across paddocks. A rigorous science program is supported by an advisory panel and collaborations with over 80 different institutions.

Results and discussion

Total grazing pressure must be managed

Arid Recovery's original focus of ecosystem recovery through removing introduced herbivores (rabbits and livestock) was challenged when a reintroduced native herbivore became overabundant. Burrowing bettongs are generalist herbivores that, from a founding population of 29 animals in 1999, increased to an estimated population of 8,000 by 2016. This resulted in reduced cover of more palatable plants and damage to sensitive perennial vegetation (Linley et al. 2017; Moseby et al. 2018). Competition with bettongs for food contributed to the local extinction of stick-nest rats, combined with increased predation pressure by goannas and reintroduced western quolls and an extended drought and record breaking hot summer (Moseby et al. 2024). Management of an overabundant threatened species within the reserve presented challenges. Unlike livestock, there was no market to sell animals and nor could they be translocated in sufficient numbers due to the very limited locations where they could be safe from predation (Radford et al. 2018). Lethal control was contemplated, but made difficult by the status of the species affording it legal protection and risks to the organisation of overstepping social licence. Contraceptive measures were trialled but were not feasible at the scale required. Some animals were allowed to self-disperse through one-way gates out of the reserve into the surrounding area where predators were controlled but not excluded (Butler et al. 2019). These animals had poor survival and persistence due to insufficient control of cats and foxes outside (Moyses et al. 2020). Ultimately, a severe drought in 2018-19 caused the collapse of the bettong population as food resources dwindled (Moseby et al. 2024). Arid Recovery now works to thresholds (50-100 bettong tracks per km) to trigger management actions such as translocation or control based on total grazing pressure measures from vegetation condition measures and interventions described in an adaptive management framework.

Ecosystems need predators

The lack of sufficient predation pressure was the main driver for overpopulation of native herbivores so western quolls were reintroduced in 2018. Quolls are marsupial predators that once occurred across 70% of mainland Australia. In the first reintroduction to an arid ecosystem, 12 adults were released in 2018 following a successful trial. One of the reserve's six paddocks was designated as a control area from which quolls were to be excluded to i) maintain insurance populations of threatened prey species, ii) measure the impact of quolls on the ecosystem, and iii) maintain prey populations naïve to mammalian predators for research (Moseby et al. 2023). Maintaining the control paddock presented a challenge, with at least one quoll incurring into the control paddock each year. Small quolls could gain access by squeezing through the 50mm aperture netting or exploit weak points at corners. However, with regular monitoring and response, quoll have consistently been removed and the control area's integrity maintained. Six years since the release of quolls, there is clear evidence of suppression of prey species and early evidence of trophic cascades (Stepkovitch et al. 2023). Bettong populations in quoll-occupied areas have been maintained below the acceptable thresholds, while bettongs in the quoll-free control paddock exceeded threshold in 2024, triggering translocation of animals out of the paddock. On a smaller scale, our experience reflects the major issue of overabundant kangaroos in the southern Australian rangelands, largely due to the absence of a predator, the dingo (Dawson et al. 2023).

Unique rangeland biodiversity must be preserved
Species restricted to arid ecosystems are dependent upon conservative rangeland management. An Australian example is the kowari, a small marsupial predator that occurs primarily on pastoral lease estate and exclusively so in South Australia. The species has a 20% risk of extinction within 20 years and was recently upgraded to the category of Endangered (Greenville et al. 2018). In 2022, 12 adult kowaris and their small dependent pouch young were translocated to Arid Recovery to establish an insurance population safe from predation by cats and foxes. The population has established and is being compared with remaining wild populations to understand causes for the kowari's decline and what management could be implemented on pastoral stations to improve its prospects. As climate change increases the frequency and intensity of droughts and heatwaves, arid species are in great need of large, interconnected protected areas under conservation management to buffer them against stochastic shocks.

Ecosystems operate across tenure
While using fencing to exclude threats is effective (Moseby et al. 2011), it is not a feasible tool for broadscale, sustained biodiversity recovery. This requires collaboration with diverse rangelands users because species and threats operate across property boundaries and tenures. The Arid Recovery Reserve presents an opportunity to seed the wider landscape with otherwise locally extinct species that have some tolerance to predation by introduced predators or may develop improved anti-predator traits through accelerated evolution (Ross et al. 2019). Effective control of cats and foxes will be necessary to elicit recovery beyond fences, especially as such reserves can attract predators like cats (McGregor et al. 2020). Another key challenge in recovering biodiversity in open landscapes is control of introduced predators in rangeland ecosystems where rabbits are present. We are pursuing the goal of leveraging the predator-free reserve to recover biodiversity in the wider Arid Recovery region in collaboration with Aboriginal communities, pastoral and mining partners. Feral predator control and monitoring of threatened species such as quolls has been coordinated with the Kokatha Aboriginal Corporation that manage three large pastoral leases around the reserve. Predator-proof safe havens like Arid Recovery are an essential bastion against extinction, but risk becoming a long-term holding pattern if efforts to recover biodiversity at scale in open landscapes are not pursued simultaneously (Read et al. 2023).

Conclusions
No rangeland system is immune to the risk of overgrazing. Earlier management of overpopulation could have prevented impacts to the Arid Recovery ecosystem from overpopulated bettongs. Native herbivores in reserves must be managed much as stocking rates for livestock during periods of scarcity in the rangelands. The return of the quoll is showing early signs of being an effective natural solution. Collaboration by different land users is essential to maintain and recover biodiversity in the rangelands as threats operate across tenures and protection of refugial areas for threatened species becomes more important under climate change. The broadscale coordinated control of feral predators required will only be possible through collaboration with a network of land managers over large areas. Equipping and energising rangeland communities for this work is essential, as is investing in research for 'beyond the fence' solutions and suitable policy for retaining the unique biodiversity of the Australian rangelands.

Abstract

Approximately eight million beef calves are produced annually in the western U.S., and ranchers must maintain profitable operations while addressing the growing number of consumers seeking environmentally, economically, and socially sustainable food. In response to such challenges, a diversity of deep-rooted perennial legumes and non-legume forbs high in nutrients and functional phytochemicals, are being grown and stockpiled in resource patches or “islands” across a “sea” of grass-dominated rangelands. These islands of multifunctional diversity are being tested across monotonous landscapes to be used as a low-cost and sustainable supplementation strategy for beef cattle with the aims of increasing biodiversity, animal productivity and health, while reducing environmental impacts. We are screening native and introduced plant species for their establishment and persistence in replicated studies at different ecosites in northern, central and southern Utah. Continuous culture fermenters are being used to evaluate how these forages and their combinations alter rumen fermentation, microbial growth, methane production, and nutrient digestibility. These forages are being strategically deployed in islands across the landscape aiming at higher probabilities for seedling success. This research is being integrated at the regional and local level through grazing schools, demonstration sites, and assessments of potential for adoption through online surveys and subsequent semi-structured in-depth interviews. This transdisciplinary project is progressing to create more sustainable beef production systems while engaging and educating a wide range of stakeholders including current and future land stewards, outreach personnel, and consumers.

Introduction

Approximately eight million beef calves are produced annually in the western U.S. alone (NASS 2024), and beef producers must maintain profitable operations while addressing growing consumer demands for environmentally, economically, and socially sustainable food (Villalba et al. 2019). Under this context, we are developing a transformative paradigm for western U.S. beef production systems through landscape interventions -smart foodscapes (SFS)- in order to increase American agricultural production with a reduction in environmental footprint. Our reasoning for this project stems from the idea that cattle evolved in the Mediterranean region grazing a diverse palette of broadleaf and grass species (Grove and Rackham 2001), but cowherds grazing U.S. rangelands today consume a diet dominated by a monotony of grasses like intermediate, tall and crested wheatgrass (Robins et al. 2020). The feeding value of these grasses plummets in mid-summer, disrupting nutrient cycles and necessitating costly supplementation (Putnam and DelCurto 2020). In turn, declines in the nutritional quality of grasses cause significant increments in the production of the greenhouse gas (GHG) methane by livestock (Lee et al. 2017). Legumes and some forbs are of greater nutritional value than grasses (Phelan et al. 2015), and, unlike grasses, many of these species also contain functional biochemicals or plant secondary compounds (PSC) (e.g., phenolics, terpenoids) that enhance cow-herd health and decrease nitrogen and GHG emissions to the atmosphere (Min et al. 2020). In addition, islands of diversity have the potential to increase landscape connectivity and structural complexity in rangelands, enhancing ecosystem biodiversity and resilience (Leroy et al. 2020). We are creating multifunctional alternative foodscapes using strategically selected legume and non-legume forb species (Objective 1), that synergize nutritionally (Objective 2), and are spatially distributed as resource patches or islands of diversity across the landscape (Objective 3), solving these key challenges to current and future food and agricultural production systems. This research is being integrated at the regional and local level through producer engagement and assessments of adoption (Objective 4).

Methods

Objective 1. The establishment and persistence of two dozen plant species with the potential to provide late-season supplemental protein when seeded as "resource islands" was assessed in strategic locations across semi-arid rangeland. The species include crested wheatgrass and native and introduced legumes and non-legume forbs, with excellent forage value, that are commonly included in rangeland grazing or restoration seed mixtures. Replicated monoculture plots were drilled at four rangeland locations from 1370-2000 m a.s.l. in northern, central and southern Utah in 2022. In July 2023, establishment was assessed as plants m^{-2}, although monoculture plots ranged from 11 to 74 m^2 depending on location. Average annual precipitation, primarily as snowfall, ranges between 247 and 457 mm $year^{-1}$.

Objective 2. Our objective was to evaluate the effect of potential forage candidates for the "islands" on rumen fermentation. The study was conducted as a 5 × 5 Latin square design using continuous-culture fermenters. All treatments contained 75% of crested wheatgrass plus (1) 25% alfalfa, (2) 25% sainfoin, (3) 25% small burnet, (4) 12.5% sainfoin + 12.5% small burnet, and (5) 8.3% sainfoin + 8.3% small burnet + 8.3% birdsfoot trefoil. The diets (60 g DM/day) were fed twice daily. The periods were 10 d long with 6 d of adaptation and 4 d of sampling. Data were analyzed using a mixed model including the fixed effect of treatment and the random effects of period and fermenter.

Objective 3. Nine 30x40 m (0.12 ha) islands were established in a 22-ha grass-dominated pasture (Meadow brome; *Bromus inermis*), with locations selected for higher probabilities of seedling success and a spatial arrangement that optimizes livestock distribution. The limiting resource for plant establishment in semi-arid regions is water availability (Zhang et al. 2020). Thus, areas within the pasture with a higher density of vegetation represented locales where moisture was greater. To identify these locations, temporal sequence of satellite imagery was analyzed utilizing the European Space Agency's Sentinel-2 platform to generate yearly maps of vegetation density via the normalized difference vegetation index (NDVI). Cloud-free Sentinel-2 images spanning the current and preceding 5 years for July and August were identified and NDVI values extracted for each pixel. Median July-August NDVI for each year was calculated for each pixel in the pasture and all pixels were reduced to the mean and standard deviation. These metrics were used to locate pixels within a pasture whose greenness consistently deviated in a positive direction (higher than average greenness) from average pasture greenness. Spatial groupings of these consistently greener pixels served as candidate locations for island establishment, with potential better access to water and nutrients. After spatial selection, islands were seeded with strips (8x30 m each) of: 1-Alfalfa (*Medicago sativa*, containing saponins), 2-Birdsfoot trefoil (*Lotus corniculatus*, containing condensed tannins-CT), 3-Sainfoin (*Onobrychis viciifolia*, containing a different array of CT, 4-Small burnet (*Sanguisorba minor*, containing hydrolizable tannins), and 5-Forage kochia (*Bassia prostrata*, containing phenolic compounds). The percentage establishment of the five-forage species was monitored using the frequency grid method (Vogel and Masters 2001).

Extension personnel is working with a group of livestock producers across the state of Utah to establish a series of demonstration plots using the same approach described above. Locations that represented some of the varied range types throughout the state were selected, as well as those sites with the greatest potential benefit from the intervention proposed, such as those dominated by crested wheatgrass. The team is taking measurements using the frequency grid method (Vogel and Masters 2001) to determine how sites establish and persist under the typical grazing regime of the different operations and speak with producers to understand what they perceive as the primary costs and benefits of the proposed landscape interventions.

Objective 4. During the first year of the project, we sought input from Utah ranchers who are currently grazing livestock by distributing a short online video about the project through team networks, relevant listservs, and social media groups, and to a sample purchased from a private vendor and subsequently asked the ranchers to fill out a brief online survey. Utilizing insights from the survey, we then conducted structured in-depth interviews with 14 Utah ranchers in 2023.

Results

Objective 1. The introduced species sainfoin, small burnet and alfalfa were able to establish in relatively dense stands at every location, and the native species showy goldeneye, Rocky Mountain penstemon, Utah sweetvetch, and prairie coneflower as well as falcata alfalfa all averaged more than 5 plants m^{-1} at some locations. Of the species that performed well at multiple locations, sainfoin accumulates condensed tannins (CT) while small burnet and Utah sweetvetch accumulate both CT and hydrolizable tannins (HT) and are of particular interest because of the synergies between the two types of tannins in improving ruminant health and reducing environmental impacts.

Table 1. Plant species ranked by number of locations with at least 1 plant m^2, and within location, by plant count. Values are final 2023 plant counts.

Genus species	Common name	#Locations	Plants m^{-2}
Onobrychis viciifolia Scop.	Sainfoin	4	36
Medicago sativa L.	Alfalfa, 'Ladak'	4	12
Sanguisorba minor Scop.	Small burnet	4	12
Lotus corniculatus L.	Birdsfoot trefoil	4	3
Heliomeris multiflora Nutt.	Showy goldeneye	3	11
Medicago sativa L. ssp. falcata (L.) Arcang.	Alfalfa, falcata	3	7
Penstemon strictus Benth.	Rocky Mtn. penstemon	2	13
Hedysarum boreale Nutt.	Utah sweetvetch	2	9
Astragalus cicer L.	Cicer milkvetch	2	4
Agropyron cristatum L. Gaertn.	Crested wheatgrass	2	4
Helianthus maximiliani Schrad.	Maximillian sunflower	2	3
Penstemon palmeri A. Gray	Palmer's penstemon	2	2
Ratibida columnifera (Nutt.) Wooton & Standl	Prairie coneflower	1	8
Securigera varia L. Lassen	Crownvetch	1	4
Dalea purpurea Vent.	Purple prairie clover	1	2
Linum lewisii Pursh	Lewis flax	1	1
Balsamorhiza sagittata (Pursh) Nutt.	Arrowleaf balsamroot	1	1

Objective 2. Fiber digestibility was affected by the treatments ($P < 0.01$). The NDF digestibility of Treatment 1 (75% crested wheatgrass and 25% alfalfa) was the highest followed by Treatment 2 (75% crested wheatgrass and 25% sainfoin) and 5 (75% crested wheatgrass, 8.3% sainfoin, 8.3% small burnet, and 8.3% birdsfoot trefoil), while Treatments 3 (75% crested wheatgrass and 25% small burnet) and 4 (75% crested wheatgrass and 12.5 sainfoin, and 12.5% small burnet) had the lowest NDF digestibility values. Among the short-chain fatty acid analyzed, acetate was the only one affected by treatments ($P = 0.04$). The highest acetate concentration was observed for Treatment 1, which was followed by Treatment 2 and 5. Treatments 3and 4had the lowest acetate concentration. The ammonia nitrogen produced from treatment 1 and 2 had greater values, followed by treatment 4 and 5, treatment 3 did not differ compared to treatment 4 and 5, but when compared to treatments 1 and 2, it had the lowest value. No treatment effects were observed for protozoa cell count and pH. Similarly, no treatment effect was observed for microbial growth.

Objective 3.

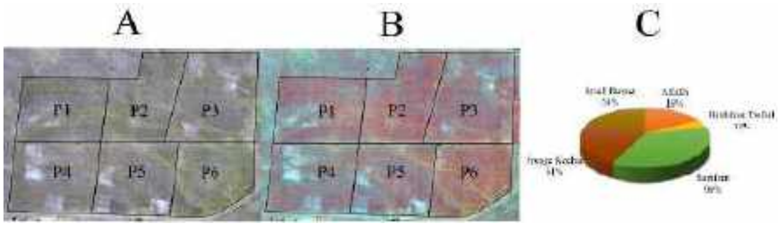

Figure 1. **A.** Natural color orthoimage generated from imagery collected on August 14, 2023, using a DJI Mavic 2 Pro unmanned aerial system (UAS). The 22-ha grass (Meadow brome; *Bromus inermis*)-dominated pasture in northern Utah (111° 48' 6" W, 41° 53' 22" N) shows the nine "islands" of 30x40 m (0.12 ha) each, distributed in three different fenced paddocks (P3, P4 and P5). Islands were seeded with strips (8x30 m each) of alfalfa, birdsfoot trefoil, sainfoin, small burnet, and forage kochia. Differences in color across the pasture represent variations in grass cover and species. **B.** Color infrared orthoimage generated from imagery collected by the same UAS filtered to the near infra-red of the same pasture taken on August 15, 2023. Differences in color across the pasture represent variations in grass cover and species. **C.** Overall percentage of frequency of forages in the islands shown in A and B.

Objective 4. The survey data indicates the participants are excited about the project, for gaining economic benefits, and in hopes of improved land management. Beyond themselves and the rangeland, they are also hopeful the project yields an outcome that will be beneficial and shared with the larger community in Utah such as increased environmental stewardship and enhancing plants and biodiversity. The ranchers who participated in the survey in Utah also stated several perceived potential challenges, largely centred around managing the smart foodscapes (SFS) within their existing ranching system, cost and time involved in comparison with future benefits, and external factors such as drought and weather change. Improved rangeland and optimistic perceptions about SFS are among the motivators for the ranchers for trying SFS in their operation in the future. Participants noted they still needed more information before trying SFS in their operation, particularly about the economics of making such transitions. Five key themes emerged, highlighting concerns about the time and resource intensity of SFS, management within existing operations, resistance to change, the need for more information, and the applicability of SFS to diverse landscapes. Economic considerations, water scarcity, and the reluctance to adopt new practices are key hurdles. These nuanced perspectives contribute valuable depth to the challenges identified in the survey, providing a comprehensive view of the complexities involved in the adoption of SFS in Utah's ranching community.

Discussion [Conclusions/Implications]

This project is filling the gap in knowledge about optimal synergistic/associative benefits for cattle and for the environment when animals graze a diversity of forage species with bioactive compounds. This research is devising diverse rangeland-based grazing systems aimed at optimizing ruminant production and health while reducing environmental impacts and enhancing biodiversity. This effort requires extensive analysis and synthesis of knowledge on the adaptability of plant species in the seeded islands, nutritional interactions among plant species, as well as a clear understanding of barriers to adoption. In turn, this new understanding is being communicated to producers and the public through demonstration plots and grazing schools. In summary, the transdisciplinary team assembled for this project is blending these variables into research, extension, and education programs to solve challenges to the sustainability of western rangelands. This project is improving natural resources quality through functional approaches that enhance livestock production and ecosystem diversity, while reducing the environmental footprint of beef production systems.

Key words: ecological condition, grazing, management interventions

Abstract

Opportunities for ecological restoration are rapidly increasing and require consistent tools to assess outcomes. In Australia, state and transition models have been used as a communication tool for land managers, to support ecosystem condition assessment on pastoral leases, and more recently, in the federal Nature Repair Market. A three-day expert elicitation workshop was conducted with government rangelands officers, pastoralists and restoration practitioners to develop a state and transition model for shrub-grass mulga in the WA rangelands. A reference and nine modified states were described, including four regenerating states. Modified states reflect key differences in ecosystem condition along gradients of degradation and regeneration. The key drivers of degradation are overgrazing and associated hydrological dysfunction as grazing impacts worsen, while restoration and regeneration are largely implemented through grazing management and (where soil surface condition has been degraded) hydrological interventions to increase water infiltration. Overall, the state and transition model provides a synthesised, coherent model of WA shrub-grass mulga ecology that is accessible to both experts and non-experts. The model is targeted at supporting the development of rangelands monitoring and condition standards, and the planning and implementation of appropriate management interventions for restoration, enabling land manager access to emerging nature markets.

Introduction

Rangelands represent 81% of the Australian continent (DCCEEW 2005). Their long-term use for livestock production, combined with feral herbivores and introduction of exotic species, have led to widespread decline in ecosystem condition (Landsberg *et al.* 2003). Despite this, the rangelands are often overlooked in ecological restoration initiatives in favour of more intensively used agricultural landscapes (WWF 2021). Opportunities for ecological restoration are rapidly increasing, driven by global and national drivers such as the Nature Positive Initiative, UN Decade on Restoration, Kunming Montreal Agreement, and Australia's Nature Repair Market. These initiatives require consistent tools for ecosystem assessment and projection of outcomes. One approach emerging to facilitate this in Australia is the widespread application of state and transition models (STMs), for example, to underpin the Nature Repair Market, to support ecosystem condition assessment on pastoral leases (Richards *et al.* 2023), and more generally as a communication tool for land managers (Westoby *et al.* 1989).

State and transition models describe the integrity of different states in an ecosystem (including a historic and/or best-available reference state and current modified states) and the drivers of transitions between states (Westoby *et al.* 1989; Bestelmeyer *et al.* 2017; Richards *et al.* 2020). The application of STMs to ecological restoration requires ecosystem specific models that focus on restoration pathways. Although the concept was developed in Australian rangelands, STMs have only been patchily implemented in Australia (Bestelmeyer et al. 2017), and restoration pathways are often weakly developed. In this paper, we used an expert elicitation process to develop a STM for Australia's shrub-grass Mulga woodlands in the extensive production zones of Western Australia (WA), with a special emphasis on restoration pathways.

Methods

The WA mulga shrublands occur across the semi-arid zone of central WA, averaging 250-350 mm rainfall per annum (DCCEEW 2005). Mulga shrublands are areas where mulga (*Acacia aneura* species complex) are dominant in the tree or tall shrub stratum. This study focused on 'shrub-grass mulga' within the Murchison and Gascoyne IBRA regions, and the Hamersley (Pilbara) and Tallering (Yalgoo) IBRA subregions (Figure 1). Shrub-grass mulga include the range of *A. aneura* complexes found across the '*Acacia hardpan*' and '*Wanderrie grass'* pasture types (Waddell *et al.* 2023). Much of the area has been grazed by domestic livestock since the late 19th Century, first predominantly by sheep and more recently by cattle. Livestock numbers peaked in the 1930s before severe drought, while accumulated land degradation has prevented stock numbers from recovering and has a lasting and ongoing impact on ecosystem condition. During this period, total grazing pressure was also affected by feral goats, rabbits and changes in kangaroo numbers, potentially promoted by dingo culling and provision of water (Landsberg *et al.* 2003).

The model-building process took place through a series of meetings and a three-day in-person workshop held in Perth (13-14 August, 2024) with 30 experts in rangelands ecology participating, supported by an extensive literature of peer-reviewed science publications and rangeland management reports (e.g. Waddell *et al.* 2023). Experts included government rangelands officers, ecologists, pastoralists and restoration practitioners. The purpose of the workshop was to develop a STM for shrub-grass mulga (including identifying restoration-specific dynamics and interventions), following the methodology of Richards *et al.* (2023). At the workshop, experts were provided with an overview of the Australian Ecosystem Models Framework (Richards *et al.* 2020), state and transition modelling and key ecological information about shrub-grass mulga, including pasture types and maps. Starting from a preliminary model developed by the core project team, experts were asked to describe the key states for a 'reference' model (highest ecological integrity). This process was then repeated for the modified states. Finally, experts were asked to describe plausible transitions (including drivers, timeframes and conditions for transitions to occur) including both degradation and restoration drivers and to identify potential indicators for monitoring ecological recovery. Following the workshop, the models underwent further development by the authors.

Results

A reference and nine modified states were described for the shrub-grass mulga STM, including four regenerating states (Figure 2).

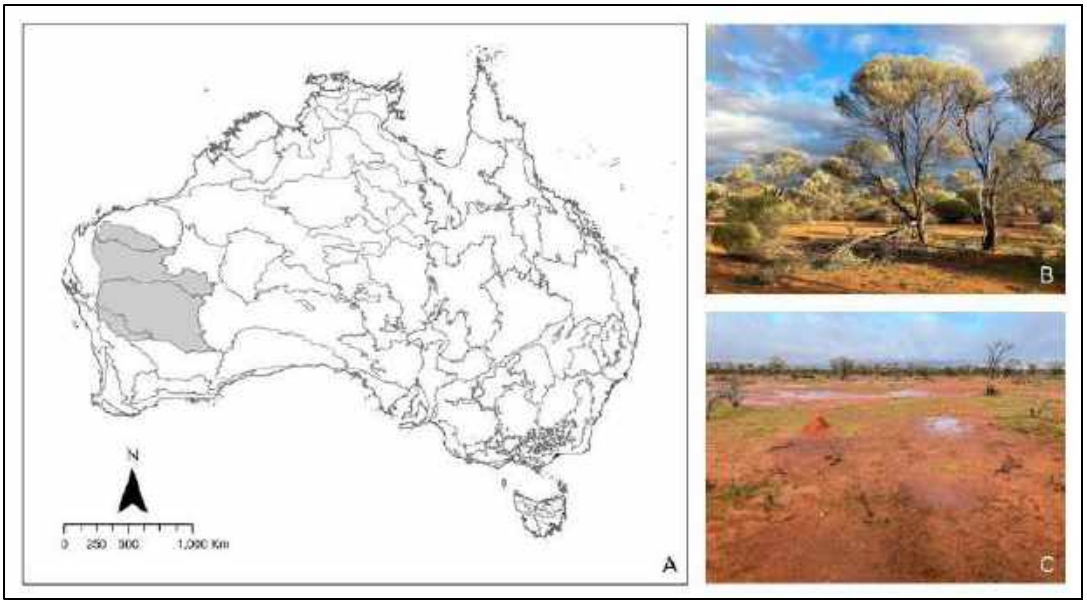

Figure 1. A) IBRA bioregion boundaries of Australia, showing the study region (grey shading): Murchison, Gascoyne, Hamersley and Tallering. Examples of mulga shrubland in B) fair, and C) collapsed condition. Source of IBRA data: DCCEEW (2023). Photo credits: S. Luxton.

Reference state: consists of a mosaic of mulga-dominated vegetation with grassy to shrubby understorey, with high grass richness and cover in more fertile parts of the landscape (including under trees). Uniform tree distribution may occur in the more productive environments, while banded or clustered groves become more pronounced in less productive areas. Reference fire regimes in shrub-grass mulga are inferred to be patchy and infrequent (>100 years based on mulga fire sensitivity, as it takes at least 50 years for mulga woodland to regain structure). Mulga is usually killed by even mild fire, and fire can lead to mulga shrublands moving temporarily to an expression where mulga are absent or sparse (i.e., grassland and/or sparse mulga expressions). The term ‘expression’ is used here in alignment with Richards et al. (2020) to recognise transient and reversible dynamics within states that differ substantially in one or more ecosystem attributes, relative to other expressions.

Modified states reflect key differences in ecosystem condition for biodiversity and pastoral value, along gradients of degradation and regeneration (Figure 2). The key drivers of degradation are overgrazing and associated hydrological dysfunction as grazing impacts worsen. Mulga harvesting, fire, drought and heatwaves, and isolated hail damage also contribute to ecosystem condition decline, leading to the removal and/or death of the mulga overstorey. As grazing pressures increase, the most palatable component of the flora declines (good to fair condition) and then disappears (fair-poor to poor condition). Less palatable grasses such as *Eriachne helmsii* become more common in grassy areas, and bare ground and exposed hardpan increase in cover. Unpalatable shrubs also increase in abundance (e.g., *Eremophila clarkei* and. *Acacia tetragonophylla*) and the overstorey shifts from healthy with good cover, to sparse with strong browse lines to collapsed (Figure 2). At the extreme, landscape hydrology becomes so dysfunctional that it can no longer support Mulga. This “collapsed” state (collapsed Mulga with collapsed understorey) is characterised by dying and dead trees and an understorey dominated by sparse annuals.

Recovering states with regenerating mulga overstorey (Figure 2, dashed boxes) were included to recognise the long timeframes for recovery of mulga overstoreys, including an approximately 50 year period from seedling establishment (defined at approximately 3 years since germination). Within this period, two distinct states of overstorey recovery we considered useful to recognise:0.3-2 m mulga and 2-3 m mulga. Given these long timeframes, understorey was considered to shift from collapsed to fair-poor and potentially to fair over this period, depending on management. The potential for the mulga understorey to recover to good condition was considered more likely over a 60-year timeframe, with the ongoing removal of grazing and natural recruitment.

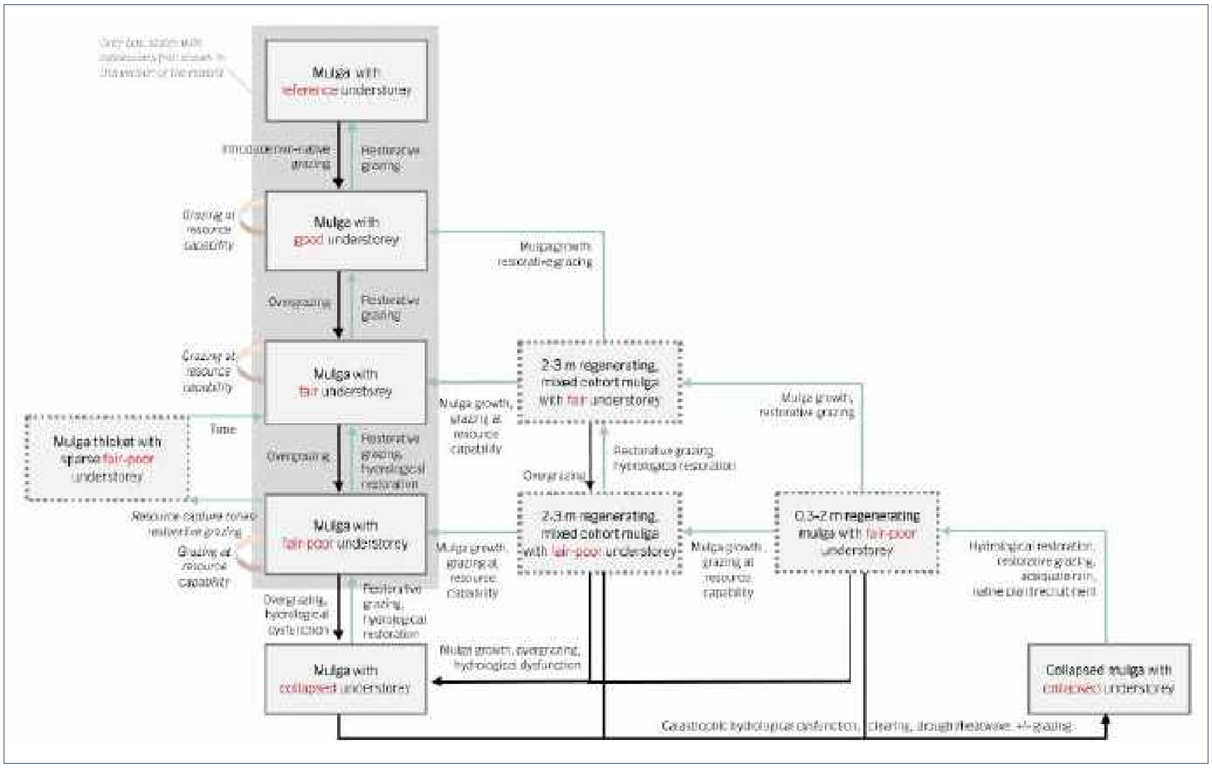

Figure 2. Simplified state and transition model for WA shrub-grass mulga showing degradation (black arrows) and restoration (teal arrows) transitions. Curved arrows (orange) indicate drivers that maintain a state in its current condition. Boxes with solid borders show reference and modified states, while boxes with dashed borders are regenerating (i.e. transitional) states. Text on arrows describe the drivers that are causing transitions between two states.

Restoration and regeneration in the mulga rangelands are largely implemented through grazing management and where soil surface condition has been degraded, through hydrological interventions to increase water infiltration. A range of restoration interventions were identified by the workshop participants, falling into two categories: tools to manage total grazing pressure (e.g., water point management, reduced dingo control, and rest-based grazing strategies), and tools to expedite recovery of landscape hydrology (e.g., water ponding with grader and bulldozer-built banks). Finally, a set of potential indicators for monitoring ecological recovery in the WA mulga rangelands were identified. They include indicators from Tongway and Hindley (2004) Landscape Functional Analysis procedure (e.g., soil cover, litter cover, cryptogam and perennial grass basal cover, and microtopography) and additional ecosystem attributes like the ratio of increaser:decreaser species, invertebrates and plant recruitment.

Discussion & Conclusions

The simplified STM presented above provides an expert-led synthesis of ecosystem dynamics for WA shrub-grass mulga (Figure 2). It integrates and organises information from experts and the current WA Department of Primary Industries and Regional Development (DPIRD) pasture condition assessment system (Waddell *et al.* 2023) to build a model of ecosystem function. This includes distilling the key drivers that either maintain the ecosystem in its current state, or lead to degradation or recovery - explicitly relating the intensity and/or duration of grazing pressure to different ecosystem condition states. While not presented here for brevity, each state includes a description of dominant species, and ground cover, hydrology and soil attributes alongside quantitative data where available. The STM provides a synthesised, coherent model of WA shrub-grass mulga ecology that is accessible to both experts and non-experts. General applications include supporting DPIRD to develop rangelands monitoring and condition standards. For restoration, the STM will assist with planning appropriate management interventions and their correct timing and scale. It also provides an estimate of recovery timeframes for regulatory purposes. These factors can support land managers to access emerging nature markets, including with the development of restoration plans and the measurement of outcomes using indicators.

Acknowledgements
The development of WA mulga STMs is a collaboration between CSIRO and the WA Department of Primary Industries and Regional Development. We would like to acknowledge the generous contribution of time and knowledge by the experts that participated in the three-day workshop. The restoration component of the study was supported by funding from the Valuing-Sustainability Future Science Platform. Ethics and privacy approvals obtained for this study are **075/23** and **084/24**.

Abstract

Rangelands cover more than half of the world's land area, providing vital support for around 500 million pastoralists and playing a key role in global livestock production and the livelihoods of pastoral communities. However, approximately half of these rangelands are degraded, negatively impacting both livestock production and pastoralist well-being. This underscores the urgent need for sustainable interventions to restore these ecosystems and improve global livestock production and pastoralist livelihoods. Transforming rangelands into more productive and climate-resilient systems, such as silvopasture (SPS) offer a promising solution. Research conducted by ICAR-IGFRI, Jhansi, India, in degraded semi-arid rangeland conditions of Bundelkhand converted to SPS via planting with native fodder trees, shrubs, and pasture species revealed significant findings. Under 12-years of evaluation, SPS was found to produce year-round fodder, with grasses yielding approximately 30–40 Mg ha^{-1} yr^{-1} green fodder and forage legumes yielding 10–12 Mg ha^{-1} yr^{-1} green fodder, supplying high-quality fodder from July to December. Trees produced 12–15 kg/tree of green top feed, and shrubs yielded around 7–8 kg/shrub of green top feed, ensuring supply of green fodder during lean months from December to June. These SPS systems were estimated to maintain 4–5 ACU ha^{-1} yr^{-1} and in addition to it sequestered 14.35 to 30.68 Mg C ha^{-1} in above and below-ground biomass, equivalent to 52.66 to 112.60 Mg ha^{-1} of atmospheric carbon dioxide equivalent storage. Furthermore, the SPS accumulated 31 to 48 Mg C ha^{-1} in the soil layer up to 60 cm and released around 38.31 to 81.92 Mg ha^{-1} of oxygen under various trees, shrubs, and grass/legumes combinations. The eco-restoration efficiency of these SPS systems was also found to be approximately 10 times greater than that of fallow land and also boosted TOC by 2–3 folds in soil over fallow land. The findings clearly demonstrate effectiveness of SPS as a climate-resilient approach for transforming degraded rangelands into profitable land use system ensuring diversified production and income generation to pastoral communities.

Introduction

Over half of the Earth's land area is occupied with the rangelands ecosystem which is very crucial for sustaining global livestock production and livelihoods of more than 500 million pastoralists. However, rangelands are currently facing degradation owing to overgrazing, developmental activities, fire, climate change etc. which is hampering livestock production, livelihood of pastoralists and ecosystem services negatively (UNCCD 2024). Thus, there is an urgent need to restore these ecosystems and sustain livestock production, pastoral livelihoods and ecosystem services in long run. Restoring degraded rangeland via transforming them to silvopasture systems offers a nature based solution to enhance productivity, carrying capacity, climate-resilience and ecosystem services in rangeland ecosystems. Considering this, a study for 12 years was conducted on silvopasture systems established on semi-arid central India's degraded landscapes with the aim to find out the fodder production potential, carrying capacity, carbon storage and oxygen release potential of SPS.

Methods

The silvopasture systems (SPS) consisting of indigenous high value fodder trees of semiarid zone *viz*. *Ficus infectoria*, *Morus alba*, *Acacia nilotica*, and a shrub *Leucaena leucocephala*; perennial grass species *Megathyrsus maximus* and *Chrysopogon fulvus* along with the perennial fodder legume *Stylosanthes seabrana* was studied for 12 years. The study receives average rainfall of 867 mm/annum; is prone to drought; and faces high temperature during summer (maximum: 47.4 °C in June); 4.1°C of minimum temperature in December with 60% mean annual relative humidity. Soil of the site is typical inceptisol having shallow depth, poor fertility, poor water holding capacity and low organic matter. Trees were planted at the spacing of 5 × 5 m; shrub at 5 m (row to row) × 2 m (plant to plant) and grasses as well as legumes at the spacing of 50 × 50 cm in rows between two trees/shrub rows.

The system was maintained in 4.32 ha area under rain-fed conditions and each treatment was replicated thrice under randomized complete block design. Green biomass yield of grasses and legume was measured by harvesting 1 × 1 m area at six random places in each plot and then calculated per hectare basis as Mg ha^{-1} (green fodder). For tree species, canopies were imposed to 30% pruning and shrub was pollarded at 1 m height and green pruned fodder biomass (leaves and soft twigs) per tree/shrub was recorded and was calculated per hectare basis as Mg ha^{-1}.

Total biomass carbon stock of trees, grasses and legume species under silvopasture system was calculated by adding their per hectare above ground biomass carbon (AGBC) and below ground biomass carbon (BGB) content. Above ground biomass carbon (AGBC) stock of trees/shrub, grasses and legume species was calculated by multiplying respective dry above ground biomass with a conversion factor of 0.50 and was expressed as Mg C ha^{-1} (IPCC 2006). Below ground biomass carbon (BGBC) stock of trees/shrub was calculated by multiplying AGBC with 0.26 (IPCC default value: IPCC 2006) and of grasses/legume by multiplying AGBC with their root: shoot ratio (*C. fulvus*: 0.59; *M. maximus*: 0.51; *S. seabrana*; 0.44). Finally total biomass carbon stock under each SPS was calculated by adding total biomass carbon stock of the respective trees/shrub with total biomass carbon stock of grasses/legume under each combination. This total carbon stock potential was converted to carbon-dioxide mitigation potential or carbon dioxide equivalent storage (CO_2e) (carbon stock × 3.67) as per IPCC (2006). Soil carbon stock in system was calculated as per the methodology of Ghosh et al. (2018) using fallow land as a reference. Total oxygen release in the system was calculated as Mg ha^{-1} using the formula (total oxygen release = total carbon stock (Mg ha^{-1}) × 32/12) (Nowak et al. 2007, Keerthika and Chavan 2022). Data were analyzed using analyses in online OPSTAT software, a statistical software package for agricultural research workers (Sheoran et al. 1998).

Results

Twelve years of evaluation of SPS revealed that the grass component have green fodder biomass production potential of around 30–40 Mg ha^{-1} yr^{-1} and forage legumes component have green fodder biomass production potential ranging between 10–12 Mg ha^{-1} yr^{-1}. Grasses and legume are capable of ensuring quality green fodder supply from July to December months. The trees have potential to produce 12–15 kg/tree of green top feed, and shrubs have potential to produce around 7–8 kg/shrub of green top feed during lean period from December to June months. These SPS can easily sustain 4–5 ACU (Adult Cattle Unit) ha^{-1} yr^{-1} along with ensuring round the year quality green fodder supply for livestock.

Biomass carbon storage studies revealed that these SPS have a huge capacity to store between 14.35 to 30.68 Mg C ha^{-1} in above and below-ground biomass under various trees/shrub and grasses/legume combinations. This carbon stored in biomass is equivalent to sequestration of 52.66 to 112.60 Mg ha^{-1} of CO_2e. In addition to this, these SPS can accumulate around 31 to 48 Mg C ha^{-1} in the 0-60 cm soil layer (Kumar et al. 2022). Further, the oxygen release capacity of these SPS is around 38.31 to 81.92 Mg ha^{-1} of oxygen under various trees, shrubs, and grass/legumes combinations. Moreover, these SPS have also been reported to have eco-restoration efficiency of approximately 10 times greater than that of fallow land and have capacity to enhance total organic carbon content by 2–3 times in soil over fallow land (Kumar et al. 2022).

Discussion

Thus, twelve years of evaluation of these SPS under semi-arid conditions at Jhansi, India demonstrated that establishing these systems on degraded landscapes including rangelands can sustain round the year quality fodder supply and thereby ensure pastoral livelihoods in the long run. Besides this, silvopasture systems can help in mitigating climate change via carbon storage in biomass, thus helping to offset the green house gases emission from grazing livestock. Huge oxygen release capacity of these SPS makes them viable option to help in oxygen shortage owing to rising pollution. Prioritizing the establishment of SPS on degraded rangelands, underutilized wastelands, permanent grasslands, and pastures across various agro–climatic regions in India as well as across globe can help to address the ongoing need for premium–quality fodder, enhance livestock productivity, bolster pastoral economies, and promote environmental sustainability.

The manure value chain in the North of Senegal. What social, economic and environmental sustainability?

Ferrari, S.[1]; Boubtana, S[2]

[1] Cirad, Umr Selmet; [2] Institut Agro Montpellier

Key words: manure; value chain; sustainability; pastoralists; rangelands

Abstract

In northern Senegal, due to the recent surge in the price of chemical inputs and the need to diversify the methods of fertilization and amendment of plots of agrobusinesses, manure has become in a few years the black gold of the region. The manure value chain is a relatively young sector; thus, it has not yet been the subject of research, despite its potential for expansion and impact on the territory. This study aims to assess its sustainability in social, economic and environmental terms, by considering and comparing different governance mechanisms in the value chain. Through semi-directive interviews with stakeholders all along the value chain, we identified three different sub-value chains based on what kind of stakeholder take the lead in manure processing. This can be made by specialized processors, manure producers (pastoralists), or consumers (agrobusinesses). The three sub-value chains have different impacts in terms of sustainability, depending mainly on job creation, the appropriation of added value, and rangeland degradation coming from manure grabbing. In any case, and depending on the governance mechanisms put in place to regulate the transactions, manure seems to have great potential for poverty reduction and crop soil fertilization. Indeed, it not only helps to strengthen the structure and fertility of soils; but also, its use for energy purposes allows more than 80 households to cook and reduce their expenses. Other rural households in the area use the sale, collection or transport of manure to supplement their income. Nonetheless, the manure value chain may have negative impact on family farming. Peasants struggle to obtain manure due to competition with manure collectors. Also, agribusinesses have diversified their manure supply strategies by switching to compost production, thus reducing the share of added value that other stakeholders – be they pastoralists or specialized processors – achieve to grab from the processing activity.

Introduction: a growing interest for manure

In northern Senegal, due to the recent surge in the price of chemical inputs and the need to diversify the methods of fertilizing and improving the plots cultivated by industrialists in the area, manure has become the region's black gold in just a few years. The methods of valorization are varied, as are the different supply chains (Belmin et al., 2022). Whether we are talking about raw manure or manure valorized into compost, the actors involved in the sector are multiple. The study area focuses on the Municipality of Mbane to the east of the Guiers Lake. This municipality has been prone, for several decades, to tensions over the resources it contains, due to its proximity to the lake. Irrigated and industrial agriculture is encroaching on pastoral territories and the removal of manure linked to the manure trade raises questions about the future of fertility in the bush and in pastures (Bourgoin et al. 2019).

This study aims to understand the value chain from the point of view of the actors who make it up, starting with the producers of manure, namely the livestock farmers. Whether from an economic, social or environmental point of view, this first study on the subject also aims to look further into the future, by understanding the sustainability of the governance mechanisms put in place within the value chain.

Methods: value chain approach and qualitative survey

The method used in this work is based on an analytical framework in terms of value chain (VC), that allows to understand the governance mechanisms and analyze the linkages, interdependences and unbalances between different stages of the life cycle of a product (Gereffi et al., 2005). Nowadays, literature has been focusing more and more on VC sustainability from multiple points of view. Several methods have been developed with this aim, such as FAO's Sustainability Assessment of Food and Agriculture Systems Guidelines (SAFA) (Scialabba, 2014), the Framework for Assessing the Sustainability of Natural Resource Management (MESMIS) (Lopez-Ridaura et al., 2002), the Value Chain Analysis for Development (VCA4D) (Fabre et al., 2012) and the Bellagio SusTainability Assessment and Measurement Principles (STAMP) (Pinter et al., 2011). Methods and studies mainly consider VC sustainability from a social, economic and environmental point of view (Duteurtre et al., 2020; Malak-Rawlikowska et al., 2019; Munasinghe et al., 2017; Muñoz López et al., 2020; Pacheco et al., 2017). Thus, starting for the existing frameworks, we built a set of social, economic and environmental indicators.

To collect information in the field, we conducted semi-directed interviews with all the actors involved in the manure value chain. These actors include: manure producers, i.e. local pastoralist households, who can be at the same time collectors and processors on a small scale; medium and large-scale collectors; manure processors into compost and/or digesta; consumers, i.e. agribusinesses. The study area is the Municipality of Mbane; however, the study also considers the regional scale, which represents the manure collection basin, and national, when the different national programs and policies come into play. The information collected was used to trace the value chain and its sub-chains (see governance mechanisms) and then compare them in terms of sustainability. By sustainability we mean the positive impact of the value chain on the area and we adopted the point of view of pastoralist households since the are the local inhabitants.

Results: a young and varied value chain

The manure value chain is relatively young. Before manure transporters set up, farmers and pastoralists used to exchange manure and crop residues, through the installation of animal pens as "common pastures" in the crop fields after the harvest. Some of these exchanges have persisted over time and the common pasture remains a widespread practice. Since the 2000's, as a result of the structural adjustment plans and several State programs to boost private investments, some huge agri-businesses were set up in the area, like the Indian *SenegIndia*. This led to the emergence of the first manure transporter, who travelled along the Senegal river valley to collect manure and sell it to those agri-businesses. From the 2010's, new methods of using manure were developed – that are composting and biomethanization – and some firms processing the manure into compost appeared. This raised awareness on the economic value of manure and led to its monetization. More manure transporters appeared, travelling up and down the silvopastoral area and collecting manure from pastoralist households, thus increasing the pressure on the resources of the rangelands. Nowadays, some agri-businesses are setting up internal compost platforms, so that they can buy raw manure and process it by themselves, thus bypassing intermediaries and contributing to a more vertical integration of the VC.

Three different sub-value chains

By identifying VC actors and activities, we distinguished three sub-VC (see Figure 1). The first one, that we call "producers-processors", involves pastoralist households who have set up small biomethanization platforms on their site, thank to loans granted by the *Building Successful Business* firm. This firm covers the installation costs and recover them over time through the supply of digesta (the by-products coming from processed manure). It then sells this digesta to the agri-businesses. Pastoralist households benefit from the payment of the digesta (once all the grants are recovered) and the production of biogas resulting from the process of biomethanization. The second sub-VC, called "consumers-processors", links households and agri-businesses via simple transporters. Indeed, the supplied agri-businesses have on-site compost platforms and prefer to buy cheaper raw manure. In this sub-VC, some household members (especially women and youth) collect manure from the bush and bring it to collection points that were previously agreed with transporters. In the third sub-VC, that we call "big processor", there is one firm (*Éléphant Vert*) which collect manure from pastoralist households and process it into compost to be sold to agri-businesses.

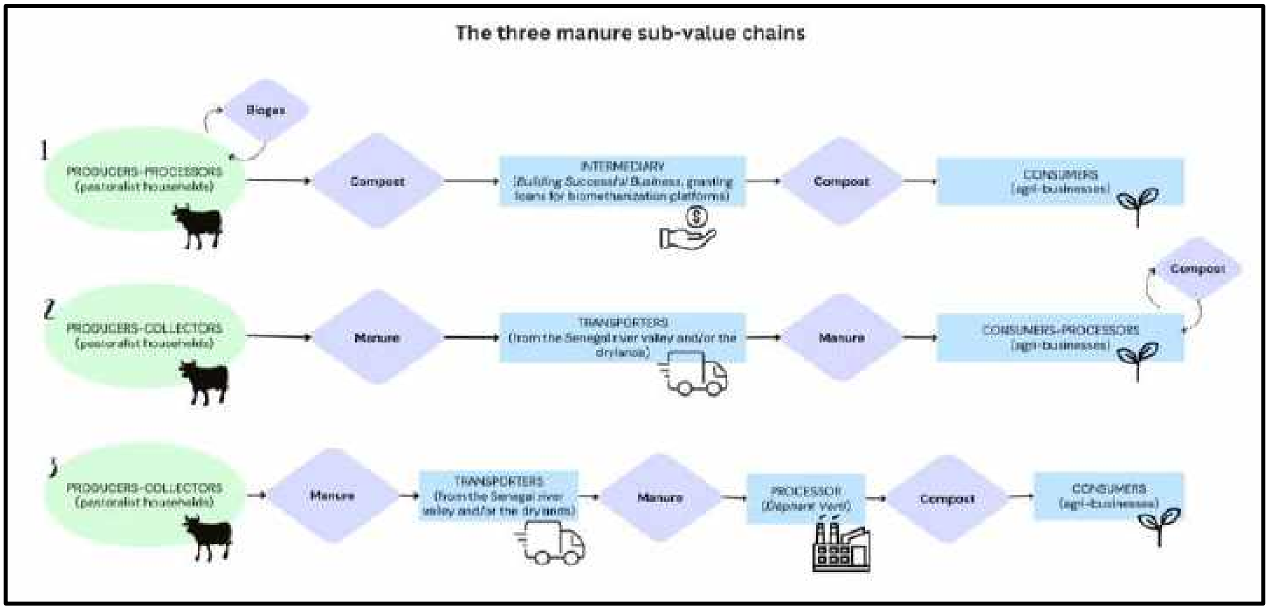

Figure 1 – The three manure sub-value chains: actors and products

The social, economic and environmental sustainability of the three sub-value chains

We compared the impacts of these three sub-VC on the area using a set of social, economic and environmental sustainability indicators. Based on the qualitative and quantitative data collected, we assigned plus (+) or minus (-) to each of the indicators according to the sub-VC, which made it possible to obtain an overall sustainability score for each of the sub-sectors (see Table 1).

Table 1 – Scores of social, economic and environmental sustainability of the three manure sub-value chains

Indicators	Sub-value chain 1 “producers-processors”	Sub-value chain 2 “consumers-processors”	Sub-value chain 3 “big processor”
Social			
Number of workers	+	++	++
Numer of jobs under contract	++	--	--
Access to accident coverage	+	--	-
Sub-total social sustainability	4	-2	-1
Economic			
Gross added value	+	0	++
Price payed to pastoralist households	++	--	-
% of added value to pastoralist households	++	+	-
Accessibility to a method of manure valorization	--	++	++
Sub-total economic sustainability	3	1	2
Environmental			
Distance traveled for collecting manure	++	--	-
Preferred collection area	++	-	0
Quantity of water used for composting	-	--	-
Sub-total environmental sustainability	3	-5	-2
Total	**10**	**-6**	**-1**

The scores show that it is sub-VC 1 (“producers-processors”) that presents the best social, economic and environmental impacts in favor of pastoralist households. Indeed, households are not only producers but also processors, thus grabbing a higher share of the added value coming from manure. This comes down to discussing the balance of power between actors: here households’ negotiating power is the strongest, which results in higher manure price. In sub-VC 2 (“consumers-processors”), it is the downstream actors who are favored in the balance of power: the monopolization of the processing activity, which resulted in the set-up of their own composting platform, leads to a vertical integration of processing and even transport intermediaries. Also, these giants are the sole buyers of some transporters and are therefore in an oligopoly position. In sub-VC 3 (“big processors”), the balance of power is exercised by the intermediaries, which creates a certain balance within the sub-VC. This sub-VC presents a high gross added value, however the percentage of added value which returns to pastoralist households is very low.

Discussion and conclusions: need to regulate the governance of the manure value chain

Through this work, we have noticed that the uses of raw manure are numerous and deployed on the study area. Whether through its uses in industrial or family agriculture, manure helps to strengthen the structure and fertility of soils. On the other hand, its use for energy purposes allows more than 80 households in the Northern zone to cook and supplement their income by selling processed manure. Other rural households in the zone use the sale, collection or transport of manure to supplement their income. At the same time, small crop producers struggle to obtain manure due to competition with manure collectors. We have also seen how agribusinesses have diversified their manure supply strategies by switching to compost production. This new production activity tends to threaten the activities of processors specializing in compost production in the zone. In general, it seems that interest in this black gold tends to increase in the coming years. Approaching the sector from a sustainability perspective would make it possible to perpetuate everyone's activities by changing practices.

In order to strengthen the basis for thinking about the sustainability of the manure sector and anticipate its potential impacts, other studies should be conducted to explore and deepen the three aspects of sustainability addressed – social, economic and environmental.

Fertile Bajra-Napier Hybrids of *Pennisetum* are a potential candidate for "de-ranging" Indian rangelands to other food production systems

Rana, M[1]; Shashikumara, P[1]; Singhal, RK[1]; Ahmed, S[1]; Kaushal, P[1]

Key words: de-ranging rangelands; Fertile BN Hybrid; *Pennisetum*; Seed producing

Abstract

Pennisetum Syn. *Cenchrus* is an important C4 genus of the family Poaceae, and comprises of more than 140 species. *P. glaucum* (L.) R. Br. (commonly known as Bajra or Pearl millet - diploid; 2n=2x=14) is one of the most important and well domesticated species utilized as a food and fodder crop in the arid and semi-arid tropics of the world. However, it is an annual crop, so Bajra needs to be grown every season/year. It also has less biomass than other species and so is not a suitable candidate for "de-ranging" rangelands. The *Pennisetum* genus contains other important species namely *P. purpureum* Schumach (commonly known as Napier or Elephant grass - allotetraploid; 2n=4x=28) widely known for its adaptability, high biomass, high tillering habit, fast regrowth capacity and tolerance to various biotic and abiotic stresses. However, it is cultivated vegetatively because of its very small seed size (1000-seed weight; 0.5-0.6 gm) along with high heterozygosity, poor seed setting and seed viability issues. It too is thus not a potential candidate for "de-ranging" rangelands. However, we have successfully developed an interspecific fertile cytotype (4x) of *P. glaucum* x *P. purpureum*, popularly known as fertile Bajra-Napier (BN) Hybrid by employing modified ploidy coupled with embryo rescue techniques. This fertile hybrid was selfed to produce a large F_2 population which was assessed for various agro-morphological and seed related traits, especially number of seeds per panicle (NSPP) and thousand-seed weight (TSW). All the F_2 lines are fertile and produce viable seeds in a differential pattern with NSPP varying between 13 and 550, and TSW from 0.62 to 4.77 gm. We now have fertile seed producing BN Hybrid in its F_6 generation through recurrent selfing. Having attributes of both *P. glaucum* (high palatability, grain type millet) and *P. purpureum* (wider adaptability, perenniality), these BN hybrids are a potential source of plant material for "de-ranging" rangelands to other food production systems as they can survive better under harsh climatic conditions and become an excellent source of food (grain type millet) and feed (green and dry biomass) to the pastoral communities depending on these rangelands.

Introduction

Bajra Napier (BN) hybrid, belongs to Pennisetum genus, is one of the most biomass producing plant with multiple benefits. It's a man-made hybrid popular among dairy farmers due to its high biomass and bioenergy potential. It is widely known as Bajra-Napier (BN) hybrid in India and King's grass & PMN hybrids worldwide (Dowling et al. 2014). It combines the unique features of both *P. glaucum* (Pearl millet; Bajra) and *P. purpureum* (Napier) species, which makes it more resilient to harsh environments with superior fodder quality (Burton 1944; Jauhar, 1981; Hanna et al. 1984). Since Napier (2n=4x=28) is an allotetraploid with A'A'BB genomes and Bajra is a diploid (2n=2x=14) species with AA genomes, the obtained interspecific BN hybrids with triploid genome AA'B

(2n=3x=21), is sterile due to irregular chromosomal segregation during meiosis and no fertile seed set (Techio et al. 2006). Several workers accomplished *in vitro* polyploidization with the perspective of restoring its fertility (Gildenhuys and Brix, 1964; Hanna, 1981; Hanna et al. 1984; Gonzalez and Hanna, 1984; Rajasekaran et al., 1986; Diz and Schank, 1993; Abreu et al. 2006; Barbosa et al. 2007; Campos et al. in 2009; Faleiro et al. 2016). However, till date no such seed producing hybrid is available and still these are propagated vegetatively either through rooted slips or stem cutting which is a major bottleneck and limitation in dissemination and widespread use of this highly potential fodder cum bioenergy crop. In India, ICAR-IGFRI being a premier research institute working on fodder crops, has developed the world's first fertile tetraploid seed producing BN hybrid (TBN-20-15) utilizing modified ploidy coupled with embryo rescue technique (Rana et al. 2023a,b). This fertile BN hybrid was subsequently selfed to produce F_2 population for studying traits segregation and again selfed for subsequent generations to make them homozygous and stable in F_6 generation. Overall objective of the study was to stabilize fertile Bajra Napier hybrid along with identification of potential candidates for "de-ranging" Indian rangelands to other food production systems.

Methods

Plant material and experimental site

Experimental material consisted of immortalized F_2 population of 250 individuals derived from an intraspecific cross of *P. glaucum* (Tetra Bajra) and *P. purpureum* (N27). For immortalized F_2 development, rooted slips from a single F_2 plant were harvested and transplanted through vegetative means. The immortalized F_2 were grown at Central Research Farm of ICAR-Indian Grassland and Fodder Research Institute, Jhansi, UP, India (latitude, 25.5114° N; longitude, 78.5337° E and 271 m altitude above sea level).

Morphological characterization of immortalized F_2 lines of Fertile Bajra Napier Hybrid

A population of 250 immortalized F_2 lines were characterized for 14 biomass related traits. The plants were grown in a single row having row to row distance of 1.5 meter and plant to plant distance of 1.0 meter in an augmented randomized complete block design (RCBD) in 8 blocks. The block-to-block distance was 2.0 meter. The recommended agronomic practices were followed during the cropping period. The list of traits recorded along with their description are as follows:

Trait	Trait wise description
AGRO-MORPHOLOGICAL TRAITS	
Plant Height (PH)	From ground level to the tip, 60 days after transplanting **(cm)**
Leaf length (LL)	Measured from ligule to tip of leaf (4th node from top on main tiller) at 60 days after transplanting **(cm)**
Leaf Width (LW)	Measured at the widest point of the leaf (4th node from top on main tiller) at 60 days after transplanting **(cm)**
No. of tillers per plant (NTPP)	No. of basal tillers were counted at 60 days after transplanting
Stem Thickness (ST)	The thickness of the stem (without leaf sheaths) between 3rd and 4th node from base at 60 days after transplanting **(mm)**
Inter Nodal Length (INL)	Distance between 3rd and 4th node from top at 60 days after transplanting **(cm)**
No. of Leaves Per Plant (NLPP)	Total number of leaves from base to panicle
Spike Length (SPL)	Calculated from the last leaf to the tip of the spike **(cm)**
Green Fodder Yield (GFY)	Recorded at 60 days after transplanting and continued for every 45 days interval upto 5 cuts for per plant basis **(kg)**
Dry Matter Yield (DMY)	Part/ fixed amount of green fodder harvested at 50% flowering, dried and weighed for per plant basis **(kg)**
SEED RELATED TRAITS	

No. of Seed Per Plant (NSPP)	Counted as total number of seeds produced from a plant from all their spikes **(Number)**
Seed Length (SL)	Measured with the help of measuring scale **(mm)**
Seed Breadth (SB)	Measured with the help of measuring scale **(mm)**
1000 seed weight (TSW)	Weight of 1000 seeds from each plant **(g)**

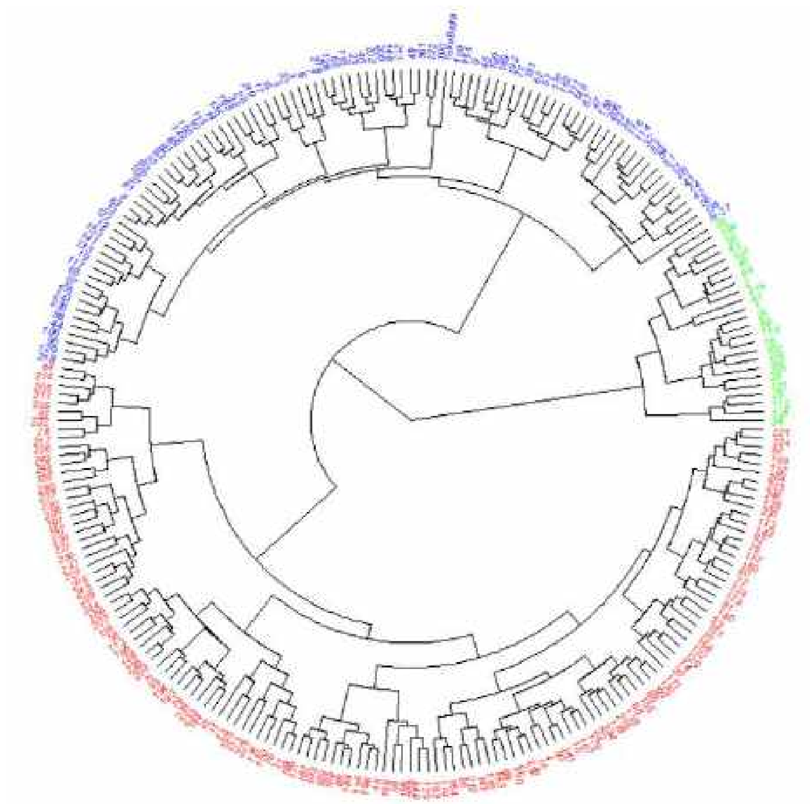
Statistical analysis

The experimental data collected in respect of various traits on 250 Fertile BN Hybrid immortalized F_2 lines along with two parental checks were compiled by taking the mean values of selected plants in each plot and subjected for statistical analysis. The data was statistically analyzed through R package and statistical software StatistiXL version 2.0.

Results and Discussion

Analysis of variance and trait correlations

Significant differences for all the 14 measured traits were observed among the population. Analysis of Variance (ANOVA) of 250 immortalized F_2 lines revealed significant differences for all the traits. In general, the mean values of F_2 lines were intermediate to that of parents. The values of F_2 lines outside the parental range were also observed for the traits under study. This indicated that the alleles that increased phenotypic values were dispersed in both parental lines, even when their values differed markedly, thus indicating transgressive segregation for all traits. The traits associated with biomass assessed in this study appeared to be quantitatively inherited as shown by the presence of nearly continuous distribution of mean phenotypic values of the traits. The ANOVA revealed the presence of non-significant differences between the blocks based on the parameters evaluated indicates that all the traits exhibiting variation (Gupta 2023). Mean for NSPP was 145.54 seeds which ranged from 11.50-546.00 seeds. Whereas, the maximum number of seed per plant was recorded for F_2-222 (550) and minimum number of seed per plant was recorded for F_2-135 (13). However, mean for TSW was 1.97 g which ranged from 0.59-10.31 g. Whereas, the maximum thousand seed weight was recorded for F_2-41 (4.77) and minimum thousand seed weight was recorded for F_2-133 (0.62 g).



Spherical dendrogram for 250 immortalized F2 lines of Fertile Bajra Napier Hybrid showing extent of variation present among the population

Range, mean and standard deviation for biomass related traits in Fertile Bajra Napier Hybrid

Trait	Mean	Std. Deviation	Range
PH	184.34	29.76	112.81-287.51
LL	40.81	6.51	22.06-66.03
LW	1.72	0.35	0.81-2.95
NTPP	7.24	2.53	2.83-17.03
ST	10.51	1.99	6.47-18.90
INL	12.32	1.73	7.81-20.30
NLPP	8.23	1.37	5.23-13.43
SPL	29.06	3.84	18.85-38.50
GFY	7.05	2.06	2.41-14.73
DMY	0.29	0.2	0.05-1.24
NSPP	145.54	73.72	11.50-546.00
SL	2.49	0.32	1.11-3.21
SB	1.28	0.24	0.82-2.25
TSW	1.97	0.92	0.59-10.31

Conclusions/Implications

Having attributes of both *P. glaucum* (high palatability, grain type millet) and *P. purpureum* (wider adaptability, perenniality), these fertile BN hybrids are a potential source of plant material for “de-ranging” rangelands to other food production systems as they can survive better under harsh climatic conditions and become an excellent source of food (grain type millet) and feed (green and dry biomass) to the pastoral communities depending on these rangelands.

Nurturing communities and ecosystems: the power of community engagement and silvopastoralism in drylands

Haddad, F; Chnais, E

Food and Agriculture Organization of the United Nations. fidaa.haddad@fao.org; eliechnais@gmail.com

Key words: arid and semi-arid regions, rangeland restoration, Al-Hima system, ecosystem services, socioeconomic benefits.

Abstract

This paper examines two case studies of ecosystem restoration in arid and semi-arid regions of the Near East and North Africa (NENA). The first study evaluates the economic benefits of rangeland restoration in Jordan using the traditional "Al-Hima" system, a community-based approach to sustainable grazing management. A cost-benefit analysis revealed that Al-Hima restoration increased forage production, groundwater infiltration, and carbon sequestration, resulting in a positive benefit-cost ratio of 2:1. The second study analyzes a silvopastoral restoration project in Tunisia, where the integration of trees and shrubs with livestock grazing led to increased biomass production, improved ground cover, and enhanced water use efficiency. This project also demonstrated socioeconomic benefits through reduced livestock feeding costs. Both case studies emphasize the importance of community engagement, sustainable land management practices, and the integration of ecological and socioeconomic considerations in successful ecosystem restoration initiatives.

Introduction

Drylands encompass a significant portion of the world's land area, supporting diverse ecosystems and communities such as rangelands and pastoralist communities. The Near East and North Africa (NENA) region is the world's driest area with Mediterranean zones, large swaths of arid and hyper-arid deserts, and a diverse array of ecosystems and barren deserts with almost no vegetation (UNCCD, 2024). Rangelands are a vital ecosystem, essential for the livelihoods of millions of people in the NENA region. They provide critical ecosystem services like livestock grazing, water regulation, and carbon sequestration. This region, however, faces substantial environmental challenges, including desertification and soil degradation, primarily driven by unsustainable land management practices and climate change. Rangelands are important socioeconomic drivers, e.g., Morocco's rangelands deliver 1.5 foraging units/year (FAO, 2022). This paper examines two case studies of ecosystem restoration in arid and semi-arid regions, highlighting the potential for ecological and socioeconomic benefits. The first explores rangeland restoration in Jordan using the traditional "Al-Hima" system, while the second analyses a silvopastoral restoration project in Tunisia.

1. **Jordan**

Methods
An ex-ante cost-benefit analysis was conducted to demonstrate the value of large-scale restoration through the Al-Hima[12] system implemented by the Ministry of Agriculture and IUCN in the Zarqa River of Jordan (Myint and Westerberg, 2014). The project involved establishing a community-managed Hima area, where sustainable grazing practices were implemented, and access to grazing resources was regulated.

The economic valuation study by Myint and Westerberg (2014) used a combination of valuation methods (stated preference, avoided cost, replacement cost, and market price), the study compared a baseline scenario (no change in land-use management) with a Hima restoration scenario (large-scale adoption of the Hima system). High-resolution remote sensing, GIS, and biophysical soil and water assessment tools were used to calibrate the impact of land-use changes on ecosystem services. The study compared two scenarios:

- Baseline Scenario: This scenario assumes no change in current land-use management schemes.

- Hima Restoration Scenario: This scenario assumes large-scale adoption of the Hima system where each plot of land was divided into four units, with three under the Hima system and one kept as open access. A rotational grazing system was adopted where one of the Hima units would be open for grazing in any given year and closed the year after.

Results
The study revealed significant economic benefits from Hima restoration. Firstly, by substantially increasing forage production and reducing the reliance on livestock feed purchases, the Hima system ***enhanced rangeland productivity***. Over a 25-year period, the total discounted value of avoided fodder costs was estimated at 23 million USD. The study concluded that in rangeland units with open-access (unrestricted grazing), productivity decreased by 2 kg of dry biomass per year. Another key benefit of Hima restoration was ***increased groundwater infiltration.*** GIS modelling showed that large-scale restoration through the Hima model led to an annual increase of 14% in the yield of the Zarqa River Basin and valued at approximately 19 million USD per year. Additionally, there was a notable ***reduction in sedimentation.*** The avoided cost of replacing lost storage capacity due to sedimentation and maintenance was estimated at 3.4 USD/m3. Finally, the value of ***sequestered carbon*** over 25 years in the restored rangeland was estimated at 30.5 USD/ha. The study also identified costs associated with Hima restoration, including implementation (community engagement, equipment purchase, surveillance infrastructure), management, and opportunity (forgone benefits of current grazing practices). Despite these costs, the net present value of Hima restoration was calculated at 17 million USD with a benefit-cost ratio of 2.1; meaning for every 1 USD invested in Hima restoration, pastoral communities would receive 2 USD in benefits.

2. Tunisia

A pilot project implemented by the FAO, the International Center for Agricultural Research in the Dry Areas,, and the Tunisian Forestry Directorate in the Sbaihia community, Tunisia, showcased the benefits of silvopastoralism (FAO and ICARDA, 2020) in enhancing community resilience to drought, increasing income, and restoring rangelands.

Methods
The project adopted a participatory/multidisciplinary approach, engaging the local community, national institutions, and researchers. A series of activities were implemented to demonstrate the feasibility of silvopastoralism and grazing with trees. One of the main interventions was the ***restoration using native species.***

---

[12] Traditional communal rangeland management practice in the Levant and the Arabian Peninsula dating back to ancient times that governs resource allocation through a community-based decision mechanism .

Drought-tolerant and palatable shrub and tree species (e.g., Opuntia ficus-indica), along with the native forage legume Hedysarum coronarium (sulla), were planted on slopes to reduce erosion and increase biomass and fodder availability. Another main intervention was the ***reseeding of degraded lands with sulla***, a native and highly palatable shrub, to evaluate its performance under different treatments. These treatments included assessing the adaptation of sulla to tillage under three conditions: sulla with soil scarification, scarification alone, and an untreated control. The primary field measurements for this evaluation were dry matter yield (DMY), rain use efficiency (RUE), and pastoral value (PV). Additionally, the effects of the interventions on biodiversity, biomass, and vegetation cover were examined using three treatment types: plots reseeded with sulla, plots protected from grazing for two years, and plots subjected to grazing. Finally, rotational grazing schemes were established to prevent overgrazing.

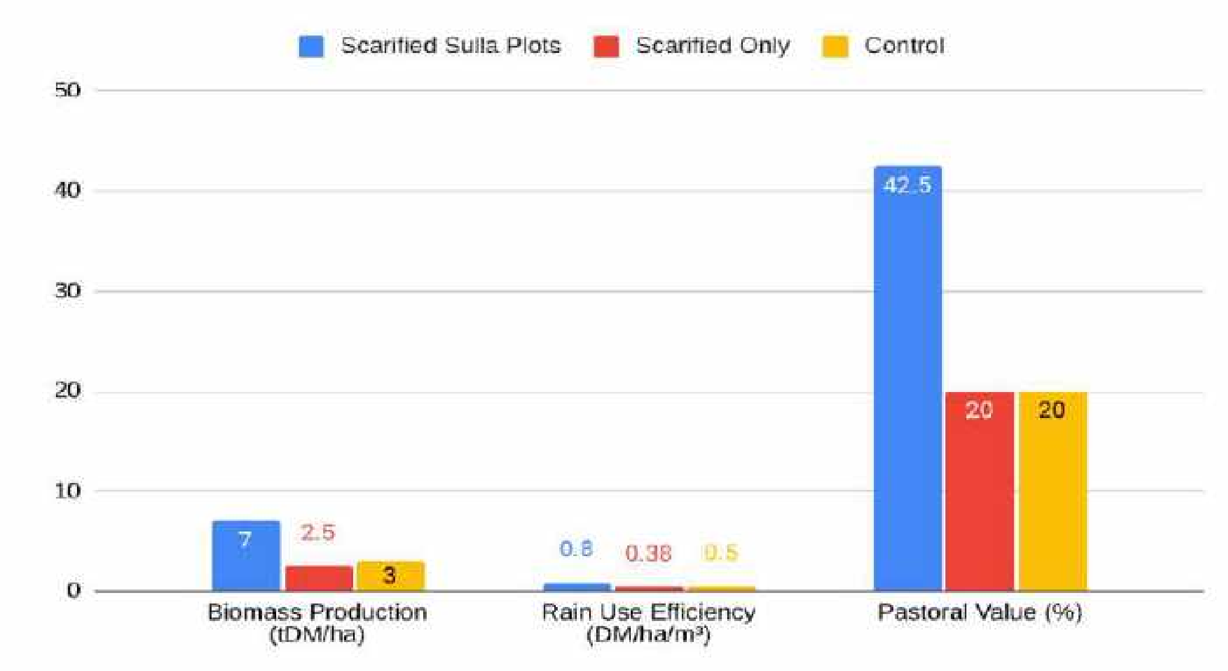
Results

The restoration activities were highly successful as illustrated in Table 1, with all species demonstrating good survival rates. *Ceratonia siliqua* had the lowest survival rate at 78 percent, while *Opuntia* had a 100 percent survival rate. The selected species provided local communities with increased fodder biomass for their livestock.

Table1: Focus on key results (the project had several experiments; in the paper we focused on the main ones listed below).

Experiment One	Scarified Sulla Plots	Scarified Only	Control
Biomass Production (tDM/ha)	7	2.5	3
Rain Use Efficiency (DM/ha/m³)	0.8	0.38	0.5
Pastoral Value (%)	42.5	20	20
Experiment Two	**Reseeded**	**Protected**	**Grazing**
Ground Cover (%)	100	100	59
Species Composition (No. of Species)	30	77	20
Biomass production (tDM/ha)	10	2.2	1

Figure 1 shows that the biomass production was significantly higher in the scarified sulla plots (>7 tDM/ha) than in the scarified (around 2.5 tDM/ha) and control plots (3 t DM/ha). RUE was also highest in the scarified sulla plots (0.8 DM/ha/m3), followed by control (0.5 DM/ha/m3) and scarified plots without sulla (0.38 DM/ha/m3). PV was 42.5 percent in the sulla plots and less than 20 percent for the other two. Reseeding with sulla and protecting the land from grazing both resulted in complete (100 percent) ground cover, primarily consisting of protective plant litter. In contrast as illustrated in Figure 2, land open to grazing had much sparser plant cover (only 59 percent), with most of the ground consisting of bare earth (69 percent). Protected rangelands had the richest species composition (77), followed by sulla reseeded plots (30) and grazed plots (20). In terms of biomass production, reseeded plots achieved the highest yield (10 tDM/ha), compared to protected plots (2.2 tDM/ha) and control plots (1 tDM/ha). The socioeconomic benefits of reseeding integrated with rotational grazing were also evident, as managed grazing reduced the cost of livestock feeding by about $0.13/day/head.



:

Figure 1 illustrate the findings from experiment 1 on restoration using native species

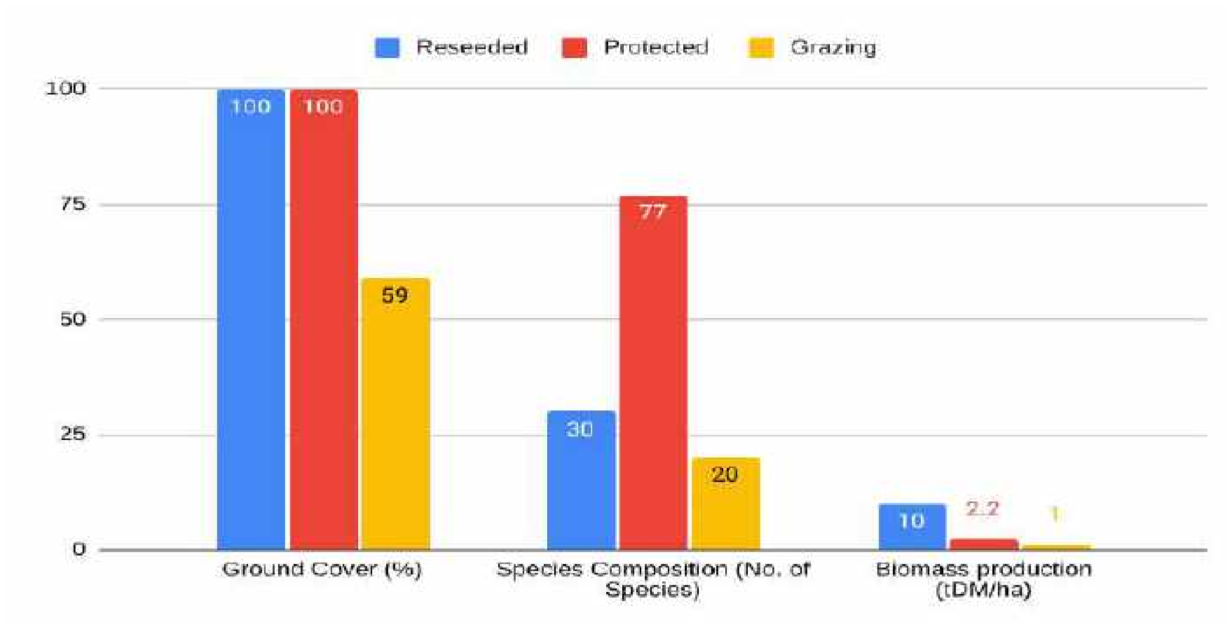


Figure 2 illustrate the findings from experiment 1 on reseeding of degraded lands with sulla

Discussion

Both the Jordanian and Tunisian projects highlight the importance of enhanced rangeland management and restoration through better community engagement and rangeland enrichment via reseeding and planting native species. These results highlight the critical role of reseeding with native species such as sulla in enhancing biomass production, protecting soil from erosion, and enhancing water infiltration and use efficiency. However, it is also important to consider potential drawbacks related to biodiversity. The importance of community involvement for the successful restoration of rangelands is gaining traction globally. For instance, in Kenya, the inclusion of Maasai tribes in rangeland management proved beneficial (Nyongesa et al., 2023). Similarly, research in Mongolia demonstrated the benefits of community inclusion in restoration and management (Ulambayar and Fernandez-Gimenez, 2019). Adopting a silvopastoral approach within the broader framework of landscape restoration can lead to more effective outcomes, delivering enhanced socioeconomic and environmental benefits (Vetter, 2020). The promising results from Tunisia reflect this paradigm shift, advocating for the integration of silvopastoralism in restoring both forests and rangelands.

Conclusion

The case studies from Jordan and Tunisia demonstrate the effectiveness of integrated approaches in combating land degradation and promoting sustainable land management. By combining ecological restoration with socioeconomic considerations and community engagement, these projects successfully enhanced ecosystem services, improved livelihoods, and built local capacity. Their success highlights the potential for replicating and scaling up similar initiatives in other regions facing desertification and land degradation.

Using the Australian tropical forages collection to develop new pasture legumes for Australian rangelands

Cox, KG[1]; Dayes, SA[1]; Bambling, LR[1]; Lemin, CD[1]

Key words: genetic resources, regeneration, Queensland

Abstract

Beef cattle production is the key agricultural industry in the seasonally-dry and moderate rainfall zones of northern Australia. Uncleared natural woodlands are the key feed resource in the northern monsoonal zone, whereas sown pastures dominate the moderate rainfall zone further south. In additional to seasonal feed gaps, beef producers face emerging challenges from declining land condition, a warming and more variable climate and pasture dieback associated with mealy bugs. Sown deep-rooted legumes (*Desmanthus, Leucaena, Macroptilium, Stylosanthes*) can improve productivity on these pastures by improving nitrogen cycling and improving diet quality. The development of tropical pasture cultivars in Australia is underpinned by the Australian Tropical Forages Collection (ATFC), now held in the Australian Pastures Genebank supported by state and federal governments and primary industry research and development corporations. The ATFC comprises ~10100 warm season grasses and 7300 legumes sourced from other tropical countries and within Australia over 40+ years, including over 4000 legumes from genera with potential in permanent or semi-permanent pastures in the dry zone. Comprehensive plant evaluation and release activities by federal and state governments saw the development of a network of on-property plant evaluation sites and the release of useful legume cultivars for key beef production land-types. However, some environments have no well-adapted pasture legumes. The evaluation site network has recently been exploited to develop legumes for frost-prone areas on light-textured soils and clay soils in the monsoonal zone. A Queensland government regeneration and characterisation program has also prioritised the development of legumes for the seasonally dry and moderate rainfall zones to enable access to seeds and plant traits to breeders both in Australia and overseas.

Challenges faced by north Australian beef producers to manage their feedbase

The production of beef cattle is the dominant primary industry and land use in northern Australia. The total Australian cattle herd was 29.9 M head in June 2023, with over half in the 'North' (44.5% in Queensland and 6.4% in the Northern Territory) (Meat and Livestock Australia 2024). Most of the lower rainfall sub-coastal and inland zones comprise native grasslands within extensive savannah woodlands (*Bothriochloa, Dichanthium, Heteropogon*) and naturally treeless (*Astrebla*) plains (Tothill and Gillies, 1992). The northern range of this zone is characterised by a 7-9 month dry-season, and businesses mostly target feeder steer and live export markets. Key profit drivers in the northern dry zone are breeder productivity (weaning and death rates) and heavier sale weights (McLean et al., 2014). Cattle production further south in central and southern Queensland and extending into northern New South Wales is supported by a greater proportion of sown tropical grass (*Cenchrus, Chloris*) pastures on previously cleared woodland. This is the principal area of beef production in northern Australia, where a more even rainfall distribution combined with many relatively fertile soils enables additional marketing options including backgrounding cattle for slaughter.

Limitations to cattle production on native and grass pastures relate to the amount and quality of feed produced over the year. In the northern monsoonal zone, the short summer growing period results in a few months of high quality feed before native grasses seed, senesce and become dormant. This presents the greatest challenge to graziers seeking to raise young cattle over the dry season and maintain reproductive females (Rolfe et al 2016). Management of the dry-season 'feed gap' is exacerbated by a significant decline in land condition on many soils within the seasonally dry zone (Shaw et al. 2024). This includes declines in useful perennial grasses and increases in herbaceous and woody weeds, resulting in decreased sustainable carrying capacities. The productivity of sown grass pastures is compromised by a decline in nitrogen cycling which limits grass growth. This limits both the productivity of the grazing business and the capacity to sequester carbon within the pasture system, an emerging consideration for beef producers. Peck et al. (2011) tested a range of methods to overcome this problem in southern and central Queensland and concluded the adoption of legumes as the best long-term economic solution. A recent challenge to graziers using sown grasses has been damage or death of plants due to 'pasture dieback', a condition associated with mealy bugs and which can significantly affect profitability at a beef business level (Buck et al. 2022). Legumes seem unaffected, so can potentially act as a temporary source of feed and competition for weeds while grass pastures recover. Finally, the omnipresent trend in increasing temperatures and recently measured increases in rainfall and temperature anomalies (CSIRO, 2024), all which can influence pasture growth in extensive grazing systems, presents a new and perhaps greatest challenge to beef graziers managing their feed-base.

Historical development of pasture legumes using the Australian Tropical Forages Collection (pre-2000s)

The use of legumes to lift the productivity of grass pastures through nitrogen fixation and improving the quality of the ruminant diet is well understood and has been applied for over 150 years throughout the world. The development of sown grass pastures in northern Australia was initiated by acclimatisation societies and individuals, including a small number of legumes (Clements and Henzell, 2010). However, it was not until federal and state programs from the 1960s, championed by the Commonwealth Scientific and Industrial Research Organisation (CSIRO), that development began *en masse*. Targeted plant collecting trips were conducted for promising taxa, with most legumes originating from south and central America. Seeds of up to 29,000 accessions were held by CSIRO in the Australian Tropical Forages Collection (ATFC) by the 1990s (Hacker et al, 1997). Refer to Smith *et al*. (2021) for a detailed description of the development of the ATFC.

Seed increase and plant evaluation programs were conducted by federal and state government agencies from the 1960s to the mid-1990s. Co-funded by the Beef Industry, the well-resourced and world-leading evaluation programs targeted a wide range of land-types with a particular focus on Queensland and the Northern Territory. Some involved assessment of a wide range of grasses and legumes across land types (Pengelley and Staples 1996), while others targeted legume development (Bishop and Hilder 2005; Clem and Jones 1996). Tropical pasture plant development was highly successful and supported by an effective pasture seed industry. By 1997 72 tropical grass and 65 tropical legume cultivars had been released in Australia, mostly in Queensland (Hacker et al., 1997), with approximately 220 t of legume seed (half stylos for light textured soils) being produced in Queensland (Walker and Weston 1990). There were still major gaps, however, particularly on clay soils where *Desmanthus* spp. and *Stylosanthes seabrana* cultivars had recently been developed (Walker et al. 1997).

Disinvestment in tropical sown pastures research from the 2000s saw the dismantling of research teams and reduction of the ATFC to priority taxa for development in Australia before transfer to the Queensland Government. The tropical forages database (www.tropicalforages.info) was developed to preserve 50 years of data and experience from international teams (Cook et al. 2020). A range of methods were used to progress promising international legume cultivars, but only one species (S. guianensis) has some application to the seasonally dry tropics (Cox 2014). A review of seed viability and stocks found approximately 25% of the collection required regeneration (Lawrence 2002). A Queensland Government regeneration program in north Queensland regenerated 380 grass and 609 legume accessions over 3.5 years from 2005 (Cox et al 2009).

New legume development using the Australian Pastures Genebank
Uncertainty over the funding of genetic resources to support forage and pasture development resulted in the formation of the Australian Pastures Genebank (APG) in 2014, an amalgamation of 11 genebanks from across the country (Hughes et al 2017). The APG includes ~10100 warm season grasses and ~7350 legumes selected by an expert panel as having potential for development in Australia. The regeneration program resumed in 2014. Priority was placed on legumes for seasonally dry areas, multi-purpose legumes and high-quality grasses (Cox and Dayes 2019). The new program better accounted for genetic diversity within accessions and 170 grasses and 318 legumes were regenerated over 4 years. Traits useful for plant breeders were measured and the data transferred to a public access website for breeders to assess and request seeds for evaluation (https://pir.sa.gov.au/research/services/australian_pastures_genebank).

A specialist panel review and meta-analysis of 40 years of plant evaluation data (persistence and herbage yield) covering 950 species across 567 sites collected was used to identify priorities for future sown pastures development in northern Australia (Bell et al. 2015). The analyses identified large potential for legume adoption broadly to improve beef productivity and profitability across northern Australia. Priority areas for investment in new legumes for the dry zone included legumes for sandy soils in cooler (frost prone) areas of the subtropics and legumes for clay (grey and black) soils in northern areas. The ATFC contains a wide range of legume taxa with application to the dry zones of the tropics and sub-tropics (Table 1). The accessions represent a wide range of growing environments so have the potential to address current and emerging needs.

The operation of the APG continued in 2023 under a new funding arrangement facilitated by Meat and Livestock Australia. The regeneration and characterisation program resumed, with a focus on legume taxa for the dry zones of northern Australia (Table 1). The 2024 regeneration included 40 *Desmanthus* accessions identified (APG website) by James Cook University (JCU) researchers. Expanded plots were grown to supply seed for evaluation over the next few years (in addition to the 5000 seeds for the APG), principally on heavy clay soils in the seasonally dry zone. This complements recent activities (Queensland Government/Tropical Dairy) in north Queensland to assess 17 *Vigna parkeri* APG accessions (entire collection) for herbage and seed production performance to improve supply to beef and dairy farmers (Gorman 2021), plus progressing the development of *Macroptilium atropurpureum, M. gracile* and *Centrosema brasilianum* accessions (one of each) considered by researchers to have application for the seasonally dry tropics (Cox *pers. comm.* 2024).

Table 1. Number of APG accessions of key taxa with potential in the dry zones of the tropics and subtropics. Genera marked with * included in the 2024 Queensland Government regeneration program.

Taxon	Habit	Number	Key genera (in decreasing order of accessions in APG)
Alysicarpus	Herbaceous	311	*vaginalis*, rugossus*, monilifer*
Centrosema	Herbaceous	928	*molle*, pascuorum*, brasilianum*, schottii, pubescens**
Chamaecrista	Herbaceous	155	*rotundifolia*
Clitoria	Herbaceous	157	*ternatea**
Desmanthus	Shrub	490	*virgatus*, leptophyllus+, bicornutus*, pernambucanus*, pubescens**
Leucaena	Small tree	627	*leucocephala*, hybrid
Macroptilium	Herbaceous	691	*atropurpureum*, lathyroides*, bracteatum*, gracile**
Stylosanthes	Shrub	2050	*scabra*, hamata*, guianensis*, viscosa*, seabrana*

Developing new cultivars using old plant evaluation sites

The historical plant evaluation activities saw the establishment of a large network of sites over some 40+ years, particularly in Queensland. Records of many of these sites, the plants sown and plant performance data are held in the Queensland Government QPastures database. Although active work at these sites has been long completed and fences removed, the sites provide an opportunity to identify material originally sourced from the ATFC which has persisted under grazing over decades. Used in combination with data from the various final reports and scientific papers and senior researcher experience, this can be used to identify new legumes where there are perceived shortages. Critically, this addresses the need for long term assessment of pasture plants to identify those persistent under long-term climate cycles (droughts), changes in soil fertility and the capacity to coexist with pasture grasses. Two recent examples include:

Desmanthus* spp. *for heavy clay soils in the tropics

Desmanthus is a diverse genus of sub-shrubs and shrubs, many originating from dry areas on clay soils in central and southern America, and a large collection was introduced from the 1950s (Smith et al, 2021). Plant evaluation included six sites established in the 1980s across the semi-arid, cracking clay region of north and western Queensland. JCU researchers revisited the sites and collected seeds of the best survivors at sites in the Mitchell Grass Downs Bioregion (Gardiner et al 2016). Queensland Government seed increase and further plant evaluation was conducted on these, and other, accessions from other abandoned sites (Gardiner et al. 2017). Further development and selection resulted in the release of 'Progardes', a blend of *D. bicornutus, D. leptophyllus* and *D. virgatus* accessions with a range of growth habits and flowering times. Another five lines were selected and similarly commercialised, including high-biomass types better suited to higher rainfall areas. There are currently reliable supplies of commercial seed and adoption has steadily increased since release.

Stylosanthes for cold (frost-prone) areas within the sub-tropics and tropics

Pasture legumes are sought to address pasture productivity decline associated with nitrogen rundown but there are no reliable options for light-textured soils in the frost-prone sub-tropics (Peck et al. 2011). Observations by pasture researchers that legumes, mostly stylos, were persisting in old evaluation sites in frost-prone areas of southern Queensland resulted in a Queensland Government-Beef Industry program to collect, test and release new stylo varieties (Peck et al. 2022). Forty lines, mostly *Stylosanthes scabra* and *S. seabrana*, were collected and seed increase conducted in north Queensland before field testing over 3 years against current cultivars on two soil types in three frost-prone districts. The capacity to produce commercially viable amounts of seeds and susceptibility to diseases of historical significance (*Colletotrichum* spp.) was assessed at this time. Three *S. seabrana* and two *S. scabra* lines which out-yielded commercial legume varieties were identified for release and seed increase undertaken to progress commercialisation. Although the stylo lines have immediate application to frost prone areas in the dry sub-tropics, stylo persistence is also poor on productive alluvial soils in the tropics where cold air is concentrated along waterways (Cox pers. comm. 2024), and the new stylos might therefore have broader application.

Conclusions

The legacy of fifty years of (mostly) government investment in sown pastures in northern Australia presents on-going opportunities to develop new pasture plants for the dryer zone of northern Australia. Decades-old plantings of thousands of accessions of pasture legumes across land types can yield useful cultivars but only while records are maintained and there are pasture researchers to exploit them. Similarly, the APG contains a wealth of useful germplasm collected from a wide range of environments for developing new pasture legumes to address current productivity gaps and respond to emerging needs such as climate adaptation. Current funding and regeneration and characterisation programs are focussed on ensuring these resources are accessible for plant breeding programs.

Acknowledgements

The authors wish to recognise the broader APG team of genetic resource specialists and the funding provided by the Australian and State Governments, Meat and Livestock Australia and other primary industries agencies.

Suitability of biomass from riparian areas of the Noteć River Valley for renewable energy production

Goliński, T[1]; Goliński, P[2]

[1]Poznań University of Life Sciences (PULS), Centre of Innovation and Technology Transfer, Wojska Polskiego 52, 60-627 Poznań, Poland; [2]PULS, Department of Grassland and Natural Landscape Sciences, Dojazd 11, 60-632 Poznań, Poland

Key words: biomass; IFBB technology; renewable energy; riparian areas; storable biofuel

Abstract

In the Wielkopolskie region (western-central Poland), the largest protected area under the Natura 2000 network is located along the Noteć River Valley. The problem of these riparian areas is lack of utilisation and abandonment of grass communities. The production of storable biofuel from harvested biomass using the IFBB (Integrated generation of solid Fuel and Biogas from Biomass) technology of such communities should be a suitable strategy for conservation and maintenance of semi-natural grassland in this region. Analysis of natural conditions and harvesting tests showed that the middle and lower parts of the Noteć River Valley – an area of 770–790 km^2 covering the 180 km-long and 2–13 km-wide floodplain – are the most appropriate areas for the implementation of the IFBB technology. The dominant species were *Phalaris arundinacea*, *Carex acutiformis* and *Carex gracilis*. The briquettes from this biomass after IFBB processing had a high heating value (on average 17.54 MJ/kg) and high level of combustion. The concentration of nitrogen in the biomass was very low, on average 1.23% in DM. The biomass after IFBB processing had a low level of ash in comparison to typical grassland used for forage purposes. The average yield of harvested grass communities was ca. 5 t DM/ha. A plant in Osów village was proposed for applying the IFBB technology in the Noteć River Valley. This was considered profitable with an Internal Rate of Return of 11.05%. Economies of scale apply since, with an IFBB plant of that size, investment costs disproportionately decrease relative to the large amount of output (grass briquettes, power). Cash flow calculations show a positive result from Year 1. With an annuity of 68.814 €/annum, the entrepreneurial risk of investing in a new technology such as IFBB might not be covered entirely. However, potentially reducing investment costs – e.g. by making use of regional investment subsidy programmes for investments in new renewable energy technologies – should make this investment attractive.

Introduction

Floodplain grass communities are frequently characterised as high-nature-value areas and, furthermore, fulfil various ecological services (Verhoeven & Setter 2010). Considering flood protection, they play an important role as riparian areas to reduce the risk of flooding by increasing the infiltration capacity. In addition, the year-round plant cover minimises soil erosion and loss of nutrients. However, the management of these grass- and/or rangeland sites is comparatively challenging due to particular soil conditions and, in many cases, the low nutritive value of the vegetation. Hence, these areas are becoming increasingly abandoned in many European regions. Many farmers managing these grass communities are looking to diversify their activities. Therefore, agri-environmental programmes have been established that are focused on protection of endangered bird species, habitats and natural sites. Farmers receive financial support for fulfilment of special management of these grass communities. One of the main conditions is late harvest time – typically in the middle of July or beginning of August. Because the harvested biomass can be used for bioenergy purposes, we evaluated the quantity and quality of the biomass from selected grass communities.

The aim of the study was to analyse the suitability of biomass from riparian areas of Noteć River Valley for renewable energy production in the form of storable biofuel using the IFBB technology.

Methods

The study was carried out in the years 2014–2016. We focused on the Noteć River Valley (Wielkopolska region, western-central Poland), where the largest riparian grass- and/or rangeland sites are located. This area contains high-nature-value riparian semi-natural grasslands and rangelands that are included in the European network Natura 2000 as areas of special bird and habitat protection. The area is a second largest peatland in Poland. It is a part of one of the most important ecological corridors between the Odra and Vistula Rivers and a refuge for wild birds at a European scale. For possible use of those areas towards their conservation and maintenance, we analysed the suitability of biomass for renewable energy production using the IFBB (Integrated generation of solid Fuel and Biogas from Biomass) technology (Wachendorf et al. 2009, Blumenstein et al. 2012). Preliminary analysis of natural conditions and harvesting tests showed that the best potential for the IFBB technology was in the middle and lower parts of the Noteć River Valley from Nakło nad Notecią town in the east to Santok village in the west, an area of 770–790 km^2 covering the 180 km-long and 2–13 km-wide floodplain. The botanical composition using the phytosociological method and the yield (quadrat frame method) of harvested biomass from 20 grass communities located in the valley were estimated and samples of biomass for chemical analyses were collected. In the samples, the crude protein (XP), NDF, ADF and ash (XA) using commonly accepted methods were determined. The economic calculations were based on the annuity method according to the guidelines for economy calculation systems for capital goods and plants (VDI 2002). The annuity displays the average yearly net operating result as calculated over the life span of 20 years. If the annuity is > 0, the investment is profitable. The Internal Rate of Return (IRR) is a key profitability measure. If the IRR exceeds the target rate, the investment is profitable.

Results

A majority of the vegetation was classified as *Arrhenatherion*, *Calthion* and *Filipendulion* as well as *Phragmition* and *Magnocaricion* alliances. The dominant species in the sward of the grass communities were *Phalaris arundinacea*, *Carex acutiformis* and *Carex gracilis*. The average yield of harvested grass communities was ca. 5 t DM/ha with huge deviation depending on site and type of plant vegetation. Therefore, the technical production potential for the IFBB technology was estimated to be on the level of 316.5 thousand tons.

In Table 1, the results (average values) of chemical composition of biomass after ensiling and after hydrothermal conditioning from raw materials harvested in the Noteć River Valley are presented. It turned out that the biomass after IFBB processing (press cake) had a low level of ash in comparison to typical grassland used for forage purposes. In particular, the most detrimental minerals Cl, K, N and S were leached into the press fluid resulting in concentrations in the press cake, which were for K and S close to wood from beech including bark. The concentration of nitrogen in the biomass was very low, on average 1.23% in DM. In general, the analysed biomass is a promising substrate for solid fuel (briquette or pellet) produced in the IFBB technology. The briquettes from this biomass after IFBB processing had a high heating value (on average 17.54 MJ/kg) and high level of combustion.

Table 1. Chemical composition of biomass before (silage) and after (press cake) hydrothermal conditioning from raw materials harvested in the Noteć River Valley

Parameter	Biomass silage	Press cake from IFBB	Difference (%)
Dry matter (%)	39.5	31.7	-20
Ash (g/kg DM)	72.2	35.4	-51
N (g/kg DM)	12.3	7.0	-43
Cl (g/kg DM)	6.1	0.8	-87
S (g/kg DM)	2.8	0.9	-68
K (g/kg DM)	8.2	1.1	-87
Ca (g/kg DM)	11.7	4.1	-65
Mg (g/kg DM)	2.4	0.5	-79
P (g/kg DM)	1.8	0.4	-78
Na (g/kg DM)	0.8	0.4	-50

A plant in Osów village (52°49′04″N 15°48′03″E) in the Drezdenko Commune was proposed by the research team for applying the IFBB technology in Noteć River Valley. Assuming that the average distance between the harvesting site and the potential plant location is 15 km, more than 1000 ha of extensive grassland and rangeland are available for bioenergy production. The average size of a riparian grass community plot is 100 ha per single site. Harvesting in many cases takes place after 1 August, due to agri-environmental schemes, mainly 'Protection of endangered bird species and natural habitats in Natura 2000 areas'. For this reason, harvesting is done once a year. There are possibilities to deliver biomass from Noteć River Valley located further away from the biogas plant by river transport, which could create an additional advantage concerning sustainability of a locally feasible processing mode.

After many analyses and much research, the best solution suitable for Noteć River Valley was identified as the IFBB technology as an add-on option (conventional biogas plant with IFBB module). The two main products of the IFBB technology are solid fuel (briquette or pellet) and electricity from biogas. Electricity from cogenerated biogas combustion is used to provide energy for the installation. Surpluses of electric energy could be sold through the Polish Power Grid Company, manager of the public grid network. Solid fuel could be offered in retail locally, but the main target market should be the wholesale one for large combined heat and power (CHP) operators.

Considering an average yield of 5 t DM/ha and an extensive grassland and rangeland area of 1000 ha, a total of 5000 t DM biomass are provided (or approximately 16,100 t FM, respectively), available for energy generation with the IFBB process. Based on the substrate available, a total of 4686 t (85% dry matter) of grass briquettes for heating purposes are produced per year. All of these can be sold, since the internal heat demand of 4,882,835 kWh_{therm} per annum is more than covered by the adjacent biogas plant, which provides approximately 6.3 Mio. kWh_{therm} per annum. In addition, about 1.35 Mio. kWh_{el} per annum electricity are generated from the IFBB press fluids by the CHP of the biogas plant. The proposed IFBB add-on plant in Osów can be considered profitable under the given circumstances. The IRR of 11.05% is close to being considered appropriate regarding the volume of investment. Here, economies of scale apply since, with an IFBB plant of that size, investment costs disproportionately decrease related to the large amount of output (grass briquettes, power). Cash flow calculations show a positive result from Year 1 on. With an annuity of 68,814 €/annum, the entrepreneurial risk of investing in a new technology such as IFBB might not be covered entirely. However, potentially reducing investment costs – e.g. by making use of regional investment subsidy programmes for investments in new renewable energy technologies – should make this investment attractive.

Discussion

Riparian areas of Noteć River Valley in western Poland are high-nature-value areas, mainly in terms of biodiversity. The semi-natural grasslands and rangelands are mostly covered by Natura 2000 network and included in agri-environmental schemes. In a previous study, we already indicated that, because of late cutting, the harvested biomass is fibre-rich and can be used for bioenergy production (Goliński & Goliński 2013). The study of Wachendorf et al. (2009) and other authors shows that the IFBB technology helps to improve the process of bioenergy conversion from riparian grassland biomass.

Biomass obtained from riparian areas of Noteć River Valley is a potential feedstock for renewable energy production. As reported by Hensgen et al. (2012), technical and environmental limitations exist in using this biomass for combustion, due to the presence of harmful elements. Converting biomass using the IFBB technology produces a press cake with lower concentrations of harmful elements and a press fluid usable for biogas generation. The concentration of harmful elements such as N, S, Cl and K in the solid fuel was significantly reduced compared to the original biomass silage. Comparatively high heating value (on average 17.54 MJ/kg) of received briquettes indicates a high performance of this material for combustion. This result was similar to the findings presented by Blumenstein et al. (2012) and Bühle et al. (2014).

The proposed IFBB add-on plant in Osów, Poland, can be considered profitable with an IRR of 11.05% under the given circumstances considered in the investment plan. Economies of scale apply, since with an IFBB plant of that size, investment costs disproportionately decrease relative to the large amount of output (grass briquettes, power). Cash flow calculations show a positive result from Year 1. It can be concluded that the production of storable biofuel from biomass harvested from riparian areas of Noteć River Valley using the IFBB technology should be a suitable strategy for conservation and maintenance of semi-natural grassland and/or rangeland in this region and other central European floodplains.

Acknowledgements

The authors would like to thank the EU Central Europe Programme for co-financing the study within the DanubeEnergy project (Grant Agreement 4CE561P3).

The territorial land planning in consideration of natural belt and zones' features

Shuurai, N[1]; Nayanbaatar, B[2]

[1] Mongolian Land Management Association NGO, sh.naranochir@gmail.com, [2]Key to Business Success NGO, nboloroo@gmail.com

Key words: natural belt; zone; territory; development plan

Abstract

The study shows possibilities to improve land quality by researching ways to implement proper policy of protecting and using land that is suitable to the features of the local land by carefully integrating it into the soum[13] development plan using participatory approach. The study looked into the causes of land degradation beyond the overuse of land carrying capacity, improper land use activities and climate change that has become evident in almost all the natural belt and zones in Mongolia.

The study includes nationwide collection of data on natural zones and belts and transferring it into a digital mapping system. The database provides key meanings of the factors affecting the natural zones, individual features and characteristics of each zone. The livelihood activities of the local people residing in these areas, and the use of the land, the types of existing land use of these areas were identified as well as forms of land uses in these zones and belts.

We discovered that the land is currently used for 130 different types purposes. It is evident that as the purpose and types of land use increase natural yield, service and capacity are decreasing. Thus, a rational plan that includes the appropriate type of land use in line with the features of the natural zones and belts in which it locates is necessary. By allowing the forms of land use in consideration of features of zones and belts of Mongolia, our study shows that we can keep the negative impacts of excess use of land, overgrazing, and degradation of the land at minimum as well as avoiding any reduction in the natural yields.

Introduction

In the recent years, the negative impact like degradation and overuse of land carrying capacity has become evident in almost all the natural belt and zones in Mongolia due to the improper activities of land use and climate change. Therefore, it is absolutely necessary to develop a rational plan suitable to the features of natural belt and zones in order to reduce the negative impact. As the purpose and types of land use increase natural yield, service and capacity are decreasing. Thus, it shows that it is possible to improve land quality by researching ways to implement proper policy of protecting and using land that is suitable to the features of the local land. One of such possible

---

[13] Small administrative unit of a province.

ways is developing soum development plan based on the local land resources and the participation of the local residents.

Methods

In the study we have use the methodology outlined in the soum territorial development plan, approved by the order no.A/139 (2019) of the Head of ALAGAC, which proposes a holistic approach that consists of 3 main parts: (i) analysis on the condition and resources of nature, (ii) socioeconomic data relevant to the whole territory of the soum and the types of land use, and (iii) creation of database and processing the data. A study on natural resources and conditions is done based on the 11 core data types, that is topographic, climatic, demographic, geological and hydrological data, and data on above-ground natural resources, flora and fauna, soil, and forestry. Socioeconomic study is conducted using data on demography, employment status, and information pertaining to economic growth like animal husbandry, agriculture, light industry, service industry, and mining.

Based on the principles of development, that is ecologically sustainable, environmentally friendly, economically beneficial, and various suitable solutions of land use types, the secondary information was compared with the primary data, which is collected from the total of 16,450 local residents representing different zones – 1,560 residents from high mountain zone, 878 from mountain taiga zone, 8,710 from forest steppe zone, 4,560 from steppe zone and 2,302 from Gobi zones.

Results

The tendency of dividing Mongolian territory into zones and belts was practiced by scholars in their respective field of studies, namely Yunatov.A.A, 1968; Tsegmid.Sh, 1962; Avaadorj.D, 2003; and Dash.B, 2005. They have divided the Mongolian territory into natural zones based on the characteristics: the amount of heat decreases due to the reduction of solar radiation that forms the climate in the Northern hemisphere; natural conditions are different in each latitude; temperature and humidity regimes; air flow characteristics; unique surface conditions; elevation; and composition of flora and fauna in differentiating one area from another.

Such natural zone information is collected nationwide and transferred into the digital mapping system. The database provides key meanings of the factors affecting the natural zones as well as the individual features and characteristics of each zone. We have determined the mapping of the natural zones based on these information and database.

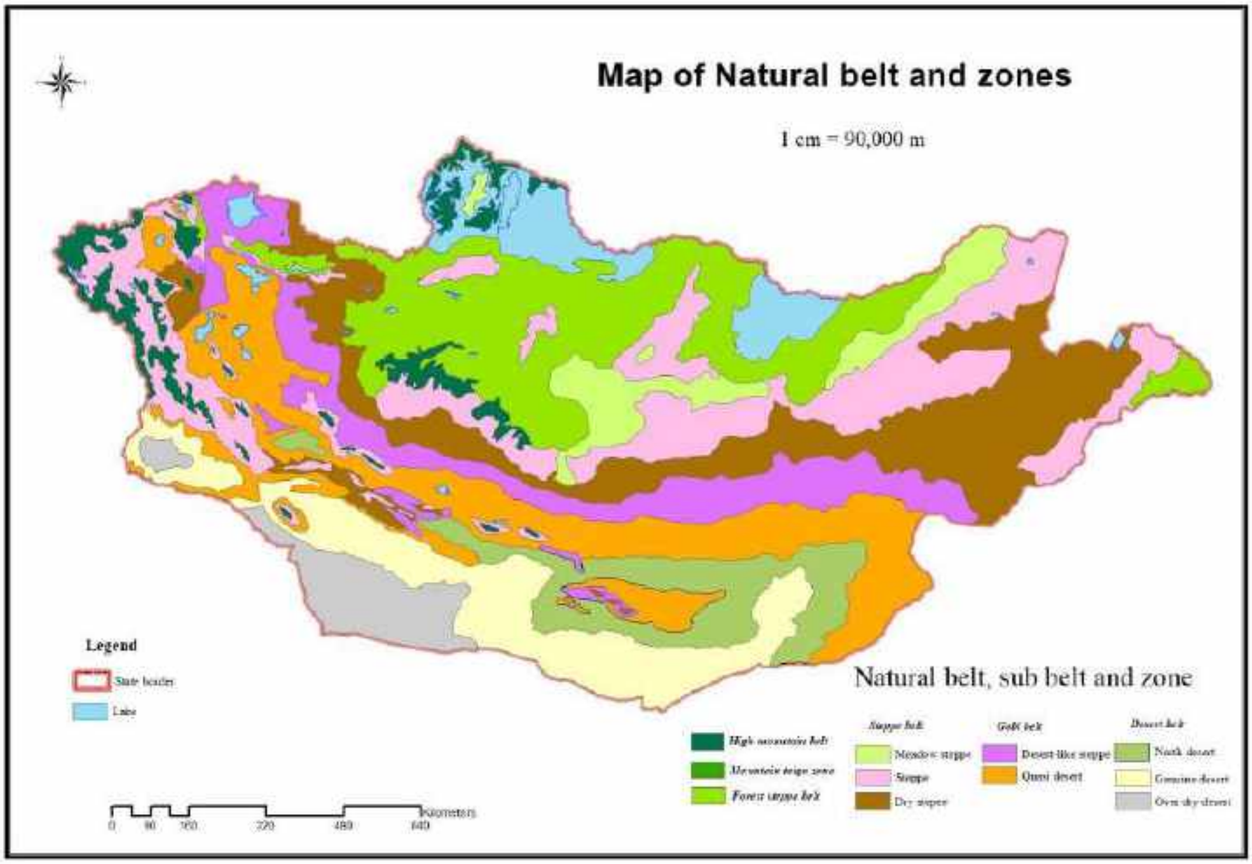

Figure 1. Map of Natural Belt and Zones of Mongolia

When mapping and determining the area covered by natural zones and belts in Mongolia with appropriate factors, high mountain belt that is 3.6 percent or 5,711,628.3 hectares that is the lowest, mountain taiga zone 4.3% or 6,725,556.7 ha, forest steppe 15.1% or 23,813,912.9 ha, and great steppe zone is 34.3% or 59,979,158.7 ha, the highest land covering zone. From that, 22.8% or 35,980,610.5 ha is Gobi zone, 19.0% or 30,082,860.1 ha is desert zone.

Upon determining the features of the area, livelihood activities of the local people residing in these areas, and the use of the land, the types of existing land use of these areas were identified as well as forms of land uses in these zones and belts.

According to the land use types in these zones, currently the land is used for 130 different types purposes. At minimum in the high mountain zones land is used for about 60 different purposes, and at maximum in the forest steppe zones the land is used for about 130 different types of purposes and are included in the territorial land use planning. The study result indicates that there are 60 types of land use in the desert zone, 70 in gobi zone, 80 in high mountain zone, 90 in mountain taiga zone, 110 in steppe zone, and 130 in forest steppe zone.

Therefore, when developing land use planning, first it needs to be defined in which zone the soum territory belongs to and determine the most appropriate uses suitable to the features of the zones and belts.

Discussion

There are total of 130 different forms of land use in the country. Soum development plan shall be developed based on the features of these belts and natural zones to which it belongs to. For example, Bayangol soum of Selenge province belongs to the forest steppe zone, and there are 20 planning measures included for the soum. Out of that, 5 forms of land protection measures, 8 forms of measures of proper land usage, 5 measures for proper usage and protection of land, and 2 measures of rehabilitation of land.

The result of the study shows that the forms of land use in consideration of features of zones and belts of Mongolia have the minimum impact on soum land use. The key here is to have appropriate development plan considering the natural zones and belts and the features of the area and implement it thoroughly.

Acknowledgements

We sincerely thank Dr. Sainbayar S. and Dr. Baasandorj Ya. For their guidance, and staff at Information Center of ALACAG and “Gazar Orchin” LLC, a professional organization of land administration for providing us the fundamental data for the study.

Transitioning meat goat production systems in western NSW - Learnings from the Going Ahead with Goats project

Smith, K[1]

[1] Western Local Land Services. Po Box 1048, Dubbo NSW 2830. kieran.smith@lls.nsw.gov.au

Key words: Meat Goats; Rangelands; Extension Program

Abstract

Historically, meat goats were considered a niche industry in Australia. However, goats are now viewed as a viable addition to livestock production systems in western New South Wales (NSW) rangelands, providing valuable income diversification. In the 2021-22 financial year, Australian goat exports were valued at $298.6 million, with 55% of these goats produced in western NSW. The sector saw rapid growth following an 83% goat carcass price rise between 2018 and 2019, prompting landholders to invest in infrastructure and genetics, transitioning from opportunistic harvesting of rangeland goats to managed production systems. The Going Ahead with Goats (GAWG) project commenced in 2022, facilitating this transition by providing targeted extension support to landholders and the broader industry. Through extensive consultation with industry, the project delivers a suite of research, development, and extension activities aimed at improving the sustainability, productivity and profitability of the meat goat industry. The GAWG project combines traditional extension methods of knowledge dissemination such as producer groups, workshops, and field days with innovative digital platforms, including podcasts, video case studies and online discussion groups. To create landholder engagement and enhance on-farm decision-making, the project integrates advanced agricultural technologies, including satellite tracking tags, GPS collars, and satellite pasture monitoring systems, capturing real-time data on managed goat production. Despite adoption barriers such as market volatility, limited infrastructure and capacity to implement controlled mating programs, as well as labour shortages, the GAWG project has seen significant industry engagement, with over 65 western NSW goat businesses involved. These businesses are either transitioning to managed goat production enterprises or have identified an intent to transition, as well as adopt recommended management practices including; resting pastures, rotational grazing, weaning, infrastructure improvements and genetic selection decisions. This transition to managed goat production enables landholders to include goats in their overall grazing strategy, incorporating landscape management objectives such as recruitment of perennial pasture species and the control of invasive native scrub.

Introduction

Unmanaged rangeland goats are a common feature of western NSW landscapes, originating from a combination of dairy and Angora goats that were either released or escaped from domestication and have survived in a wild state for decades (Hacker and Alemseged 2013). Approximately 90% of goats slaughtered annually in Australia are rangeland goats, with Australia being the largest exporter of goat meat globally, valued at $298.6 million in the 2021-22 financial year (Meat and Livestock Australia 2024). Historically, the sale of goats from rangeland properties has been seen as an opportunistic enterprise to supplement alternative income streams, relying on harvesting unmanaged goats through self-mustering trap yards as well as land-based and aerial mustering (Robertson et al. 2020). The opportunistic harvest of goats is heavily dependent on seasonal conditions, population density, sale price and processor capacity, leading to limited continuity of supply. The low labour requirements of goats in comparison to Merino sheep and the ability of goats to survive on diets containing high browse and shrub contents have seen goats increase in popularity in western NSW rangelands (Hacker and Alemseged 2013). However, inadequate fencing and handling infrastructure as well as a lack of knowledge and skills associated with goat management have limited the development of managed meat goat enterprises in NSW rangelands.

The Australian goat industry experienced a major transition following an 83% Over The Hook (OTH) carcass price rise from 2018 to 2019, with goat export carcass prices exceeding lamb and mutton prices from 2019 to 2022 (Meat and Livestock Australia 2024). Many producers used cashflow from goat sales to invest in fencing, watering point and yard infrastructure improvements enabling the management of goats, contributing to an estimated 82% increase in managed goat production from 2015-16 to 2020-21 (Meat and Livestock Australia 2023). Significant investments were also made in purchasing Boer and Kalahari meat goat genetics to improve growth rates. There is currently a spectrum of managed goat enterprises in western NSW, from producers who have one securely fenced goat paddock that is being used to hold goats and grow out smaller harvested goats, through to multiple paddocks and managed breeding programs (Robertson et al. 2020). The management of goats allows for greater control over total grazing pressure and more predictable turnover and forecasting of goat sales. The GAWG project, delivered by Western Local Land Services, is a three-year extension program that aims to support and upskill goat producers in western NSW (40% of the state, covering 314,500 km²) and enhance the goat industry more broadly through a suite of research, development and extension activities.

Extension Methodology

The methodology used for the GAWG project incorporates multiple extension activities in combination with the creation of accessible digital resources. Extension activities were designed to be regionally specific and use a whole-of-systems approach, delivering information that meets the needs and interests of producers and stakeholders in the western NSW rangelands. Prior to the delivery of educational activities, project staff undertook industry consultation activities including one-on-one interactions, group discussion sessions and a literature review to identify knowledge gaps and areas of interest for future research, development and adoption activities. Extension activities used in this project include the formation of two producer groups, promoting ongoing peer-to-peer learning, as well as workshops and field days for the broader goat industry. In addition, a core component of the extension project has included on-farm agricultural demonstrations and data collection including the use of Ceres Tags, GPS tracking collars, satellite pasture monitoring technologies and electronic eartags (eID tags) for individual animal data collection. Digital resource creation was another key aspect of the project, creating legacy documents in readily accessible formats including podcasts and video case studies.

Project Outcomes

Two goat producer groups comprising of 20 businesses were formed, which meet quarterly to partake in customised workshops and engage in peer-to-peer learning. These producers currently have managed goat enterprises or have identified an intent to transition to managed goat enterprises, and are seeking to improve their knowledge and skills, with approximately 150,000 goats managed across these businesses. Knowledge and experience levels vary in these groups, with a combination of producers who have been managing goats for less than 3 years, to over 25 years. Producer group members identified and ranked their top three categorised topics and areas of interest for further learning as part of the GAWG project. There was a mix of responses (Table 1) with the top three topics being labour saving technologies and goat infrastructure, genetic improvements and goat nutrition. This trend was also shared with wider industry when assessed by one-on-one producer consultations, provided direction for extension activities and resource creation.

Table 1. Ranking of topics of interest for further knowledge and skills development amongst western NSW goat producers.

Western NSW Goat industry producer topic of interest	Ranking (1 = Highest, 6 = Lowest)
Labour saving technologies and goat infrastructure	1
Genetic selection and improvement	2
Goat nutrition and supplementation	3
Marketing and sales	4
Pastures, species identification and feed budgeting	5
Goat health and disease	6

The GAWG project has also supported several industry research and data collection projects in collaboration with producer group members to further increase goat production data in western NSW including genetics, growth rates, grazing behaviours of goats and management factors affecting reproductive outcomes in goats. In addition to producer group events, broader goat production field days and workshops have been run across western NSW, including; goat infrastructure tours, along with workshops focusing on drone mustering, genetics, marketing options, as well as business, pasture and herd management. Ten podcast episodes were produced, focused on; genetic selection, target markets, pasture management, transition to managed goat production and weaning. Several episodes captured methods of "re-domesticating" harvested rangeland does to establish a core breeding herd, including segregating offspring by age and sex, and increased movement of animals to new paddocks and watering points to control grazing distribution and educate animals. Video case studies and resources created include goat infrastructure and trapping, as well as performing condition score and udder assessments on goats. To date, podcast episodes have received a total of 1600 downloads and two video case studies have received over 70000 views. There have been over 275 attendees at 20 events across western NSW, highlighting the significant ongoing interest in meat goat production in rangeland environments. Producers have identified an intent to change management practices including; spelling pastures, rotational grazing, weaning, infrastructure improvements, genetic selection decisions, as well as gastrointestinal worm control. Factors influencing intent to change and adoption of management practices presented at workshops include; inability to control mating regimes, limited infrastructure and number of goat paddocks and limited confidence in price and knowledge of target markets.

Project Challenges

Designing and delivering an extension program for an emerging industry transitioning to more managed production systems has highlighted several ongoing industry challenges. Some of these have been overcome through the project, with other challenges requiring further research and development. Firstly, extension programs for developed livestock industries including sheep, beef and dairy sectors focus on the adoption of demonstrated best management practices (BMPs) supported by relevant literature and research (Nelson and Robinson 2009; Bell 2019). While there are now several multi-year goat research projects being undertaken in the genetics, methane and reproduction space in Australia, there is currently very little scientific data on many aspects of goat production in Australian rangelands (Hacker and Alemseged 2013; Alemseged and Atkinson 2015). Hence, there is a reliance on information from international studies, often with exotic breeds in vastly different production systems. Thus, providing specific herd management advice based on peer reviewed literature and evaluated BMPs has been challenging in this extension project, with reliance on anecdotal evidence and small field trial data for some aspects of goat production in Australian rangelands. The depth of experience within the goat producer groups has been a major benefit, with early innovators and adopters of managed goat practices being able to share their experiences and observations of managed goats in rangeland environments. However, these experiences and observations sometimes contrast between producers. To create a complete BMP framework for goat production in Australian rangelands, further research and economic evaluations are needed for management practices such as weaning, sex separation, castration, as well as joining time and age to validate the anecdotal evidence of production benefits.

Controlled mating programs have been demonstrated as a key tool to optimise stocking rate, sales timing and manage pasture demands (Reeve and Sharkey 1980). A major limitation to the transition and further management of goats highlighted throughout the GAWG project is the difficulty in implementing controlled mating programs. This is due to multiple factors including the incursion of unmanaged rangeland goats disrupting breeding programs and slowing genetic progress, combined with maiden does reaching sexual maturity as young as 5 months of age, resulting in year-round kidding (Robertson et al. 2020). In addition, continuous mating adds challenges to timing of livestock movements and resting pastures, as well as performing business benchmarking due, to constantly changing livestock inventories and difficulties in calculating cost of production. Additional fencing improvements are needed for many properties to have greater livestock control.

A further challenge identified during the project was a lack of clarity on the ideal carcass specification requirements and the ideal breed composition, weight and sex of goats at a processor level, with limited feedback on goat consignments, consistent with the findings of Tesse et al (2023). Some producers were hesitant to introduce meat goat breeds into their managed rangeland goat herds due to reservations of potentially being penalised for breed composition in future, despite most processor carcass grids only including carcass weight as price differentiation criteria. Part of the GAWG project involved interviewing processors and sharing their ideal carcass specifications with producers to overcome this barrier to adoption. Further research is still needed into the effects of breed composition on yield and meat quality attributes.

Moreover, industry confidence associated with short term market price, which went from the highest average OTH price on record in Australia prior to the commencement of the project to the lowest average OTH price on record since prior to 2003 (Meat and Livestock Australia 2024b), was another challenge identified during the project. Several producers who had begun to transition from opportunistic harvest systems to managed goat production systems began to question their decisions and look into alternative livestock enterprises that suited existing infrastructure improvements such as Dorper sheep. Explaining the factors that influenced this price shift as well as delivering data on comparative long term average enterprise profitability was a key part of maintaining project engagement from these participants.

Learnings from the Going Ahead with Goats Project

There have been several key learnings through the delivery of the GAWG project. These include:

1. Drawing on the knowledge and experience of early adopters and innovators in the industry is critical when there is limited relevant production data. However, these experiences and observations can often be conflicting and require further validation through production research and economic evaluation.
2. Agricultural technologies and on-farm data collection has been a useful median for ongoing and real time engagement with project activities, as well as the delivery of extension messages.
3. There is the capacity for a number of new research projects in the goat industry, particularly in the nutrition space, as well as economic analysis of best practice goat management methods.
4. Short term market price is a limiter to extension program engagement and adoption of new practices for emerging industries. Many participants in the project began infrastructure improvements to run more managed goats during periods of high prices. These investments have slowed and stalled in some cases with participants focusing their time on alternative enterprises that are perceived to be more profitable or spending more time pursuing off-farm employment as an alternative income stream.
5. Barriers to adoption are enterprise specific. The transition from harvested goat production to managed goat production systems has its own unique set of challenges, with infrastructure limitations, labour and property scale remaining as ongoing challenges.

In summary, the GAWG project has identified and delivered a range of extension events to meet the needs of producers transitioning from harvested rangeland production systems to managed production systems, as well as assisted producers who are currently managing goats. This extension project has faced some unique industry challenges with several key learnings. On-ground, locally relevant information and data collection have enabled ongoing industry engagement. With further research, coupled with the experiences and knowledge of early adopters and innovators within the industry, the goat industry is set to continue to advance into the future.

Land systems, soils and vegetation survey of the southern Goldfields and Great Western Woodlands of Western Australia

Waddell, PA[1]; Galloway, PD[1]

[1] Department of Primary Industries and Regional Development;
Peter-Jon.Waddell@dpird.wa.gov.au; Paul.Galloway@dpird.wa.gov.au

Key words: Ecology; Erosion; Geomorphology; Habitat; Soil science; Nature markets

Abstract

The southern Goldfields region is ecologically significant as it closely aligns with the Great Western Woodlands– the world's largest intact Mediterranean-climate woodland ecosystem, dominated by *Eucalyptus* species and encompassing diverse mosaics of woodlands, mallee, shrubland, and grassland. The region has been subjected to significant ecological perturbations since European colonisation. Despite multiple land-use pressures on a unique environment, the region is the last large area in Western Australia (WA) to be comprehensively surveyed for biophysical resource condition to promote sustainable use.

This survey presents a comprehensive assessment of the biophysical environment of WA's southern Goldfields region, covering 151,753 km². The survey maps land systems and refines soil-landscape zones at 1:250,000 scale. The accompanying report describes the geomorphology, soils and vegetation, offering new insights and revisions to existing physiographic data.

The survey advances prior studies by refining mapping in alignment with WA and national standards, thereby providing consistency in data presentation and analysis across regional and national scales and complementing the Interim Biogeographic Regionalisation for Australia. This survey's integration into WA's hierarchical soil-landscape mapping system enables data describing the southern Goldfields to be interpreted within broader regional, statewide, and national contexts. Key contributions are:

- complete biophysical mapping that meets national and state standards
- a multidisciplinary explanation of key aspects of landscape evolution
- revised physiographic mapping that reveals patterns of erosion, deposition, and landscape maturity
- defining 101 land systems and 88 habitat types that summarise key elements of landform, geology, geomorphology, soil and vegetation characteristics.

The survey's hierarchical mapping framework and associated biophysical information provides comprehensive baseline data and improves understanding of the region's ecological processes and environmental pressures. It thus constitutes a valuable resource for agencies, companies, and individuals involved in strategic land-use planning,

land management, monitoring, conservation and rehabilitation, and the sustainable use of rangeland habitats across the southern Goldfields region.

Introduction

The southern Goldfields region of Western Australia (WA) is ecologically significant as it closely aligns with the Great Western Woodlands–the world's largest intact Mediterranean-climate woodland ecosystem, dominated by *Eucalyptus* species and encompassing diverse mosaics of woodlands, mallee, shrubland, and grassland (Watson et al. 2008). The vegetation evolved over the Cenozoic from rainforest with a significant proteaceous element to become increasingly scleromorphic and then xeromorphic as southern WA aridified from the Late Miocene to present. The long history of isolation in a progressively drying climate resulted in a megadiverse vegetation suite adapted to fire (Martin 2006).

Prior to European colonisation the area was populated by indigenous inhabitants who used fire in patchwork mosaics to secure food and manage the vegetation and landscapes. Since then, the region has been subjected to significant ecological perturbations. Early European settlers extracted sandalwood. Gold was discovered in the region in the 1890's. Mining required structural wood and firewood to power steam engines for transport and water supply. Extensive areas were temporarily cleared for wood production until the late 1960's, and the wood-fired steam power increased the incidence of wildfire from ember strike. The combination of both pressures changed structural characteristics of vegetation. Pastoralism, based initially on wool production and more recently on cattle and opportunistic harvesting of feral species, has skewed vegetation composition by the preferential grazing habits of introduced herbivores. This highly mineralised region has extensive open pit mining and mineral exploration, because it contains world class deposits of gold, nickel, lithium and iron ore. Both mining and pastoralism require access, and the vehicular track network affects overland water flows, affecting vegetation growth and altering geomorphic processes (Raiter et al. 2018).

Since the 1950's, rangeland areas of WA have been progressively surveyed to document resources, identify condition, and promote sustainable use. Despite multiple land-use pressures on a unique environment, this southern Goldfields region is the penultimate WA pastoral area to be surveyed, with the final area still pending.

This communication summarises key findings of a recently completed comprehensive assessment of the biophysical environment of the southern Goldfields region. The survey covers 151,753 km² and extends from latitude 30°00'S to 33°00'S and from longitude 118°00'E to 124°00'E. The survey maps the region's land systems and characterises the geomorphology, soils and vegetation, offering new insights and revisions to existing physiographic data. This survey, together with adjacent rangeland surveys (see 'Methods' chapter in Waddell and Galloway 2023), provides mapping at a land system scale of 1:250,000. Together these surveys describe the biophysical features of the Great Western Woodlands, except their southernmost extremities.

The bulletin and accompanying land systems maps provide a reference for land managers, advisers and administrators, the people most involved in planning and implementing land management practices. They also provide a baseline reference on landscape resources of the region. Land system surveys also enable recognition and location of land systems and landforms with particular habitat or conservation values for land use planning.

The survey advances prior studies by refining vegetation, soil, and physiographic mapping in alignment with WA and national standards, thereby providing consistency in data presentation and analysis across regional and national scales and complementing the Interim Biogeographic Regionalisation for Australia. This survey's integration into the State's hierarchical soil-landscape mapping system enables data describing the southern Goldfields to be interpreted within broader regional, statewide, and national contexts (Schoknecht et al 2004). A notable contribution is the revision of physiographic descriptions and soil-landscape zones of Tille (2006). These zones are based on geological and geomorphic criteria that reveal patterns of erosion, deposition, and landscape maturity, facilitating understanding of the region's evolution and environmental processes.

Accompanying the land system map is a report in two volumes. The climate chapter provides a synopsis of past and present climates with reference to the vegetation and geomorphic evolution. The landscape evolution chapter describes the region's geology, relevant tectonic processes and geomorphology, then discusses how the landforms formed and are distributed. These chapters contextualise evolution of landscape and vegetation.

The remaining chapters detail the region's biophysical features relating to soils, vegetation and ecology, and land systems. They provide information on landforms, soil and vegetation and, used in conjunction with the maps, provide a comprehensive description of biophysical resources. Included within these chapters are references to the impacts of certain management practices on the soils and vegetation, which are directed towards land managers to provide general information to assist in land use planning.

Methods

A detailed description of the methods and the types of data collected during the survey is provided in the 'Methods' chapter in Waddell and Galloway (2023).

Results

Our investigations at 606 inventory sites sampled during the survey and data from another 57 inventory sites from previous work in the area augmented knowledge of the region's biophysical features. Using this data, we were able to assimilate our comprehensive literature review of the geology (petrology and tectonics), geomorphology, and paleoclimate to interpret the landscape in an interdisciplinary manner.

At inventory sites we identified 69 WA Soil Groups and 88 habitat types. This great diversity reflects the complexity and diversity of the landscapes and vegetation associations present. The 88 habitat types, being combinations of landforms, soil types and plant communities, were clustered into 13 broader groups to aggregate ecologically similar types in topographically comparable positions. Forty-nine habitat types were described for the first time.

We identified 101 land systems in the survey area: 62 are described for the first time and the other 39 were previously described in adjacent surveys. The descriptions of some land systems identified in the adjacent rangeland surveys were modified to account for vegetation changes associated with the southerly transition from the Great Victoria Desert, Murchison, Nullarbor and Yalgoo bioregions into the Coolgardie bioregion.

We grouped the land systems into soil-landscape zones defined by geomorphologic or geological criteria, suitable for regional perspectives. Where existing physiographic mapping was inadequate (see discussion in Tille 2006), we identified and mapped 4 new zones and modified 6 others using the 'bottom-up' hierarchical approach of Schoknecht et al. (2004). We described zones using a combination of Pain et al. (2011), Tille (2006) and new information from this survey. Our new physiographic zones correlate to all prior mapping.

Discussion

The addition of the southern Goldfields rangeland survey to the long-running program of describing WA's rangeland biophysical features, with accompanying land system and zone mapping, has many benefits. Primarily this is through detailed information on landforms, soil and vegetation with references to the impacts of certain land use practices on the soils, surface hydrology and vegetation.

Implications for unified data

Inventory site data, land system maps and descriptions of their unmapped components meet State and National standards (and is the first WA Rangeland survey to do so). The data can be transferred to the publicly available

Australian National Soil Information System, and it therefore contributes to current and future research efforts to improve the resolution of soil, physiographic and other environmental mapping using 'big data'. A particularly promising research use for the baseline data generated during this survey is the estimation of carbon stocks for better modelling of global carbon storage to assess greenhouse induced climate cascades.

Adhering to standards enabled correlation of the southern Goldfields maps to soil-landscape maps of the adjoining agricultural region and existing mapping for the rest of WA (Schoknecht et al. 2004; Tille 2006). Such correlation simplifies the generation of derivative land suitability, land capability and land degradation maps that are seamless and comparable across WA's agricultural and southern Goldfields areas. These derivative products are invaluable for the land use and management implications described below.

The hierarchical nature and standardisation of our mapping permits application across scales for regional and property perspectives. The land zone mapping provides the spatial context for our explanations of regional scale geomorphic features that are present due to the interlinked evolutionary history of geology, paleoclimate, vegetation, weathering, erosion and deposition, and tectonic processes at continental, regional and local scales.

Implications for land use

Information curated enables government to administer pastoral leases and prevent or minimise land degradation. In WA, the Valuer General's Office sets pastoral lease annual rental charges based on potential carrying capacities. Carrying capacity figures derive from land system mapping in conjunction with habitat type analysis. Baseline information from rangeland survey informs rangeland assessment staff about the resource condition of habitats, enabling them to report on land degradation on pastoral leases and administer actions under the Soil and Land Conservation Act (1945; Waddell et al. 2023).

Some areas within the pastoral estate may be suited to alternative land uses. The ability to apply standard land evaluation criteria permits a regional scale 'first pass' mapping that allows a like-for-like comparison, even across diverse land uses. For example, maps could be created to identify areas best suited to sandalwood re-establishment, native animal re-introductions, or potential water supply.

Though assessments of vegetation condition are primarily relevant to a pastoral context, evaluation of community composition and physiognomy is determined in intact, ungrazed states (where possible), so they do not preclude condition assessment from an ecological context and are useful in determining (or as surrogates for determining) conservation value of vegetation and habitat (Pringle and Tinley 2001; Brandis 2008), state and transition modelling, status of carbon stocks and identifying the potential for carbon sequestration in rangeland landscapes (Williams et al. 2023).

The survey identified areas subjected to increased land use pressure. A pertinent example is the identification of stressed vegetation surrounding a gold roasting plant. Soil characterisation at an affected inventory site identified an acidic soil profile under vegetation that traditionally inhabits alkaline soil types. In other respects, the soil had morphological characteristics of the alkaline soil. The regional nature of the survey precluded a detailed study, but it identifies a potential problem and provides the basis for future research. Elsewhere a common observation was where tracks and fencelines disrupt natural water flow, altering moisture levels across the landscapes. Some areas pond water while others are water-starved and contribute to degradation.

The survey identified vegetation suites that indicate a change in state to lower production. Some locations affected by historic overgrazing have undergone a step-change in ecological state due to altered species composition, soil loss or both stressors combined. The introduction of non-native herbivores has resulted in some areas becoming degraded with reduced vegetation cover, decreased species diversity, encroachment by unpalatable perennial shrubs, weed proliferation and erosion. The condition of some habitats preferred for grazing has declined – the extent of palatable species has been reduced or totally lost. Survey data provides a baseline description of habitats facilitating the strategic location of monitoring sites (Pringle et al. 2006), restoration strategies (Tinley and Pringle 2014), and mapping supports the placement of infrastructure (e.g. tracks, fencing, watering points) and facilitate weed control programs to economically target priorities.

The inclusion of the land zone hierarchy in our southern Goldfields mapping provided a spatial context for our explanations of regional geomorphology, which enhanced our explanations of general distribution of ecological communities, plants and soil characteristics. These broad geomorphic patterns are responsible for environmental processes that exert a significant influence on all land uses. While the aspects of landscape evolution discussed are provided with evidence, where possible, the paucity of paleo-information means some ideas remain speculative and are ripe for further study. We hope the new information and mapping presented will assist and support management strategies and future management of the southern Goldfields region.

Key words: grazing management, trees and shrubs, carbon farming

Abstract

Australian rangelands are currently contributing to climate mitigation through nature-based solutions which include land management changes to facilitate forest [14]growth. Currently, >42 million ha of rangelands are being incentivised through the Australian Carbon Credit Unit Scheme to promote native woody forest regeneration through adoption of new grazing management regimes and removal of past suppression activities which have prevented the establishment of forest cover. These activities include the management of domestic animals by controlling the frequency, timing and intensity of grazing; control of feral animals; cessation of clearing activities; management of fire; and changes to infrastructure which allow enhanced control of grazing pressure to achieve native forest regeneration. The legitimacy of grazing management to influence woody regeneration in these arid and semi-arid environments has recently been challenged, sparking debate over the use of grazing management as a credible land management activity to underpin carbon market mechanisms.

Contrasting palatable *Acacia aneura* (mulga) and unpalatable *Eremophila sturtii* (turpentine) species are used to illustrate how grazing management activities can influence opportunities for recruitment, establishment and growth. Key biological features are identified for each species and used to guide reported or expected responses to grazing management interventions and influence the temporal patterns of carbon accumulation either directly or indirectly. The importance of initial landscape conditions to support the preconditions for grazing management to influence rates of regeneration as well as land management skills and capacity are identified as potentially important factors in determining successful use of grazing management in native forest regeneration.

Introduction

Australian rangelands are currently contributing to climate mitigation through land management which includes facilitation of forest[1] growth. Currently, >42 million ha of rangelands are being incentivised through the Australian

[14] An area of at least 0.2 hectares, dominated by trees and shrubs that are at least 2 m tall and provide crown cover of at least 20% (Australian Government 2024)

Carbon Credit Unit Scheme. Across many projects, these land managers are undertaking native forest regeneration by removing past forest suppression activities under the Human-induced Regeneration (HIR) method. Grazing land management activities include the management of domestic livestock to control the frequency, timing and intensity of grazing, control of feral animals, cessation of clearing activities, management of fire and changes to infrastructure which allow enhanced control of grazing pressure to achieve native forest regeneration.

Criticisms challenging the ability for grazing management to influence woody regeneration are largely based on studies of woody plant encroachment. Here, over-grazing which persistently removes grasses, alters the competitive balance between trees and grass in favour of woody regeneration. This has led to conclusions that reduction or removal of herbivores will not result in increased woody regeneration or an increase in tree/shrub growth (Eldridge and Sala 2023). However, a recent study employing remote sensing showed that long-term removal of livestock does increase woody biomass, albeit small changes over long timeframes (Retallack *et al.* 2024). Other remotely sensed approaches examining more adaptive grazing management strategies have shown variation in ground cover response across multiple sites (McDonald et al. 2024). This variation in findings highlights the complexities associated with heterogeneous rangeland landscapes and management histories which may lead to complex local site characteristics providing multiple barriers, and drivers, to regeneration.

There are few studies which have directly examined the influences of grazing management on woody regeneration in the context of carbon farming. However, the circumstances under which grazing management can influence patterns of woody regeneration has been recently reviewed (Waters et al. 2025). Here, the primary driver of regeneration was identified as climate, with grazing playing a moderating role enabling the potential regeneration set by rainfall to be achieved. Further, a set of broad, evidence-based grazing principles were developed within a framework that considered three critical stages in regeneration (site condition, germination and establishment and growth and mortality) based on the biological characteristics of widely studied, palatable woody species mulga (*Acacia aneura*). Here, we compare the responses of *A. aneura* (palatable) outlined in Waters et al. 2025) with *Eremophila sturtii* (unpalatable) and predict how grazing management regime (removal of all herbivores, manipulation of herbivore type and management of grazing intensity) may influence regeneration outcomes, outlining the importance of understanding local landscape and socio-economic factors which may modify responses.

Grazing management activities

Unpalatable species are unlikely to be directly influenced by grazing unless alternative feed is unavailable during extremely dry conditions or when safe carrying capacity of livestock and/or total grazing pressure is exceeded for a protracted period (Figure 1). For both palatable and unpalatable species, grazing management may also indirectly influence regeneration by moderating the incidence of fire which will be particularly important for fire sensitive species.

Figure 1. Impact on unpalatable species, *Acacia sclerosperma* with a clear browse line (left) and browse line and re-sprouting *Eremophila mitchelli* (right) following dry periods and little alternative forage availability.

Under all management regimes, and at all growth stages, maintaining adequate levels of ground cover is a central management outcome (Table 1). It is likely to be important in creating enhanced seedbed conditions for germination and establishment by improving landscape function through the retention of resources (water and nutrients). In the case of turpentine (*E. sturtii*), disturbance from grazing may enhance seedling germination (Robson 1995, Table 1). In the context of a carbon project, and given the infrequent rainfall driven opportunities to initiate a germination event, management aimed at enhancing seedbed would be most beneficial early in a HIR project, not just to set the trajectory of long-term plant community dynamics, but to ensure forest cover is achieved within 15 years of project commencement as required under the HIR method. Maintaining landscape function is also likely to be important later in the project to mitigate occurrence of hard setting, more compacted soils, reduced soil nutrient status/biological activities which have been reported under dense woody growth (e.g. Tighe et al. 2009). Improved landscape function can be achieved through total grazing pressure management which increases perennial ground cover through fencing and/or waterpoint management (Waters et al. 2019).

What is less clear is whether the removal of all herbivores (destocking) will constrain or increase rates of woody regeneration and result in the occurrence of high stem density cohorts. In this situation, the ability to manipulate competition between perennial grasses and seedling growth during germination and establishment phases will have been removed. A lack of herbivory may limit the capacity to achieve maximum attainable carbon carrying capacity by creating high stem density vegetation patches which may slow rates of woody biomass accumulation compared to more open vegetation (Waters et al. 2017, Table 1). Finally, a lack of herbivory may also reduce the ability to manage fuel loads and wildfires which can reduce or preserve accumulated biomass. While destocking may be an option for conservation land use, maintaining pastoral land use as well as the delivery of carbon sequestration has been shown to benefit pastoral enterprises and regional communities (Baumber et al. 2020). The management of herbivore type and grazing intensity will create opportunities for multi-use, integrated landscapes. Here, focusing on woody regeneration at the germination and establishment stages to incorporate periods of rest to promote recovery from grazing (controlling forage utilization and retaining ground cover) will enable seedlings to achieve heights above browse height (1.2 to 1.5 m) for palatable species.

Waters et al. (2025) outline the importance of land manager capacity (knowledge, skills and resources) in effective implementation of grazing management. However, local landscape features such as terrain will influence the stability of infrastructure in managing total grazing pressure. Drainage channels pose a risk of fence breaches in high rainfall events. Examples of alternative practices include fence alignment to high terrain, avoiding watercourses, adoption of low impact earth works, or minimising disruptions to natural movement to soil surface hydrology from linear surface disturbances such as vehicle tracks, fence line clearing and animal pads (Pringle 2019).

Conclusions

In areas where management can improve land condition for seedbed enhancement (soil condition and water availability), management has been shown to indirectly influence regeneration (Waters et al. 2025). In those areas, management aimed at improving site condition and germination appears critical for both palatable and unpalatable species. It is proposed that ensuring that pasture utilization does not negatively impact establishment and growth stages of unpalatable species during periods of protracted drought and limited forage availability is critical.

Table 1. The potential influence of different grazing regimes on site condition and growth stages of woody regeneration for palatable and unpalatable species. [1.] References within Waters et al. 2025.

Growth stage	Palatable species (mulga, *Acacia aneura*)[1.]	Unpalatable species (turpentine, *Eremophila sturtii*)
Removal of all herbivores		
Site condition	Maintain or improve levels of perennial ground cover and improve landscape function. Increased ground cover, soil water infiltration, nutrient retention potential to create ideal seedbed conditions.	Seedling germination enhanced with soil disturbance such as blade ploughing (Robson 1995); Maintain or improve levels of perennial ground cover and improve landscape function. Increased ground cover, soil water infiltration, nutrient retention potential to create ideal seedbed conditions.
Germination & Establishment	May remove the ability to manipulate competition between perennial grasses and seedling growth which may result in slower rates of regeneration.	Greater seedling emergence occurs under high shrub densities (approx. 32 to 6% higher) compared to open landscapes (Booth et al. 1996).
Growth & mortality	Areas of high stem density cohorts may limit capacity to achieve maximum attainable carbon carrying capacity.	Areas of high stem density cohorts may limit capacity to achieve maximum attainable carbon carrying capacity. (Waters et al. 2017).
Manipulation of herbivore type		
Site condition	Management of total grazing pressure plays a critical role in maintaining or restoring landscape function through maintaining or improvement of ground cover.	Management of total grazing pressure plays a critical role in maintaining or restoring landscape function through maintaining or improvement of ground cover (Hacker, McDonald 2021).
Germination & Establishment	Sheep, Dorpers and goats may prevent recruitment directly through herbivory. Under deteriorating seasonal conditions and lack of alternative available forage, kangaroos as well as sheep, Dorpers and goats may impact germination and recruitment. Cattle less likely to impact regenerating Mulga.	Sheep and goats will not reduce establishment unless extremely heavy goat grazing pressure (Harrington 1979). Under protracted drought, when alternative forage unavailable Dorpers and goats may impact seedling establishment.
Growth & mortality	Sheep, Dorpers and goats can prevent growth (density and height). Cattle are less likely to impact regenerating mulga, Kangaroos little impact on mature trees.	Sheep, Dorpers, goats and cattle are unlikely to impact growth (density and height) of mature turpentine unless under extreme grazing pressure by goats or when feed demand outweighs feed supply (little alternative available forage) during periods of drought.
Managing grazing intensity		
Site condition	Management of total grazing pressure plays a critical role in maintaining or restoring landscape function through maintaining or improvement of ground cover.	Management of total grazing pressure plays a critical role in maintaining or restoring landscape function through maintaining or improvement of ground cover (Hacker, McDonald 2021)
Germination & Establishment	Direct impact of herbivory from sheep, Dorpers and goats may result in higher levels of seedling mortality. Overgrazing will reduce seedling growth rates and expose cohorts to a greater susceptibility to drought, potentially amplifying mortality events.	Regulate the level of competition between perennial grasses and seedlings in the first summer after germination to increase regeneration (Waters et al. 2025)
Growth & mortality	Direct impact of herbivory from cattle, sheep, Dorpers and goats may result in reducing plant height as well as removal of branches above browse height, lowering potential carbon accumulation. This may be amplified when alternative forage unavailable.	Sheep, Dorpers, goats and cattle are very unlikely to directly impact growth (density and height) of mature Turpentine unless under extreme grazing pressure by goats or when feed demand outweighs feed supply (little alternative available forage) during periods of drought.

HOSTED SESSIONS

Strategies and tools to navigate global change in non-equilibrium rangelands

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Non-equilibrium then and now

Sayre, NF[1]; Bestelmeyer, BT[2]

[1] Department of Geography, University of California, Berkeley, 508 McCone Hall, Berkeley CA 94705 USA; nsayre@berkeley.edu; [2] USDA-ARS-Jornada Experimental Range, MSC3JER, Box 30003, New Mexico State University, Las Cruces, NM; Brandon.Bestelmeyer@usda.gov

Key words: climate change, equilibrium, precision ranching, state-and-transition models

Abstract

Non-equilibrium is a fundamental characteristic of rangelands and pastoralism. The non-equilibrium (NE) paradigm emerged primarily in response to problems in management, especially in the context of pastoral development. Aiming their arguments at the World Bank and other multilateral organizations, anthropologists and development professionals demonstrated that the use of equilibrium ideas – such as climax to evaluate range conditions, carrying capacities to set stocking rates, and succession to remedy degradation – had backfired repeatedly. Such shortcomings were familiar in the scientific community, but an alternative paradigm remained elusive until after the 2nd International Rangeland Congress in Adelaide in 1984. Following seminal publications on the topic (Ellis and Swift 1988; Westoby et al. 1989; Behnke et al. 1993), the NE paradigm was widely analyzed, debated, and largely adopted by global scholars, especially for drier, more variable rangelands (Illius and O'Connor 1999; Vetter 2005). Tools reflecting NE, such as state-and-transition models and satellite-based assessments of rangeland productivity, are now widely produced (Allred et al. 2022, Bestelmeyer et al. 2017). Widespread acceptance among scientists has not translated readily into the practices of pastoral development, however. In this paper we reflect on how the NE paradigm has shaped global rangeland management and governance over the past 30 years. Are rangeland systems better managed because of it? What are the prospects for the NE paradigm to support adaptation to global change in rangelands in the years ahead? We argue that while debates about NE concepts have faded into the background, the implications of NE are more important than ever.

Introduction: Is rangeland management better because of NE concepts?

In contrast to the equilibrium paradigm, the NE paradigm posited that 1) rangeland condition is determined primarily by abiotic drivers and non-linear (or threshold) responses to those drivers, 2) rangelands exist as alternative stable states best described by state-and-transition models rather than simple succession models, and 3) the high degree of spatial and interannual variability in rangelands requires careful attention to pastoralist mobility and flexibility, alongside governance structures that ensure access to land at needed spatial extents (Scoones 1995). NE characteristics are especially relevant to the most arid, variable, and extensive rangelands (von Wehrden et al. 2012) which have been least likely to be converted to cropland or intensified pasture systems.

While many organizations now advocate for pastoralism and mobility to conserve imperiled rangelands, and technology is providing increasingly effective solutions for perceiving and reacting to NE rangeland behavior, policies continue to limit pastoralists' ability to implement those solutions. Pejorative narratives about pastoralism and limited societal valuation of extensive rangelands continue to drive policy prescriptions irrespective of the scientific advances (Davis 2016). Especially in the Global South, governments are pressured to convert land and livestock into financial opportunities and reliable revenue streams by connecting rangelands with urban and international markets. Exclusive land tenure, capital investments (e.g., in livestock breeds), consistent output, and optimized rates of return-on-investment are viewed as necessary to meet these goals. In short, the core management requirements of NE – flexibility, mobility, and reciprocity at multiple scales – suffer not from a lack of scientific support but from incompatibility with neoliberal globalization.

Pastoralists continue to experience political and economic marginalization, compromised management autonomy, diminished access to land, and sedentarization (UNCCD 2024), reducing the spatial scale and sustainability of livestock management. With powerful outside interests seeking to appropriate land and water resources for more lucrative land uses, policies and development efforts often reduce options for livestock movements and flexibility by encouraging the conversion of rangeland to cropland to increase economic returns, afforestation to 'restore' ecosystem functions, and intensification/modernization of livestock production (via fencing, wells, and harvested forages) to increase production efficiency (Nori and Scoones 2023). And as climate change advances, the variability of precipitation on rangelands is increasing (Sloat et al. 2018). The complications associated with NE are expanding and intensifying with losses in forage productivity, amplified abiotic extremes, and widening scalar mismatches in rangeland administration. Thus, NE is becoming both more relevant and more challenging than ever.

Prospects for improved application of the NE paradigm

For practical, management purposes, the core challenge of NE is the combination of spatio-temporal variability and unpredictability. Technological advances now allow pastoralists and policymakers to perceive and react to NE in ways that were unimaginable decades ago. First, the recognition of NE behavior in rangelands catalyzed the global development of state-and-transition models (STMs) that emphasize the potential for threshold responses in different rangeland types (Bestelmeyer et al. 2017). These models provide indicators and, more importantly, have expanded the mental models of managers to include the possibility of abrupt and persistent changes in natural resources. Operationally, STMs have guided grazing strategies and the selection of restoration practices that account for spatial heterogeneity in resilience due to climate, soils, and history, and the role of climatic variability. Where STM-based thinking has been adopted, managers are more attuned to variability, risk, and opportunity (Knapp et al. 2011).

Second, the fusion of satellite-based remote sensing, standardized databases of ground-based measurements, and user-friendly web and mobile applications has produced a revolution in information about rangeland conditions (Allred et al. 2022). A manager can now detect short-term changes and long-term trends in vegetation at the scale of patches that are a few hundred square meters in size and across thousands of hectares. While this technology is recent and most advanced in the United States, progress is underway in rangelands across the world and is improving rapidly with the use of artificial intelligence.

Third, sensor technologies under the umbrella term of 'precision ranching' are also becoming more effective and attainable, including Global Positioning Systems (GPS)-based tracking collars, water-level sensors, and automated rain gauges (Spiegal et al. 2024). These sensors allow managers to track variable resource conditions and animal movements (particularly in the Global North where herding is seldom practiced; McIntosh et al. 2022). Virtual fencing combines GPS with stimuli on collars that control livestock movements. Thus, virtual fencing allows for adaptive rotational grazing and rest that does not depend on expensive physical infrastructure and fixed pasture locations and dimensions. When combined with remote sensing-based production maps and analytics, GPS collars and virtual fencing can allow grazing pressure to adapt to NE behavior of rangelands (Bestelmeyer et al. 2024).

Conclusion

NE calls for flexible access to land, variable output (including wide swings in herd sizes), traditional ecological knowledge and bottom-up decision making to cope with inherent uncertainty (Scoones 1995). How do we overcome the policy barriers to supporting NE rangeland social-ecological systems, with assistance from technological advances? In practical terms, this question remains open and will be addressed by participants in our symposium. Several approaches, however, will be essential. First, rangeland and pastoralist advocates need to reinforce the broad societal benefits of rangeland social-ecological systems and their right to exist. Society and policymakers should treat the loss of rangelands with the same sense of urgency that they treat the loss of wilderness and forests. Second, development strategies should be designed from a deep understanding of local context, communities, and livelihoods (Allington et al. 2024). Third, policies should reflect careful consideration of the heterogeneity, connectivity, and scale needed to preserve those livelihoods and the natural resources on which they depend, taking advantage of technology. Carefully crafted socio-technical solutions may at last harness the insights of NE thinking to improve rangeland sustainability and pastoral livelihoods.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

2025 situational analysis of pasture dieback in eastern Australia

Buck, SR[1]; Hopkins, KC[1]; Shadur, PG[1]

[1] Department of Primary Industries, Queensland. Rockhampton, Qld, Australia.

Key words: Pasture dieback; Eastern Australia; Tropical grasses

Abstract

Pasture dieback affects millions of hectares of highly productive grazing land in eastern Australia, specifically north, central and south-eastern Queensland, and north-eastern New South Wales. The impact to grazing industries, including beef, dairy and sheep, is significant. Improved (or sown) tropical and sub-tropical grass species are predominately affected; very few native grasses are impacted. Affected plants initially exhibit leaf discolouration, which culminates in a mosaic of patches of dead grass across a pasture. Temperate grasses and broadleaf plants including annual and perennial legumes are not affected.

Dieback has occurred previously in tropical pastures across Queensland. A large dieback event happened in central Queensland during the 1990s and a much smaller and shorter event occurred in the mid-1920s in south-eastern Queensland. The leading cause of the current situation is the pasture mealybug bug (*Heliococcus summervillei*), whereas the cause of the 1990s event remains unknown despite research at that time. This indicates potential for a disease complex. Dieback has also been recently reported in tropical pastures across multiple south American countries where varied causes have been purported.

The Department of Primary Industries (DPI) initiated research activities into this condition in 2015 which included: characterising symptom progression, factors affecting disease occurrence, diagnostic pathology, and management options for affected areas. This research has been complimented by similar activities undertaken by other organisations. Research activities were accompanied by an industry engagement program including peer-to-peer learning activities such as group workshops and field days; and published resources including online and print factsheets, articles, videos, podcasts and social media posts. All are available in an online hub (www.futurebeef.com.au/resources/pasture-dieback/).

Background to Pasture Dieback

Pasture dieback is a condition killing productive tropical and sub-tropical pasture grasses in grazed and non-grazed situations. Improved (or sown) grass species are affected, whereas very few native grasses are impacted and temperate grasses and broadleaf plants including legumes are unaffected (Buck 2017; DPI 2024). Currently, pasture dieback is affecting millions of hectares of pastures (AgForce 2021; DPI 2024) resulting in significant productivity impacts to beef, dairy and sheep industries. The concern for pastoralists and agricultural industries is pasture dieback affects the most productive pastures in moderate-high rainfall locations that support most of the beef and dairy cattle herd in Queensland.

Dieback has occurred previously in tropical pastures across Queensland. A large dieback event happened in central Queensland during the 1990s where buffel grass (*Cenchrus ciliaris* cvv. American and Gayndah) was predominantly affected (Graham and Conway 1998; Makiela and Harrower 2008). A much smaller, and shorter duration, event occurred in mid-1920s in south-eastern Queensland where paspalum grass (*Paspalum dilatatum*) was affected (Summerville 1928).

Pasture dieback is reported in other countries. A similar pasture condition was reported in multiple tropical and sub-tropical grasses in New Caledonia during 1998 (Brinon et al. 2004). In south American countries including Brazil, Argentina and Paraguay, pasture dieback has been affecting tropical grass species, namely Panic grasses (*Megathyrus* spp.) (Ribeiro-Junior et al. 2017; A. Radrizzani, pers. comm. 2018). Pathogenic soil fungi are implied in Brazil due to stress from waterlogging (Dias-Filho, 2006), whereas in Argentina or Paraguay there is uncertainty of the cause of dieback (A. Radrizzani pers. comm. 2018).

Where does pasture dieback occur in Australia?
Pasture dieback is currently affecting perennial sown grass pastures in eastern parts of southern, central and northern Queensland, and north-eastern New South Wales (Figure 1). Rainfall in these locations is summer dominated with average annual totals around or above 500mm. The total area affected by pasture dieback is difficult to estimate due to dieback spreading over time and the episodic nature of the condition.

The current outbreak of pasture dieback was first reported during 2014-15 in buffel grass (*Cenchrus ciliaris*) dominated pastures in the Dawson valley area of central Queensland, and in creeping bluegrass (*Bothriochloa insculpta*) dominated pastures in the north-western Burnett region (Buck 2017). Dieback was reported some years later in southern and northern Queensland. Pasture dieback was first reported in north-eastern New South Wales in 2020 and has continued to spread south and south-west (N. Jennings pers. comm.).

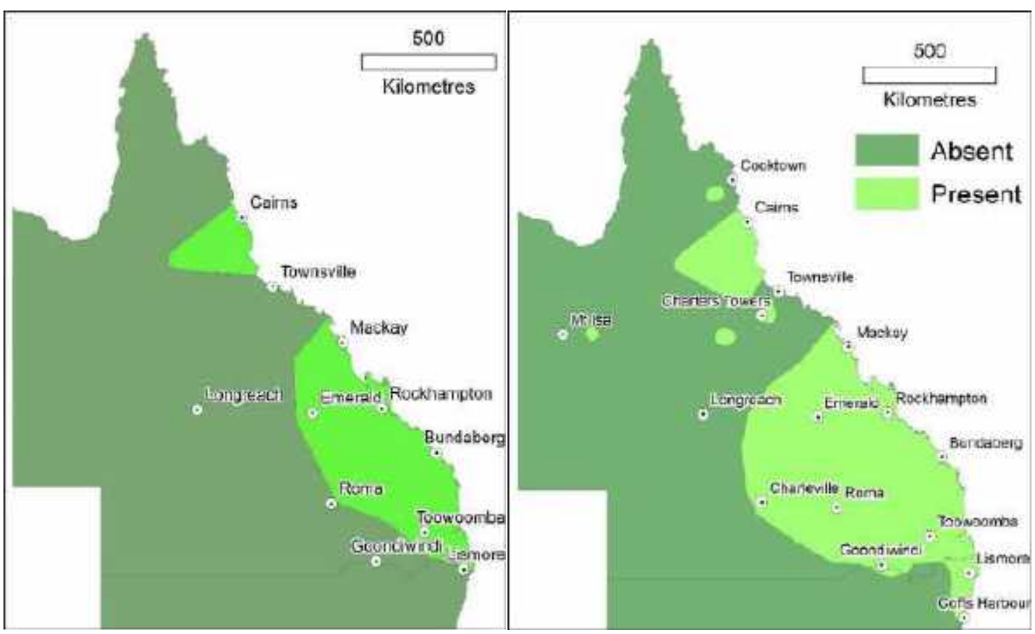

Fig. 1. Pasture dieback location (light green coloured areas). Left: observed 2021. Right: observed 2024.

What does pasture dieback look like?
Plants affected by pasture dieback typically occur in patches but larger areas or whole paddocks can be impacted. Pasture dieback can be challenging to identify. Diagnosis is easiest during the summer growing season where sick or dead patches are obvious amongst green healthy grass. However, similarities occur between dieback and other

plant disorders, for example water or nutrient stress, and so environmental conditions, landscape, soil and pasture management factors need to be considered prior to a positive diagnosis.

Affected plants progress through four stages. 1. Initial leaf discolouration. Depending on the species, leaves can turn yellow/orange, or a combination of red and yellow, or red/purple. 2. Whole plant discolouration, unthrifty growth and sick appearance. 3. Dead patches of grass plants that are characterised by a grey appearance and are easily uprooted. 4. Broadleaf plants colonising and growing in patches/whole paddocks of dead grass.

Fig. 2. Pasture dieback symptom progression. Photos left to right: Stages 1, 2, 3, 4.

What causes pasture dieback?
Over the last ten years, research has been undertaken by multiple organisations to determine the cause of pasture dieback. On-farm characterisation of affected paddocks and properties across Queensland was conducted by DPI between 2015 and 2020. Paddock observations and management, climatic conditions prior to noticing dieback, and other factors were investigated. While results demonstrated pasture dieback was more common in moderate-high yielding pastures, no factors consistently indicated a potential cause (Brazier and Buck 2021).

Research conducted since this time by DPI, Queensland University of Technology and University of Queensland, with financial support of the Australian government through Meat and Livestock Australia (MLA) Donor Company, demonstrate the cause of the current outbreak of dieback as the pasture mealybug (*Heliococcus summervillei)* (Buck et al. 2022; Hauxwell 2022). The pasture mealybug is a sap sucking insect that typically feeds on growing plants between spring and autumn. They over-winter below the ground or around the crown of the plant, under stubble/trash or manure pats and logs. Warmer than average winter night-time temperature and rainfall are potential pre-curser conditions for pasture mealybug populations the following summer (McKenna et al. 2024). Multiple other abiotic (e.g., soil nutrient and chemistry) and biotic (e.g., insects including ground pearl, and nematodes, fungi, viruses, bacteria) factors were also investigated including the potential of secondary infections killing the plant once the pasture mealybug compromises the plants natural defence mechanisms. While results indicate there are some interactions with these organisms, laboratory, glasshouse and field trials demonstrate the pasture mealybug as the main cause.

What can be done about pasture dieback?
There are three options to consider when dealing with pasture dieback, the first is whether dieback can be prevented. Currently there are no known methods to reliably prevent pasture dieback if the pasture contains susceptible grass(es) under conductive conditions with the pasture mealybug present in the local district. Conceivably, graziers could remove susceptible grasses and re-seed with more tolerant types prior to the potential infection. However, this is highly unlikely due to the cost, effort, and unwillingness to remove a healthy and productive pasture on the *potential* of infection. Due to dieback being more prevalent and severe in pastures with moderate-high biomass, another concept is to heavily graze the pasture prior to or when dieback is initially seen. Experience in commercially-grazed paddocks demonstrate this is an unreliable method. Also, there is high risk of significantly reducing pasture biomass which is needed to support stock during the subsequent dry season if sufficient follow-up rainfall does not occur. Appropriate use of biosecurity techniques such as controlling property access, careful movement of people and stock, and diligent farm hygiene (e.g., come clean, go clean) could reduce

the potential of initial infection and subsequent spread on-farm. However, graziers commonly report dieback initially occurring in pastures where stock or humans have not accessed for some time (months) indicating pasture dieback can spread through wind or other environmental factors. Ultimately, implementing biosecurity measures may only delay an inevitable occurrence.

The second option is to eradicate the pasture mealybug once the pasture is affected. Fire has been used in research trials and commercial situations with mixed results. Most graziers report dieback returns, suggesting a positive outcome is temporary at best. To eradicate the pasture mealybug with insecticides the land manager needs to first determine presence in a pasture. Plant damage and death is only caused by juveniles therefore control needs to occur before or at this lifecycle stage. However, finding juveniles without a hand-lens or magnifying glass is problematic due to their minute size. Further, gaining a thorough understanding of location across tens, or hundreds of hectares in some cases, is impractical. Other constraints occur regarding insecticide application: lack of registered products for tropical pastures in Queensland and New South Wales; cost of these, grazing withholding periods, and the impracticalities of application across extensive pastureland; inability to effectively kill all mealybugs with one spray; negative impacts on beneficial insects such as lady-beetles, lacewings and wasps. Due to these reasons the current recommendation is not to use fire or insecticides to eradicate the pasture mealybug.

The third option is to manage pasture dieback. Perennial pasture systems persist through regeneration of new plants from the soil-seedbank. Under dieback conditions, specific practices can assist this process: spraying broadleaf weeds if present in high numbers; regularly assessing pasture growth to match grazing periods to allow seedling survival. Managing for recovery is commonly how graziers are dealing with pasture dieback due to the low direct costs, and the cost, effort and outcome uncertainty of other options. However, risks include not knowing when the pasture will fully recover (may take longer than 12 months), and the potential for noxious weed incursions. For example, African love grass, Giant rats tail grass, or broadleaf weeds such as parthenium have colonised some areas affected by pasture dieback. Another method is through improving the pasture. Effective practices include renovating the paddock through cultivation, and or applying fertiliser. Planting an annual grain or forage crop to provide a disease break and produce short-term feed to transition from the old pasture into the new, is another. However, the most effective long-term option is to re-seed a new pasture with tolerant grasses and resistant perennial legumes and fertilise if required. While this mainly suits arable landscapes and graziers need to source the required machinery, productivity gains are substantial and the likelihood of pasture dieback fully impacting the new pasture into the future is low. Therefore, this option is currently recommended where feasible.

To summarise, Table 1 outlines current knowledge on options and responses to pasture dieback.

Table 1. Options for pasture dieback, likelihood of success, and management practices.

Option	Likelihood of success	Management practice(s)
Prevent	Unlikely	Biosecurity measures slow the spread at best
Eradicate	Unlikely	No insecticide registrations; variable outcomes from fire
Manage	Highly likely	Manage for recovery; or sow new pasture with tolerant grasses and resistant legumes suitable to situation, fertilise

Legume production paddocks to improve beef enterprise productivity and grassland management

Cox, KG[1]; Lemin, CD[1]; Hay, KA[1]; English, BH[1]; Dayes, SA[1]; Bambling, LR[1]

[1] Department of Primary Industries, Queensland

Key words: tropical pastures; Queensland

Abstract

Weaner or steer production of tropical cattle breeds for feeder or live export markets is the dominant primary industry in the seasonally-dry zone of northern Australia. Uncleared savannah woodlands and natural grasslands are key feed resources, with smaller cleared areas used for pasture development or cropping. Extended dry-seasons, soils of mostly low to moderate fertility and the maturation characteristics of native grasses limit animal growth and market options for producers. Land condition decline and the associated increase in early maturing introduced grasses (*Bothriochloa pertusa* and *Themeda quadrivalvis*) are emerging issues for beef producers. Recent research in north Queensland by the Queensland Government, with support from the Australian Government and Meat and Livestock Australia, has focussed on the development and promotion of ‘production paddocks’ using deep-rooted and productive legumes (*Clitoria, Desmanthus, Macroptilium, Stylosanthes*). These relatively intensively-managed paddocks target the nutrition of weaners and steers during the early to mid dry season to (1) enable earlier sale or higher sale weights of cattle, and (2) encourage sustainable grazing practices through spelling other areas on the property enabled by improved animal productivity. Small-plot studies of grass x legume combinations on commercial beef properties resulted in pasture yields 2-3 times those achieved on native pastures on fertile and infertile soils. Critically, the legume component contributed leaf with high feed value (15-20% crude protein and 8-10 MJ/kg metabolisable energy) when companion grasses had low feed value. The high quality of the dry season feed provided by legumes was confirmed using faecal sample testing.

Introduction

Beef cattle production is the principal land use in the monsoonal zone of northern Australia which includes the seasonally dry zone (600-900 mm AAR) in north Queensland north and west of Bowen. The area contains ~30% of the total Queensland herd which in turn approximates 45% of the 2024 national Australian herd of ~29.9 M head (Meat and Livestock Australia 2024). Weaners and steers of tropical cattle breeds for feeder (store) and live export markets are the key products in this zone. Key determinants of profit are breeder productivity (weaning and death rates) and sale weights (McLean et al., 2014). Native grass pastures in woodlands and natural treeless plains are the key feedbase for cattle in the seasonally dry zone, with the type of forage depending on geological soil development processes and rainfall (~600-900 mm average annual rainfall). Most (geologically older) soils are considered infertile, with low levels of plant available phosphorous and sulphur, but younger soils (basalt and alluvial) are considered more fertile and therefore productive overall.

The growth of native pastures is highly seasonal due to a brief (3-4 months) monsoonal summer growing period (December-March), followed by an extended dry season. For cattle producers, this results in deficits in feed volume and quality (digestible energy and protein) when they need to feed weaners and steers or maintain cow condition for reconception and during pregnancy. Management of the dry-season 'feed gap' in a variable climate and where pasture yields are inherently low is the greatest challenge to beef producers, requiring careful management to not damage native pastures (Rolfe et al 2016). Long-term declines in land condition, including declines in useful perennial grasses and increases in herbaceous and woody weeds presents an additional challenge and ultimately decreases the number of cattle which can be sustainably grazed on a property (Shaw et al. 2024).

A historical strategy to increase pasture productivity was to either sow introduced grasses considered to have desirable production characteristics (e.g. *Cenchrus ciliaris, Urochloa mosambicensis*) in small areas on better soils with or without legumes, or to integrate introduced hardy legumes (*Chamaecrista rotundifolia, Stylosanthes* spp.,) into native pastures by broadcasting during the wet season (Walker and Weston, 1990). In the 1990s, the potential to increase stocking rates and improve weaner and steer growth and potentially target new markets by incorporating *Stylosanthes* spp. and increasing legume growth by applying fertiliser phosphorous and sulphur was demonstrated on low fertility soils (Anon 1994a; 1994b). Development of this 'production paddock' concept stalled during the 1990s and 2000s due to disinvestment in sown pastures research and extension, but in 2014 the Queensland Government, collaborating with the Australian Beef Industry, began to assess new and historical grass and legume cultivars under management suitable for production paddocks. The results reported below relate to the second phase of the research, after which suitable grasses and legumes had been identified from single-taxa replicated plot experiments on a range of land-types (Cox et al. 2019). The specific objectives were to assess how combinations of promising grasses and legumes, exhibiting a range of growth habits, perform under grazing on soils of high or low fertility and gain insight into the potential for improving animal performance.

Methods

Two experiment sites were developed representing fertile (red basalt soil) and infertile (red earth soil) landtypes (Table 1). A complete factorial design of one grass and one legume in each plot was used: legumes were randomly allocated within grass strips laid out in a replicated (x3) complete block and seed sown into sites prepared by combinations of cultivation and herbicide to control previously established and emerging weeds. Fertiliser was applied prior to the final cultivation and sowing completed by broadcasting seeds onto a rolled seedbed and rolling again after broadcasting. Sowing rates were based on recommendations (www.tropicalforages.info) for each species and adjusted based on seed tests (top of paper, 35/20°C:16/8 hr).

The plots were not grazed in the first dry season (to allow complete establishment) and wet season spelled thereafter. Biomass accumulated over the growing season was measured before dry-season grazing (target residual of 1000 kg DM/ha). Herbage yield was estimated at the end of the growing period over 3 (red earth) or 4 (red basalt) years by cutting a minimum of two 0.5 m^2 quadrats per plot (360+/site), separating species while fresh, drying at 65°C until constant weight and separating legumes into leaf and stem components before weighing. Sub-samples were ground and submitted to an accredited laboratory (Dairy One™) for feed value analysis (presented) using wet chemistry. Once the legumes had spread from the plots into the surrounding native pastures, fresh faecal samples were collected from at least six grazing weaner heifers. The samples were submitted to an accredited laboratory to estimate feed value (eaten) using NIRS (Dixon and Coates 2010).

Table 1. Characteristics and management of sites used to test production paddocks in north Queensland.

Site feature/management	**Fertile site**	**Infertile site**
Location (°S/°E)	Mt Surprise (18.14/144.64)	Charters Towers (19.49/145.69)
Mean annual rainfall (median)[1]	791 (806)	556 (509)
Soil type	red basalt	red earth

Results

Plant establishment was successful for all grasses and legumes except for one grass (*Urochloa* hybrid) at the red basalt site (poor quality of available seed). Grasses dominated at the red earth site under higher than usual rainfall, whereas exceptionally dry conditions in first dry season suppressed grasses at the red basalt site (data not presented). Plant growth was rapid at both sites thereafter and the sites were considered to be suitable for full grazing by April in the year after sowing. Once established, rainfall was at, or above, long-term means.

Herbage yields averaged across the grass treatments and for a well-adapted competitive grass (*Bothriochloa insculpta*) are presented for 2021 and 2023 growing seasons along with legume percentage leaf and key feed value indices for samples collected in 2021 (Table 2). Yields increased from 2021 to 2023 at both sites and were higher overall on the red basalt site. The highest yields on both land-types were achieved in the plots containing *Stylosanthes seabrana*, with *Clitoria ternatea, Macroptilium atropurpureum* and *Stylosanthes scabra* also performing well on the red basalt site, and *S. scabra* on the red earth. In general, plots with higher legume yields tended to have higher overall pasture yield.

Table 2. Total pasture and legume herbage yields, legume leaf content and feed quality from small-plot testing of grass x legume combinations. Means with different letters were considered different (95% level).

[2] feed quality indices marked with a '*' represent a whole plant sample.

The legumes varied considerably in the proportion of leaf and stem and key feed value indices. The shrub legumes (*Desmanthus, Stylosanthes*) tended to have lower (~30-40%) leaf content than the twining legumes (*Clitoria, Macroptilium*) (50-60%) when sampled at the end of the growing season (at both sites). Crude protein (15-20%) and metabolisable energy (8-10 MJ/kg) contents were substantially higher in leaf than stem in the wet and dry seasons with values of both tending to decline over the growing season. Dry season values for legume stem were similar to the higher values of companion grasses (3-6% crude protein and 5-7% MJ/kg)(data not presented). Faecal NIRS testing of fresh dung from animals introduced into the red basalt site in September 2024 had higher crude protein (7.3%) and metabolisable energy (7.7 MJ/kg) than for cattle grazing in a similarly spelled adjacent native grass paddock (4.3% and 7.1 MJ/kg), presumably due to grazing *S. seabrana* and *C. ternatea* which have spread from plots.

Discussion

The small plot experiments indicate good potential for grass-legume 'production paddocks' to increase cattle productivity (stocking rate and growth rates) through improving the diet particularly in the dry season on fertile and infertile land types. The herbage yields achieved were in the order of 2-3 X those of undeveloped native pastures in good land condition (Queensland Government, 2024a; 2024b) and were sustained 3-4 years after sowing without the application of additional fertiliser (although additional application of S or S and P fertiliser is expected to maintain productivity in the longer term). Nitrogen fixation by the legumes would also likely contribute to improved forage yields through increased nitrogen cycling but this was not measured directly. Queensland Government analyses based on the findings of the experiments found gross margins per hectare after interest were 4-7 times those on native pastures when cattle prices and costs were averaged over 5 years, being higher on the fertile red basalt site due to higher herbage production and less fertiliser costs (Finlay and Cox 2022). These support the findings of Bowen et al (2019) whereupon the introduction and fertilising of stylos were found to be the most profitable interventions for beef producers in the northern Gulf region. An additional benefit of the competitive grass/legume systems was the suppression of *Bothriochloa pertusa* and *Chamaecrista rotundifolia* at the fertile and unfertile sites, respectively, providing a means to lift or restore productivity where these relatively unproductive species have become dominant (Cox et al., 2023a; 2023b). The adoption of production paddocks should enable cattle producers to spell pastures elsewhere on the property enabling grass recovery and more sustainable long-term management of native grasslands. It is recommended studies and demonstrations be completed at paddock-scale to refine methods for the establishment and management of production paddocks and confirm the economic benefits to assist decision making by graziers.

Legacy pasture evaluation trials delivering new persistent legume varieties

Peck, GA[1]; Dunbar, IT[1]; Augustin, A[1]; Walker, LK[1]; Callanan, EJ[1]

Key words: legume; pasture evaluation; persistence.

Abstract

Pasture legumes are the best long-term option to increase productivity and profitability from grass-dominated pastures in the sub-humid, sub-tropics and tropics of Australia through improving pasture yield, diet quality and performance of livestock. However, finding legume varieties that are persistent and productive in the long-term for the climatic zone and grazing systems has been challenging.

Queensland graziers report that long-term persistence (20 to 50 years) of legumes is their highest priority trait for selecting new varieties. Legume and livestock productivity was a second order priority; other traits such as seasonality of growth, ease of establishment, seed production, and methane reduction potential were considered important but of lower priority.

Research funding cycles are typically 3 to 5 years, which means long-term persistence of legume accessions cannot be directly measured before release as new varieties. However, there is a network of old pasture evaluation trial sites in the study area which provides an important opportunity for selecting persistent varieties.

Forty-eight pasture evaluation trial sites that were sown between 1978 and 2008 were inspected across southern and central Queensland to identify legumes that persisted in the long-term. Most of the sites had been 'abandoned' as research trials for >10 years and generally incorporated back into the grazing property. The two outstanding genera for long-term persistence were *Stylosanthes* and *Desmanthus* with some accessions demonstrating long-term persistence across broad geographic locations.

Legume persistence at these legacy trial sites has supported new research. Accessions of legumes were described and collected from old trial sites and evaluated across six new sites in southern Queensland. Five new *Stylosanthes* varieties have recently been released for commercial production demonstrating better persistence and 40 to 70% higher yields (averaged across trial sites) than the best performing commercially available legume stylo varieties. On-going research is identifying persistent and productive *Desmanthus* accessions for potential commercialisation as new varieties.

Introduction

Pasture legumes have been identified as the best long-term option to improve the productivity of both native and sown grass pastures across large areas of the tropics and sub-tropics in Australia, where there are suitably adapted and productive cultivars available (Peck *et al.* 2011). Finding legumes that are suitable for the Brigalow Belt bioregion of Queensland and New South Wales (NSW) has been particularly challenging due to its unique climate characterised by a sub-tropical climate with moisture deficits in all months of the year but is not arid (Hutchinson *et al.* 1992). The Brigalow Belt is important for the beef industry because it carries approximately 40% of Queensland's (10.6 million head) and 30% of northern Australia's beef cattle (13.3 million head) herd (ABS 2022).

Graziers advised that most of the legume cultivars that were previously commercially released for use in the Brigalow Belt were not persistent with competitive sown buffel grass (*Cenchrus ciliaris*) pastures typical in the region (Peck *et al.* 2011). The highest priority trait identified by graziers for new legume varieties was long-term persistence described as >20 to 50 years (i.e., graziers only want to sow legumes once). Research funding cycles are typically 3 to 5 years, which means that long-term persistence cannot be directly measured before legume accessions are shortlisted and selected for release as new cultivars. Fortunately, there is a network of old trial sites that were established between 1978 and 2008 that enables direct measurement and assessment of long-term persistence under grazing of legumes across a broad geographic area. This paper describes research conducted over the last 15 years that has utilised the old trial sites to identify legume species, cultivars and experimental accessions that have persisted and are productive in the long-term. This research provided better recommendations on which varieties to sow and identified accessions for further evaluation and release as new cultivars that are more productive in the long-term than existing, commercially available varieties.

Methods

Investigation of legume performance in southern and central Queensland

Forty-eight old pasture evaluation trials located across the Brigalow Belt bioregion were inspected to identify which legume species had persisted in the long-term. Re-visiting and describing these trial sites relied on the interest and input of multiple retired pasture scientists that were former employees of the Queensland Department of Primary Industries (DPI) or Commonwealth Scientific and Industrial Research Organisation (CSIRO) that had established the trials.

The old trial sites were sown between 1978 and 2008. Trial sites were inspected for long-term legume persistence between 2011 and 2023; 36 trials were inspected in 2011, 4 in 2013, 4 in 2016 and 4 in 2023. At the time of first inspection for long-term legume persistence, the trials ranged in age from 5 to 33 years post sowing with the average age being 18 years post sowing. Some of the trials have been inspected for legume persistence over multiple years. All the trial sites had been discontinued as research trials at the time of inspection, with most of the sites reverting to commercial grazier management for >10 years. If still fenced, most of the sites either had the gates open or fences were no longer stock proof, therefore the condition of the sites generally reflected the surrounding paddock. Due to the presence of pasture legumes, many of the sites were preferentially (and therefore heavily) grazed compared to surrounding paddocks. A full description of the methodology used to assess long-term persistence of legumes at trial sites is described in Peck *et al.* (2017).

The old trial sites were initially inspected to describe long-term persistence of commercially available legume varieties; however, these sites also enabled the identification of persistent and productive, non-released accessions for further evaluation and potential release as new cultivars. The activities to identify high-performing accessions for release as new varieties are described in the following sections.

Evaluating promising stylo lines for southern Queensland

A summary of the evaluation methodology is provided in this paper. A full description is available in Peck *et al.* (2022).

Multiple accessions of stylo from multiple species persisted and spread at old pasture evaluation trial sites at more southerly latitudes, with greater frost frequency, than considered suitable for commercial varieties. Forty legume accessions were described and seed re-collected from 8 sites (36 accessions of stylo, 3 desmanthus and 1 *Neptunia* sp.); however, the seed crop of one of the stylo accessions was severely damaged by disease, resulting in 39 accessions for sowing in new evaluation trials.

The 39 accessions, plus 3 experimental accessions shortlisted from other projects and 10 commercial legume varieties were sown in 2016 at six evaluation trial sites across southern Queensland. One of these trial sites failed to establish with adequate plant density due to soil crusting. The remaining five trial sites were assessed over nine growing seasons.

Evaluating promising shrubby stylo accessions in central and northern Queensland
Two accessions of coastal biotype shrubby stylo (*S. scabra*) have been shortlisted from the "evaluating promising stylo lines in southern Queensland" project for further evaluation across central and northern Queensland. Seven evaluation trials are planned for sowing in the 2024/25 growing season to test their performance relative to commercial cultivars.

Investigating desmanthus persistence and performance in southern Queensland
Following the success of the stylo selection project, an investigation of desmanthus persistence and performance at 12 evaluation trials in southern inland Queensland has commenced. Each of the sites had a wide range of desmanthus accessions from multiple species sown. Sites are >20 years post sowing. Sites have been inspected for legume persistence, with trials that warrant further investigation reinstated (e.g., fences repaired, or new fences erected). Identification of persisting accessions at trials that had large plots (>50 m^2) was completed in 2023 and 2024. One of the large plot trial sites was harvested to estimate yield in 2024. Investigation of persisting accessions at old small plot (approximately 6m^2) trial sites commenced in 2024/25.

Results
Performance of commercially available legume varieties in southern and central Queensland
Observations from the network of old pasture evaluation trial sites demonstrated that some commercially available legume varieties persisted across broad geographical areas of southern and central Queensland; however other legume species and varieties commonly recommended to graziers were not widely persistent. A summary of legume persistence and productivity results for commercially available legume species and varieties across the Brigalow Belt is provided below:

- *Stylosanthes* spp.: Caatinga stylo (*S. seabrana*) was widely persistent and productive on a wide range of soil types, but its productivity was impacted by high death rates of the population in southern districts on clay soils during wet winters. Shrubby and Caribbean (*S. hamata*) stylo are persistent on light textured (loamy and sandy) soils in central and northern Queensland but not in southern Queensland.
- *Desmanthus* spp.: *D. virgatus* was widely persistent on clay soils; however, in many locations, it had a very high population density of small plants with poor leaf retention. Other *Desmanthus* species (e.g., *D. leptophyllus*, *D. bicornutus*, *D. pernambucanus*) maintained an adequate plant density that contributed to animal production in a small percentage of trial sites where they were sown, but did have high dry matter production at some sites.
- *Leucaena leucocephala*: Leucaena persisted on fertile soils with high water holding capacity with good grazing management. Leucaena did not maintain adequate plant populations at multiple sites that had one or more of the following traits: sub-soil constraints, low fertility, heavy frost, and heavy continuous grazing.
- Legume species persisting in niches: Annual medics (*Medicago* spp.) are widely persistent on clay soils with regular frosts in southern Queensland. Butterfly pea (*Clitoria ternatea*) persisted on deeper, basalt derived black earth soils in central Queensland; but has not persisted on other clay soils. Round-leaf cassia (*Chamaecrista rotundifolia*) persisted on very sandy soils in central Queensland and on a wider range of soils in north and southeastern Queensland.

- Legume species that have not persisted on grazed trial sites include: Lucerne (*Medicago sativa*), burgundy bean (*Macroptilium bracteatum*), Atro (*Macroptilium atropurpureum*), fine-stem stylo (*Stylosanthes guianensis* var. *intermedia*). These legumes species should not be recommended for long-term pastures in the Brigalow Belt bio-region climate zone.

These legume persistence results are closely aligned with observations of commercial paddocks and consultation with graziers (Peck *et al.* 2011).

Superior stylo varieties identified for southern Queensland
Five stylo accessions were selected for release as new legume varieties for light textured soils in frosty locations in the sub-tropics based on the results from five evaluation trials sown in 2016. Three of the new varieties are Caatinga stylos (cvv. Dura, Cedo, Ultimo), and two are shrubby stylos from the "continental" biotype (cvv. Terra, Roxo).

The five new stylo varieties produced 40 to 70% higher average yields than the best performing, commercially available legume variety (cv. Unica, a Caatinga stylo) across five trial sites in the third and fourth growing season after sowing. These measurements were conducted during severe drought years that were in the driest 10% of years for the districts where the trials were located.

Four of the trial sites were remeasured during the eighth or ninth growing season after sowing to measure performance in average or higher rainfall growing seasons. The Caatinga stylo varieties produced 30 to 60% higher yields (averaged across the four trial sites) than the best performing commercial variety (cv. Primar, a Caatinga stylo). The two new shrubby stylo varieties produced lower average yields than cv. Primar but much higher yields than the commercial varieties of shrubby stylo (more than four times higher average yields).

Evaluating promising shrubby stylo accessions in central and northern Queensland
Two accessions of the "coastal" biotype of shrubby stylo were initially shortlisted from the "evaluating promising stylo lines in southern Queensland" project for further study. When grown in a trial at Mareeba, they produced yields that were approximately four times higher than cv. Seca, which is the industry benchmark variety for shrubby stylo and considered well adapted to the north Queensland climate. These two accessions are now being tested more broadly in a wide range of soil by climate locations across central and northern Queensland to see if they produce higher yields or other benefits compared to cv. Seca.

Investigating old desmanthus trials in southern Queensland
One outstanding desmanthus accession (breeders code: B-Six) has been identified from the old, large plot trial sites to progress towards release as a new cultivar. At the trial site that was harvested 25 years post sowing, B-six produced approximately double the yield of cv. Marc which has been a widely used and persistent desmanthus variety. B-Six also had clearly better leaf retention. The results from this trial are consistent with visual assessments that were carried out at the other old large plot trial site that was still intact (all other trial sites were ploughed out by the landowners). From historic trial data, B-Six had also produced high yields in the first 5 years post sowing at four old trial sites in southern Queensland and northern NSW and has now demonstrated ongoing persistence.

Other promising accessions are likely to be selected from the old small plot trials after more detailed assessment of performance. For example, one desmanthus accession (SPT017) collected from an old trial site has been sown at 7 new trial sites across southern Queensland and was the highest yielding desmanthus at 5 of the 7 sites.

Discussion
More widespread and successful adoption of legumes is critical to sustainably improving the productivity and returns for grazing industries in the Brigalow Belt climate zone that carries 30% of northern Australia's beef herd.

In addition to productivity benefits, these legumes can potentially reduce methane emissions intensity and improve pasture resilience to seasonal variability and grazing.

The network of old pasture evaluation trials across southern and central Queensland described in this paper provided valuable insights about the long-term performance of commercially available legume cultivars as well as identifying better-performing legume accessions for potential release as new varieties. The results from the old trial sites contributed to providing better advice to graziers when selecting legume varieties. The old trial sites also provide a legacy for selecting persistent and productive new legume cultivars. Better varieties combined with better advice will contribute to more widespread and successful adoption of legumes in northern Australia.

Five new stylo varieties that were identified and re-collected from old trial sites have the potential to increase the geographic range suitable for sowing legumes in southern Queensland (i.e. previously there were no suitable commercial legume varieties), as well as improving productivity for large areas where existing varieties are suited. Two additional shrubby stylo accessions were also identified and are being evaluated as potential replacements for cv. Seca, which is the most widely used legume in northern Australia. Additionally, new research has commenced that has identified improved desmanthus accessions, with further work potentially identifying other accessions with useful traits for industry.

Acknowledgements
The research described in this paper has been funded by Queensland Government, Meat and Livestock Australia and the Australia Government. The old trial sites were established by DPI and CSIRO. Bob Clem, Trevor Hall, Richard Silcock, Bruce Pengelly and Bruce Cook formerly of DPI or CSIRO are retired pasture scientists who established and managed the network of old trial sites for many years and have provided critical knowledge to revisit trials, reinterpret results and provide mentorship to current staff. There has been a team of people that have worked on the projects described in this paper and their contribution is acknowledged.

Pathways less travelled to forage legume practice change

Hopkins, KC[1]; Buck, SR[1]

[1] Department of Primary Industries, Queensland. Rockhampton

Key words: extension; sown pasture; pasture legumes; practice change.

Abstract

Land condition decline, pasture rundown and dieback are significant issues for beef businesses in central Queensland. Perennial pasture legumes play a role in preventing and remediating these conditions, leading to improved beef production and business profitability. Adoption of perennial legume pastures by beef producers in central Queensland is low; however, there is renewed interest in legume plantings since they have been promoted as an option for greenhouse gas reduction. An extension strategy was developed to use carbon-focused peer-to-peer learning workshops to generate interest in one-on-one support to introduce perennial pasture legumes. Workshops were delivered in three locations in central Queensland in 2023 and were designed with a mixture of group learning activities and presentations. The workshop delivery team included a carbon scientist, carbon project advisor and an experienced extension pasture specialist. Feedback collected from the workshops indicated that 10% of producer respondents intended to make a change on-property involving legume pastures on 3,387 ha. 41% of producer attendees participated in one-on-one action plan support on-property after the workshop, where a total of 16 actions plans for 2,297 ha were documented on 10 properties. In the 11 mo after the initial workshops, producers who participated in the action plan process reported 561 ha of practice change. This change was considered to be incremental towards legume planting and included practices such as soil and seed testing, timber clearing and cultivation. Despite the documented practice changes, the one-on-one support method was labour intensive. Ongoing engagement with producers is continuing into the legume-planting season, such that more data can be collected on practice change. Overall, the strategy of using carbon-focussed events to garner interest in perennial legumes and producer practice change was successful and will be repeated.

Introduction

Beef producers in northern Australia face three significant threats to the long-term productivity of perennial pasture systems – land condition decline, pasture rundown and dieback. Often these conditions occur simultaneously and compound the impacts on the grazing business. In the central Queensland region for example, it is common for pasture dieback to occur in rundown Gayndah buffel (*Cenchrus ciliaris* cv Gayndah) pastures, which then become colonised by weeds or undesirable grasses resulting in poor land condition (Buck 2017).

Perennial pasture legumes play an important role in the cost-effective remediation of pasture rundown due to the nitrogen cycling benefits to soil fertility (Peck et al. 2011). They are also unaffected by pasture dieback, which means they provide cattle feed when grass is dead and are an important component of seed mixes when resowing tolerant species in dieback-affected areas (Buck et al. 2023). Furthermore, they are important 3P (productive, palatable and perennial) species when assessing land condition and have been well documented to increase stocking rates, liveweight gains and grazing periods (Bowen et al. 2018).

Cattle eating perennial tropical legumes such as *Leucaena leucocephala* and *Desmanthus spp* have increased daily liveweight gain and reduced methane production (Stifkens et al. 2022, Suybeng et al 2020), and aged leucaena-grass pastures accumulate enough soil organic carbon to mitigate methane production from cattle grazing them (Radrizzani et al 2011). The positive impact of perennial legumes is recognised by Meat and Livestock Australia (MLA) that has a target for the red meat industries (beef, lamb and goat) to achieve carbon neutrality by 2030 through a range of activities that support the avoidance and reduction of greenhouse gas emissions, including 25 million ha of new legume plantings nationwide (MLA 2020). As a result, industry interest in carbon emissions and the role legumes play in reducing them, has increased.

Sowing perennial legume-grass pastures results in more profitable beef businesses, despite the initial costs of establishment and associated financial risk, compared to having a grass-only pasture system (Bowen and Chudleigh 2018). However, adoption rates of perennial pasture legumes in Queensland Australia are currently low (Peck et al. 2022).

Several extension methods are effective in Australian agriculture including facilitated groups, technology development, training and group presentations, information provision and access, one-on-one individual farm advisory, best management practice frameworks, E-extension, co-innovation and social marketing (Coutts et al. 2017). Nettle et al. (2022) concluded that the strongest effect on adoption was achieved through small group-learning and one-on-one consulting; however, the combination of methods that addressed the human and social elements of the adoption process produced the largest impacts.

Our first aim was to test the methodology of using carbon as a workshop topic to generate producer interest in sowing perennial legumes. The second aim was to create engagement with a one-on-one advisor support process to achieve producer practice change.

Methods

Three workshops titled ‘Carbon, cattle and sustainability’ were delivered to beef industry audiences in central Queensland at Gayndah, Moura and Emerald in December 2023. Attendance data was collected including number of producers and the businesses and properties they manage.

Workshop topics

Workshops delivered information on the carbon cycle, insetting and offsetting carbon emissions, emission intensity in beef production, the impact of pasture legumes on emissions and carbon projects. Topics were chosen to give an industry audience a background understanding of carbon emissions and how practices on farm can influence them. Carbon project information was presented in a way that allowed a producer audience to decide if a carbon project was suitable for their business.

Workshop delivery team

Workshops were delivered by a multi-disciplinary team which included a scientist currently researching carbon emissions in commercial beef operations; a carbon project advisor with experience in managing carbon projects in the beef industry; and two extension specialists with skills in adult learning and peer-to-peer facilitation techniques as well as technical knowledge in pasture management and development, and cattle nutrition and husbandry.

Workshop peer-to-peer learning techniques

Workshop rooms were set up in group tables of 4-6 people where participants were asked to meet others at the table by introducing themselves, providing some background information on their beef operation and then answering an icebreaker question. This process was then repeated with the whole room. Groups completed an expectation activity on flip chart paper answering the questions 'What do you want to learn today?' and 'What concerns you about carbon?' After a presentation on the carbon cycle, insetting and offsetting emissions and carbon baselining, a 'bus stop' activity was conducted using the method described by The Facilitators Network (2024). Questions included: 1) How can you improve weight gain of cattle? 2) How can you improve the efficiency of a breeder herd? 3) What can you do to improve soil and pasture health? and 4) What can you use to keep farm records? Participants were prompted to record learnings in a 'Carbon property plan' which provided space for practices to implement to reduce carbon emissions. After a final presentation on carbon farming projects and some final group discussion, participants were asked to individually share their key 'take home' messages from the day.

Workshop feedback

Participants completed a feedback sheet with a series of questions including rating their knowledge and understanding before and after the workshop, and their intention to make a change in their practices (including what it is, how likely they are to do it and on what area of land).

One-to-one support action plans and practice change

Participants were offered one-on-one support for pasture management and improvement to occur after the workshop and property visits were arranged. When on property, advice was documented in a pasture action plan which included detailed instructions on fallowing and planting techniques, species selection and fertiliser rates. When re-engaging with producers after the property visits, if practice change had occurred the area of land and activity undertaken on the property were documented.

Results

A total of 52 participants attended the three workshops including producers and industry advisors (public and private). Feedback forms were completed by 30 producer respondents whose knowledge and understanding of carbon increased from an average score of 2.5 to 4.8 out of 7. 80% of respondents said they intended to make a change after the workshop and 10% of these said the change would include pasture development with legumes on a total of 3,387 ha.

During the 'bus stop' activity at each workshop, legumes and pasture development were listed by attendees as farm practices that can improve breeder performance, cattle weight gain and soil health.

Properties that were visited to develop pasture actions plans after the workshop are summarised in Table 1. Practice change was recorded in the first 11 mo after the workshops. In total, 16 producers (41% of producer attendees) who managed 10 properties requested property visits. Some properties developed action plans for more than one paddock. Practice change activities were recorded in 5 action plans and included planting an annual forage crop, timber clearing, fencing, and seed quality testing, all of which were steps outlined in action plans. A further two action plans were ready to enact when the seasonal conditions were right.

Table 1. Summary of properties and action plans developed from attendees in Queensland Australia of 'Carbon, Cattle and Sustainability' workshops in December 2023 and the resulting practice change 11 mo later.

Workshop location	Participating properties (no.)	Action plans (no.)	Action plan area (ha)	Action plans with progress (no.)	Practice change area (ha)
Gayndah	4	8	1,242	2	501
Moura	2	3	67	0	0
Emerald	4	5	988	3	60
Total	**10**	**16**	**2,297**	**5**	**561**

Discussion

Workshop success in increasing interest in legume pastures

The workshops were facilitated to maximise group sharing and learning as described by Coutts et al. (2017) as opposed to workshop deliverers teaching concepts. The increase in knowledge and understanding of carbon by the feedback survey respondents demonstrated that the workshop delivery format and combination of technical presentations and several group sharing activities was successful. The introductory activities which included an ice breaker question and a 'Hopes and Concerns' activity allowed participants to feel comfortable with each other and openly discuss the positive or negative impact farm practices have on their carbon emissions. The 'bus stop' activity allowed attendees to contribute ideas for farm practices that increase breeder performance, cattle weight gain and soil/pasture. Legumes and pasture development practices were consistently included in each list across all workshop locations. This demonstrated that attendees understand the concepts taught earlier in the day around emissions intensity, and the overall benefits of perennial legumes to a beef operation. This was despite few having already implemented the practice themselves.

Feedback data indicated that 10% of producer respondents intended to make a change of introducing legumes; however, 41% of producer attendees requested one-on-one support after the workshop. This discrepancy may be due to some respondents prioritizing other practice changes when completing feedback surveys. Regardless of the discrepancy, it is clear the workshops successfully generated interest in the development of pastures with perennial legumes.

One-on-one support action plans and resulting practice change

One-on-one support action plans resulted in 561 hectares of practice change in the first 11 months after conducting property visits, demonstrating the positive impact of providing individualised advice and support for graziers. This is consistent with producer survey data reported by Peck et al. (2022) where most graziers said they preferred one-on-one interactions with advisors to implement perennial legume introduction. Practices implemented by producers after action plan support, included several practices needed to successfully sow legumes into a pasture. However, due to the limited time in which the practice change data was recorded no legumes had been sown and some had not begun any activity as seasonal conditions were not sufficient for the planned actions. This is consistent with best practice recommendations on seasonal fallowing and planting times for the central Queensland region, Australia (Peck et al. 2022) so it was not expected that any plantings would have occurred in this period.

The one-on-one support action plan process was labour intensive for advisors due to the following reasons: every property was located 100 to 400 km away by road travel, took 1 to 4 h on farm to complete plus more time planning visits and documenting action plans, and was attended by at least two advisors. It is theorised that despite the personalised support provided, not all producers who engaged in the action plan process will implement a change long term and the top two barriers to adoption as reported by Peck et al. (2022) of cost and climate/seasons are likely to be applicable here too.

Combining extension methods

Combining peer-to-peer learning workshops and follow up one-to-one support activities has led to an increase in trust between producer participants and advisors, which is an important aspect of facilitating practice change and is an example of the success of stacked extension strategies. Stacking of extension methods involves combining several methods (e.g. facilitated groups and one-on-one support) into a cohesive package for producers (Nettle et al. 2024).

Facilitated small peer-to-peer learning group workshops on perennial legume establishment techniques were conducted by Peck et al. (2022) with success in achieving large areas of legume plantings. However, those workshops were aimed at teaching legume establishment concepts to producers who were already interested in the topic. The carbon workshops delivered in this study, demonstrate the effectiveness of appealing to the values of producers who are also interested in natural capital markets that combine environmental sustainability, product provenance for consumers and the opportunity for niche sales markets.

Conclusion and recommendations

Overall, the strategy of using a carbon-focussed workshop to generate producer interest in the benefits of perennial pasture legumes and garner interest for one-on-one advisory activities was successful and incremental practice change was recorded. Due to the short time since the initial engagement with producers at the workshops, it is recommended that contact between advisors and producers is maintained so that ongoing support for practice change can be provided. More 'Carbon, cattle and sustainability' workshops are being planned for 2024, allowing the strategy to be repeated and the results confirmed.

Long term effects of different stocking strategies on land condition and profitabilty in a highly variable climate

Key Words: flexible stocking, stocking rate, spelling, weight gain

Abstract

Rainfall variability is a major challenge to sustainable grazing land management in northern Australia. We present data from a long-term grazing trial comparing the performance of different cattle stocking strategies over 27 years of highly variable rainfall. Strategies involved combinations of different stocking rates, fixed versus flexible stocking and wet season pasture spelling.

Individual live weight gain (LWG) and product price were highest at moderate stocking rates applied with or without wet season spelling. Total LWG/ha was highest at heavy stocking rates, but gross margins lowest due to reduced product value and drought feeding costs. Flexible stocking was as profitable as fixed moderate stocking but also avoided the need to destock in drought years.

Land condition as indexed by the proportion of 3P (palatable, perennial and productive) grasses declined rapidly under heavy stocking, reducing resilience and long-term carrying capacity (LTCC). Although fixed moderate stocking at LTCC initially maintained land condition, condition ultimately declined due to the failure to reduce stocking rates in droughts. Land condition also declined with drought under flexible stocking, but recovery appears greater with recent good seasons. Wet season spelling was essential to buffer drought effects and is accelerating recovery post drought.

These results show that over the long term, heavy stocking is a high risk, and ultimately an unprofitable and unsustainable strategy. Although fixed, moderate stocking strategies are lower risk, they will still lead to degradation if stocking rates are not reduced in dry years to match forage availability. We recommend that climate variability be managed using flexible stocking rates in a pro-active, risk averse manner coupled with regular wet season spelling. These should be applied adaptively based on seasonal conditions and observed responses to management actions.

Introduction
Rainfall in northern Australia is highly variable at seasonal, annual and decadal scales making sustainable and profitable livestock management extremely challenging. Failure to manage for this variability has led to a number of degradation events with large shifts in land condition to other, less productive states (McKeon *et al.* 2009). Many graziers have learnt to manage for this variability by, for example, stocking around long-term carrying capacity (Purvis 1986; Landsberg et al. 1998), spelling pastures to accumulate forage for use in drier times and varying stocking rates to match available forage.

Unfortunately, wider adoption of these strategies within industry has been disappointing (Anon. 2017) resulting in ongoing cycles of degradation and economic loss in drought periods. The reasons for non-adoption are complex, but one key factor is that while these strategies are clearly beneficial for land condition, there is little or no data on their relative productivity and profitability.

To address this issue a large grazing trial was established in 1997 in a semi-arid, tropical savanna in northern Australia. The key objective was to quantify the performance of different stocking strategies in a highly variable rainfall environment in terms of their effects on animal production, land condition and profitability. This empirical data would support development of recommendations and adoption products to assist managers to make evidence-based decisions on managing for rainfall variability and help improve adoption of more sustainable and profitable grazing strategies.

Methods
The trial was established in 1997 on the property 'Wambiana' (20° 34' S, 146° 07' E), 70 km south of Charters Towers, Queensland. Long term (114-year) mean annual rainfall is 643 mm (C.V.= 40%), with 70% falling in the hot summer months. The vegetation is an open Eucalyptus-Acacia savanna overlying C4 tropical grasses. The native shrub Carissa ovata is also becoming increasingly dominant.

The trial has five grazing strategies, replicated twice. Paddocks are approximately 100 ha in size and contain a similar mix of the three main soil types. Strategies were: heavy stocking (HSR: 4 to 5 ha/AE [animal equivalent: 1 AE=450 kg steer]), moderate stocking (MSR: 8 to 10 ha/AE), rotational wet season spelling (R/Spell: 8 to 10 ha/AE), flexible (Flex) stocking (4 to 20 ha/AE) and flexible stocking with wet season spelling (Flex+S). Stocking rates in the flexible strategies were set based on end of wet season (May) pasture availability with further check points through the grazing year. In the R/Spell and Flex+S paddocks, spelling was implemented by resting different subsections within paddocks during the wet season. Importantly, strategies are managed adaptively as 'management philosophies' in consultation with a grazier advisory committee.

The trial was stocked with Brahman steers 1.5 and 2.5 years old and managed according to industry best-practice guidelines. Cattle are weighed at the start and end of the grazing year with older steers going to commercial slaughter (O'Reagain et al. 2009). Gross margins (GM) were calculated as product value less supplementation, vaccination, drought feeding and interest on livestock capital costs (O'Reagain *et al.* 2011). Pasture yield and species composition were monitored annually in May using the BOTANAL procedure (Tothill *et al.* 1992). Here we present the % contribution of 3P (palatable, perennial and productive) species to yield as an index of land condition. The key 3P species at the site are *Bothriochloa ewartiana, Dichanthium sericeum* and *Heteropogon contortus*.

Results
Rainfall and management
Rainfall varied widely (246 to1223 mm) over the trial period, with the initial four good years leading into an extended six-year drought (Fig. 1). This was followed by a further wetter phase and then a run of dry years, with

rainfall (246 mm) in 2014/15 being the fourth lowest on record. The 2021/22 season was also extremely dry (348 mm) but conditions changed abruptly thereafter with 2022/23 exceptionally wet (1064 mm).

With the early good years and abundant forage, the Flexible strategies were initially very heavily stocked, leading to overgrazing with the onset of the first drought phase. Stocking rates were subsequently sharply reduced and a more risk-averse approach adopted, involving setting upper limits to stocking rates and increasing the number of stocking rate adjustment decision points.

The HSR initially performed well but stocking rates had to be cut sharply in both the first and second drought periods due to the extreme scarcity (<200 kg DM/ha) of grazeable forage. Drought feeding had to be provided to the HSR steers in seven years of the trial compared to only once in the other strategies (Table 1). In contrast to the HSR, stocking rates in the MSR and R/Spell treatments were maintained throughout almost the entire trial period. One exception was in 2017/18 when, in line with a 'moderate stockers/rotational spellers' management philosophy, both were destocked for the wet season to prevent overgrazing.

In May 2022, due to ongoing drought and the almost complete lack of forage, the MSR, HSR and R/Spell were all destocked, and subsequently rested for the full 2022/23 season. In contrast, as the progressive adjustment of stocking rates in preceding years had ensured sufficient forage for the approaching dry season, the two Flexible strategies were able to remain stocked in 2022/23, albeit at a very light rate (20 ha/AE). The MSR and R/Spell were fully restocked in 2023/24, while the former HSR strategy was changed to a new short duration grazing treatment (Walkington et al. 2025) to facilitate recovery of the degraded land condition. Accordingly, the data presented below are for 26 years for the HSR compared to 27 years for the remaining strategies.

Animal production and economics

Individual liveweight gain (LWG) was by far the lowest of all strategies in the HSR (Table 1). These differences in LWG were amplified in dry years with HSR steers losing 54 kg in the extremely dry (246 mm) 2014/15 season. As a result of the generally poorer LWG, carcass weights and grading were lower for HSR steers resulting in a lower product value. These findings are consistent with those reported in more detail by O'Reagain et al. (2009 and 2023).

Table 1: Average (+/-standard error) liveweight gain (LWG) per steer, LWG per hectare (ha) and gross margin (GM) per ha for different stocking strategies over the 27-year Wambiana trial. The number of years that drought feeding was needed and the number of years with negative GM are also shown. (See text for treatment abbreviations).

Treatment	LWG/hd (kg)	LWG/ha (kg/ha)	Yrs drought feeding	GM/ha (AU$/ha)	Years with a negative GM/ha
Flex	118 (+/-8.3)	15 (+/-1.7)	1	12 (+/-2.2)	3
Flex+Spell	116 (+/-6.5)	15 (+/-1.6)	1	13 (+/-2.0)	3
HSR[1]	97 (+/-10.6)	18 (+/- 2.3)	7	5 (+/-2.0)	14
MSR	116 (+/-8.1)	13 (+/-1.1)	1	12 (+/-4.3)	4
R/Spell	115 (+/-8.0)	14 (+/- 1.2)	1	12 (+/-2.0)	4

[1]HSR based on 26 years of data

In contrast, average LWG per ha was highest in the HSR (Table 1). This difference was most pronounced in wet years but was much reduced or even negative in drought years (O'Reagain et al. 2023). However, the higher LWG/ha in the HSR was only achieved with expensive drought feeding in seven of the trial years compared to only one year in the other strategies. As a result, average annual GM/ha in the HSR was less than half ($5/ha) that of the other strategies ($12 and 13/ha) due to reduced product value and higher costs (Table 1). Gross margins in the HSR were also extremely variable with a far greater number of years with a negative GM/ha relative to the other strategies (O'Reagain et al. 2023).

Land condition

Land condition, as indexed by the % contribution of 3P grasses to yield, declined rapidly under heavy stocking with the onset of the first drought post 2001 (O'Reagain et al. 2023). This decline continued in the second drought, resulting in the 3P contribution falling from 25% in 1998 to only 4% of yield in 2021. Note that in 2024 relatively little recovery had occurred in the former HSR treatment despite good seasons and the paddocks being largely unstocked or only very lightly grazed since May 2022.

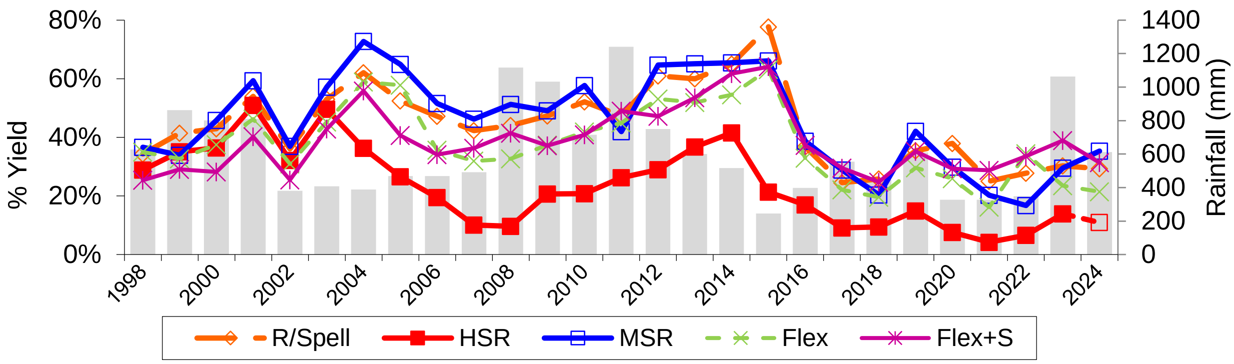

Figure 1: The change in contribution (%) of 3P grasses (palatable, productive, perennial) to pasture yield versus rainfall (grey bars) over 27 years under five grazing strategies at the Wambiana grazing trial. See text for treatment abbreviations. NB: The HSR treatment ended in May 2023.

The Flex and Flex+S strategies performed far better than the HSR in terms of land condition (Fig. 1). Nevertheless, the initial heavy stocking rates applied in these flexible strategies resulted in the %3P grasses being lower than the other strategies until about 2003. Despite the subsequent sharp reduction in stocking rates, the overgrazing at the start of the first dry cycle had a lasting negative legacy, as evidenced by the relatively lower 3P% in the Flexible relative to the MSR and R/Spell strategies until around 2014. In later, more recent years, land condition in these two strategies appears to be as good, if not better, than in the MSR and R/Spell (Fig.1).

In the moderately stocked MSR and R/Spell, land condition was largely maintained for the first 18 years of the trial. However, condition declined drastically post 2015 due to the extremely low rainfall that year and the drought conditions that ensued (Fig.1). This decline was undoubtedly largely due to drought, but the maintenance of the stocking rates in the MSR and R/Spell inevitably led to overgrazing and was thus also partly responsible for the land condition decline (pers. obs.).

Conclusion

These long-term results show that constant heavy stocking is a high risk, unprofitable strategy which leads to a marked loss of land condition. This in turn reduces carrying capacity and drought resilience making the strategy ultimately unsustainable. Although fixed, moderate stocking strategies are more profitable and have much lower risk, they can still lead to overgrazing and degradation if stocking rates are not reduced in dry years to match forage availability. Flexible stocking was as profitable as fixed moderate stocking, had similar if not better impacts on land condition and importantly, avoided the need to fully destock in the recent drought. However, flexible strategies need to be applied in a risk averse manner with upper limits set to stocking rates and stock numbers adjusted rapidly with the onset of drought. While the results presented do not show a strong benefit from wet season spelling, other data from the site (O'Reagain et al. 2023), and many other studies, e.g., Ash et al (2011), indicate that wet season spelling is essential for maintaining and improving pasture condition.

In conclusion we recommend that climate variability be managed using flexible stocking rates in a pro-active, risk averse manner coupled with regular wet season spelling. These principles should be applied adaptively based on seasonal conditions and observed responses to management actions.

Key words: annual vs biennial wet-season spelling; *Bothriochloa ewartiana*; basal cover; moderate vs heavy stocking; Wambiana grazing trial

Abstract

Pasture condition has declined across many pasture communities across northern Australia. Pasture spelling is a key recommendation for the recovery of land condition but there is limited information on the optimum length and frequency of spelling or the recovery rates possible under different spelling and stocking rate combinations. This 12-year study examined the effects of early and full wet season spelling applied annually or biennially, on the recovery of poor condition land and the demography of the key perennial grass, *Bothriochloa ewartiana*, under heavy and moderate stocking rates. The study period was characterised by low rainfall and extreme drought conditions in some years. Average basal cover of perennial species declined with the onset of dry years with the effects of drought amplified under heavy stocking. Basal cover later increased as conditions improved but cover under heavy stocking never recovered to that under moderate stocking. Annual early and full wet season spelling under moderate stocking had a positive effect on the basal cover of *B. ewartiana* but this effect was only significant ($P < 0.03$) after 12 years. Spelling had no effect on basal cover under heavy stocking, emphasising the overriding effect of stocking rate on recovery. Basal cover through the drought was largely maintained through the persistence of original tussocks, emphasising the importance of maintaining established plants through good management. In later years, an increasing number of recruits also increased basal cover. Land condition can be improved with annual wet season spelling provided stocking rates are appropriate, but recovery can initially be slow, particularly through dry years. These results emphasise the key role that spelling has in maintaining and improving pasture condition.

Introduction

Pasture condition has declined across many pasture communities across northern Australia as evidenced by the reduced density of many desirable perennial grasses (e.g. Tothill and Gillies 1992). Karfs *et al.* (2009) rated from 20 to 50% of the area of several major catchments in north Queensland as being in C (poor) condition, based on the 'ABCD' land condition rating. Areas in C condition typically have 50% or more lower carrying capacity and a much increased risk of soil erosion than those in A or B condition (McIvor *et al.* 1995; Ash *et al.* 1997).

Wet season spelling (i.e. resting through the growing season) is a key recommendation for maintaining or recovering pasture condition. Work by Ash *et al.* (2011) in northern Australia showed that recovery of condition can occur relatively quickly, at least with annual wet season spelling. However, their study was relatively short (7 years) with the best results achieved on relatively fertile basalt and granodiorite soils. Currently, there is little other relevant information, particularly on the rates of recovery with a different timing, duration, or frequency of spelling, to guide cost-effective (Scanlan et al. 2013) and practical resting regimes for managers. There is also little data available on the demographic processes underpinning how pasture condition responds to management actions like grazing intensity and spelling. As such, management guidelines are relatively unsophisticated, with consequently varying results. There thus remains a major challenge to understand the ecological processes which drive the recovery of poor pasture condition.

The aim of this study was to improve guidelines to recover poor condition land and hence carrying capacity in northern Australia. The study had two major objectives: first, to determine the optimum frequency and duration of spelling for recovery of poor (C) condition land under two stocking rates. And second, to monitor and improve the understanding of the demographics of the major perennial grasses that underpin the processes of recovery.

Method

The trial reported here was established within the larger Wambiana grazing trial (O'Reagain et al. 2009), 70 km south of Charters Towers, Queensland (20º32'S, 146º7'E). Mean annual long-term rainfall is 647 mm with most occurring between October and March. The vegetation is an open eucalypt-acacia woodland. The present study was conducted on an area dominated by *Eucalyptus brownii* and the native shrub *Carissa ovata,* on brown sodosols. The soils are moderately fertile with a pasture layer containing *Bothriochloa ewartiana, Aristida* spp*.,* *Chrysopogon fallax*, and other grasses.

The Wambiana trial was established in 1998 to test different grazing strategies (see O'Reagain et al. 1998). These included a heavy stocking rate (HSR: 4–5 ha/AE) and a moderate stocking rate (8–10 ha/AE). After 14 years of heavy grazing, the HSR paddocks were in C (poor) condition (Quirk and McIvor 2003). In 2011, part of one HSR paddock was selected and equivalent sets of 25 treatment plots (30 × 30 m) laid out in two blocks. One block was near an adjacent MSR paddock. The intervening paddock fence was realigned to incorporate this block containing all treatments into the adjacent MSR paddock, while the other block remained in the HSR paddock.

Four different spelling regimes involving either early or full wet season spelling and applied either annually or biennially were then implemented on these treatment plots in both the HSR and MSR paddocks (O'Reagain et al. 2023). Spelling was implemented by closing up plots with a temporary fence but were otherwise left open to grazing. A series of replicated unrested, continuously grazed control plots were also installed. Twelve 0.25-m^2 quadrats were permanently located in each plot with quadrats stratified to contain an adequate number of *B. ewartiana* plants (O'Reagain et al. 2023). Quadrats were surveyed annually at the end of the wet season (May/June) and the number and size of all individual perennial grasses recorded graphically on gridded paper.

Statistical analysis

Data was analysed by randomised block analyses of variance, with plots as experimental units. Treatment response patterns over seasons were analysed using repeated measures analyses of variance with GENSTAT (release 18.1, VSN International, Hemel Hempstead, UK) with the pre-treatment (2011) basal cover a covariate. For this paper, only the basal cover of *B. ewartiana* was analysed.

Results

Rainfall was good in the first 2 years and following the 3 previous, above-average years. Thereafter drought conditions ensued, with 2014/15 the fourth driest year on record (Figure 1). Rainfall remained below average and was often poorly distributed thereafter, before exceptionally good rains in the 2022/23 season.

Average total perennial grass basal cover increased slightly in the early years of the trial, but then declined in both stocking rates in the dry years between 2013 and 2016 (Fig. 1). This decline resulted from mortality of established plants and a reduction in basal cover of survivors. With the advent of drought, cover declined sooner and to a much lower level in 2016 in the HSR (0.23%) than in the MSR (0.53%). Thereafter, basal cover slowly increased in both the HSR and MSR treatments as seasons gradually improved. However, average basal cover of perennial grasses in the HSR never recovered to that observed in the MSR, even in the exceptionally wet year of 2023. These results show that while drought had a major impact on basal cover under both stocking rates, these effects were amplified under heavy stocking.

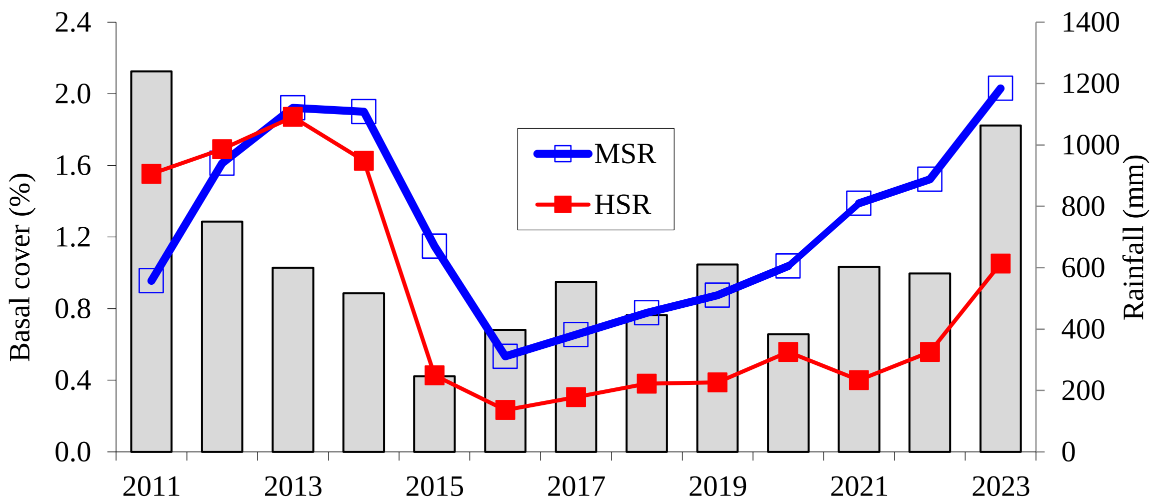

Fig. 1. Change in total perennial grass percentage (%) basal cover, averaged across the annual early wet season spell, annual full-wet season spell and unspelled control for the moderate (MSR) and high stocking (HSR) plotted against rainfall (grey bars).

Wet season spelling had a positive effect on the basal cover of the key species *B. ewartiana*, at least in the MSR (Fig. 2). However, this difference was only statistically significant in 2023 ($P < 0.03$) for the annual early and full wet season spelling, with biennial spelling having little or no effect on basal cover (Fig. 2). Importantly, in the HSR, spelling, even if applied annually and for the full wet season, had virtually no effect on *B. ewartiana* basal cover (data not shown).

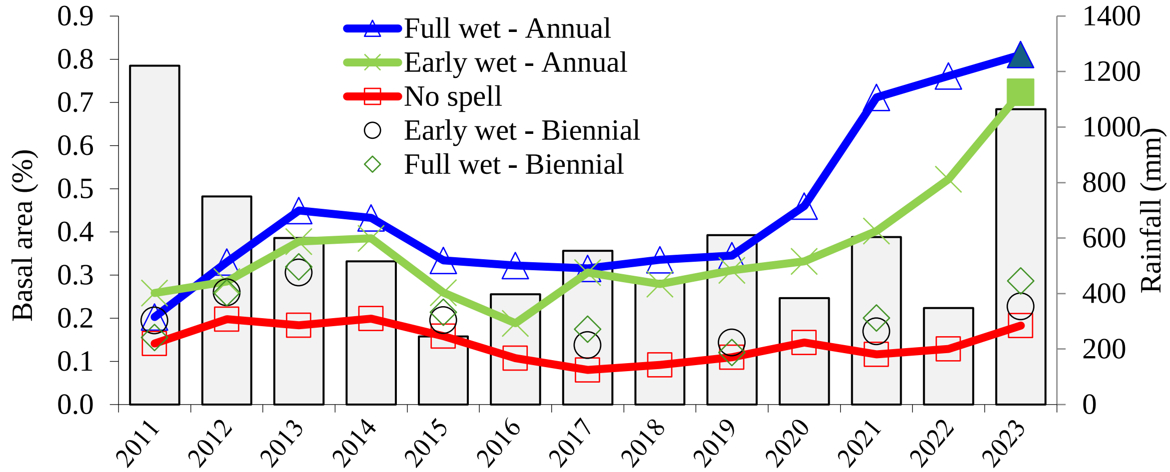

Fig. 2. Change in the basal area of B. ewartiana with different spelling treatments or no spelling in the moderate stocking rate treatment. (Values with a closed symbol in 2023 are significantly different to those with an open symbol; $P < 0.05$.)

The increase in basal cover of *B. ewartiana* in the MSR (Fig. 2) resulted predominantly from the increased basal area of the surviving, original plants from 2011 (Fig. 3). However, new recruits made an increasing contribution to basal cover in later years, at least under moderate stocking. For example, in 2017 the basal area occupied by recruits was 0.04% of a total 1.02% in the MSR.

However, by 2023, basal area from original plants was 1.72%, while the area occupied by recruits was 0.49%, almost a 12-fold increase.

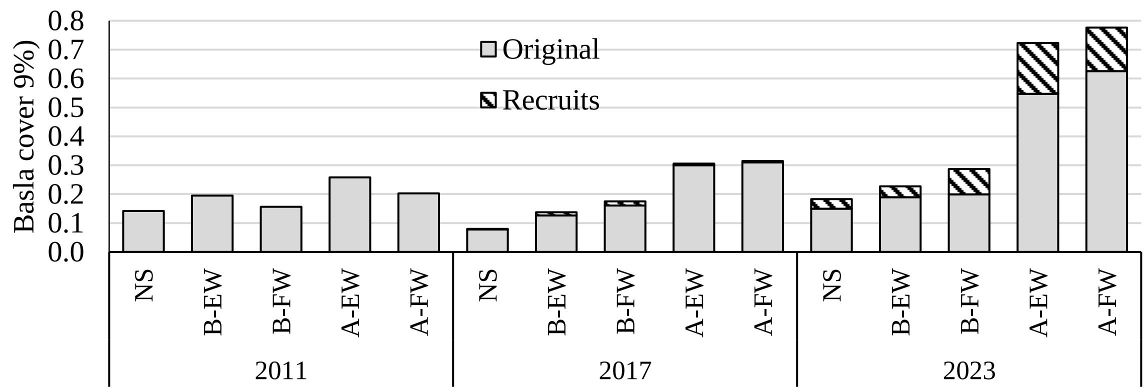

Fig. 3. Contribution of original 2011 plants and new recruits to total basal cover of B. ewartiana under different spelling regimes in 2011 and again in 2017 and 2023.

Discussion

The present study has shown that recovery of land condition can occur with the application of wet season spelling but that this can be an extended process, particularly during below-average rainfall conditions. This partly reflects the fact that *Bothriochloa ewartiana,* the key perennial grass, is a long-lived species whose recruitment appears to be limited by low seed production. These results strongly emphasise the importance of maintaining existing plants by good management, particularly going into drought, as recruitment is very slow (Orr and O'Reagain 2011).

The present results also show that recovery is far faster under annual wet season spelling than under less frequent regimes. This suggests the need for some form of rotational grazing if recovery is to occur. Importantly, spelling had no effect on *B. ewartiana* basal cover under heavy stocking. This clearly indicates that the effect of stocking rate overrides that of spelling, that is, the benefits of spelling are only likely to be realised under appropriate stocking rates.

Can the principles of multipaddock grazing accelerate land condition recovery?

Walkington, DB[A]; O'Reagain, PJ[B,C]; Bushell, JJ[B]

Key words: short duration grazing; landscape recovery

Abstract

Recovery of land condition would significantly improve livestock carrying capacity and ecosystem services on many properties in northern Australia. Unfortunately, this is often extremely slow, even with significantly reduced stocking rates and pasture resting. There is interest amongst graziers in using the principles of intensive, multi-paddock, rotational grazing systems to accelerate recovery. However, evidence for their effectivity relative to conventional recommendations is often anecdotal and sometimes contradictory.

To test the ability of these principles to accelerate land condition recovery, a short duration grazing treatment (SDG) was implemented on two poor condition paddocks in a long-term grazing trial in north Queensland, Australia. Two experienced multi-paddock practitioners have been engaged to guide management. The treatment results can assist to develop cost-effective, evidence-based guidelines to accelerate recovery on grazing lands in northern Australia.

Introduction

Land condition has declined in many parts of northern Australia due to grazing practices that have reduced carrying capacity, productivity and ecosystem services. Recovery of the land condition of these areas will have substantial financial and ecosystem benefits but can be extremely slow even with significantly reduced stocking rates and pasture rest, e.g., McIvor (2001). There is growing interest amongst graziers in the use of multipaddock rotational grazing (MPG) to accelerate recovery. These systems vary but in essence involve short grazing periods, moderate to high stock densities and long rest periods, all applied adaptively.

Evidence for the superiority of MPG systems relative to simpler, more conventional, systems involving, for example, moderate stocking and occasional spelling is nevertheless contested (O'Reagain and Turner 1992; Briske *et al.* 2008; Hall *et al.* 2014). However, previous grazing trial research on MPG systems has been criticised as being unrepresentative of industry practice due to the small, relatively uniform paddocks often involved. The rigid application of MPG treatments in research rather than the more flexible, adaptive application adopted by most MPG practitioners has also been highlighted (Teague *et al.* 2013).

To test the ability of such systems to accelerate land condition recovery relative to conventional management, an MPG treatment, termed Short Duration Grazing (SDG) was established on a long-term grazing trial in north Queensland, Australia. The treatment involves applying the key principles of short grazing periods, increased herd density, and long rests (Teague *et al.* 2013) to two previously overgrazed paddocks in poor condition. To address the issue of scale, paddocks are relatively large (100 ha) and spatially heterogenous. Two producer advisors, both experienced MPG practitioners, were engaged to guide management. Here we report on the first year's application of the SDG treatment and its performance relative to the other grazing strategies in the trial.

Procedure

The trial is located on 'Wambiana' (20° 34' S, 146° 07' E), a commercial cattle station 70 km south of Charters Towers, Queensland, Australia. Long term (114 year) mean annual rainfall is 643 mm (C.V.= 40%), with 70% falling in the hot summer months. The vegetation is an open *Eucalyptus-Acacia* tropical savanna overlying C4 tropical grasses. Soils are relatively infertile, ranging from texture contrast to heavy clays. The main trial was established in 1997 with five grazing strategies: heavy stocking (HSR: 5 ha/AE [1 AE=450 kg steer]), moderate stocking (MSR:10 ha/AE), rotational wet season spelling (R/Spell: 10 ha/AE) and flexible (Flex) stocking (4 to 20 ha/AE) applied with/without spelling (S). Treatments are replicated twice. In May 2022, the HSR strategy was terminated with these paddocks used for the SDG treatment from November 2023 onwards.

Paddocks are approximately 100 ha in size and contain a mix of soil-vegetation types in similar proportions. Treatments are grazed by Brahman cattle managed according to industry recommendations (O'Reagain *et al.* 2009). For the SDG treatment, a large herd of cattle from the surrounding property is utilised.

Grazing management and data collection

Prior to grazing, SDG paddocks were assessed and a weighted forage budget based on the proportion of usable forage and a 25% utilisation rate of the 3-P species used to calculate the number of stock grazing days available. The appropriate grazing period was then calculated for each paddock based on the number, weight and reproductive status of the cattle available.

To monitor treatment effects pasture species composition and yield were assessed in the late wet season (May) using the Botanal procedure (Tothill *et al.* 1992). Pasture species are grouped for presentation as: 3-P grasses (palatable, preferred perennials), 2-P grasses (palatable/productive, perennials), annual grasses, legumes, wiregrasses (*Aristida* and *Eriachne* spp.) or 'other' (other grasses, forbs and sedges). An attempt was made to measure animal weight gains using remote Optiweigh[15] walk over platforms but given the short grazing periods, this was unsuccessful. Faecal samples were also collected for diet quality analysis but are yet to be analysed.

Results

Seasonal conditions and treatment implementation

Following nine consecutive (2012-2022) below median, rainfall years, the 2021/22 season was particularly harsh, with extremely low pasture availability at the end of the usual wet season in May 2022. Given the lack of forage (<500 kg DM/ha), the HSR, MSR and R/Spell paddocks were destocked. The two Flexible stocking strategies remained stocked as the progressive adjustment of stocking rates in preceding years had ensured sufficient forage for the approaching dry season.

Paradoxically, the destocking decision was followed by record winter rains, resulting in exceptional (1064 mm), well distributed precipitation over the 2022/23 season. Consequently, the HSR, MSR and R/Spell paddocks

[15] Optiweigh, Armidale, NSW, Australia

experienced a full year's rest under ideal conditions. The MSR and R/Spell were fully restocked in June 2023. The former HSR paddocks were also lightly stocked (12 ha/AE) for four months from July to October 2023.

The SDG treatment effectively began in November 2023 with these paddocks rested for five months until late March 2024 when they were grazed by 354 heifers (443 AEs) for 1.5 and 2 days each. The paddocks were grazed again in late July 2024 by 406 cows (500 AEs) for 2 and 3 days each. These two grazing periods yielded 26 stock days/ha (averaged over both paddocks), compared to the 29 to 36 stock days/ha/year removed from the other treatments on the trial.

Pasture composition

Total pasture yield and 3-P grass yield increased more than four-fold in the SDG treatment between the end of the HSR treatment in 2022 and the start of the new treatment in 2024 (Figure 1). However, the fact that yields also increased to a similar extent in all treatments indicates that this response was almost entirely due to the exceptional rainfall received and the long intervening periods of rest before the SDG treatment was initiated. Interestingly, despite these favourable conditions, both total and 3-P species yield were still lower in the SDG than in the other treatments. This appears to reflect the legacy of the previous 26 years of heavy grazing on the condition of these former HSR paddocks. This legacy effect will be accounted for by comparison of pasture change relative to the other simpler, systems in the trial.

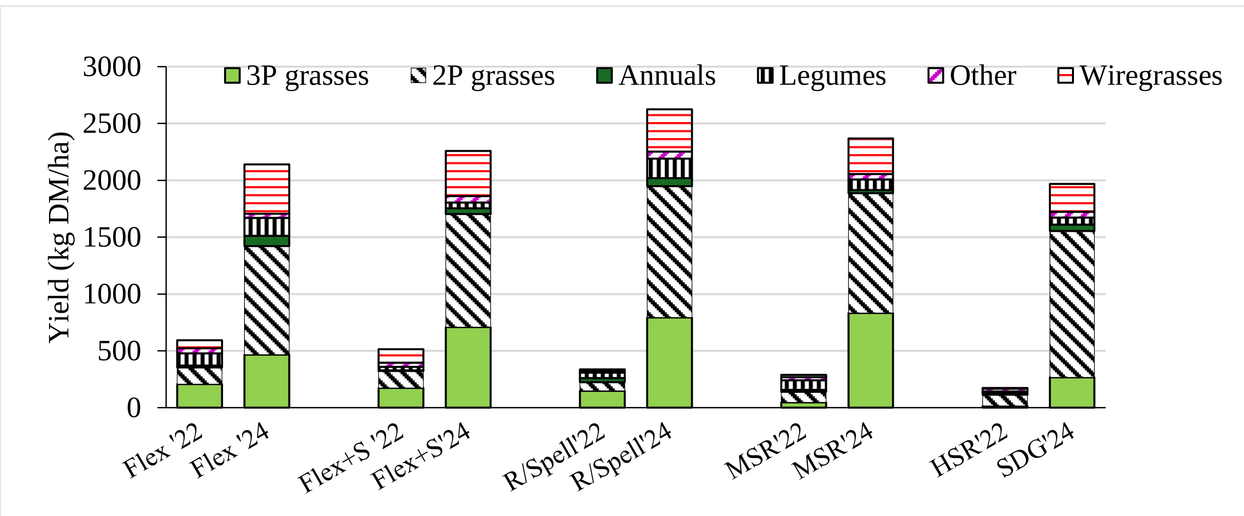

Figure 1: End of wet season (May) pasture DM yield and species contribution to yield in the Short Duration Grazing treatment (SDG) in 2024 compared to the other treatments in 2022 and 2024. See text for abbreviations.

Despite these initial positive results, the available evidence suggests that full recovery is likely to be very slow, e.g., McIvor (2001). In other work at the Wambiana trial site, the key perennial grass *Bothriochloa ewartiana* took nearly 12 years to recover following previous overgrazing, despite reduced stocking rates and annual wet season spelling (O'Reagain *et al.* 2023). Nevertheless, recovery could well be faster in the SDG treatment given the longer, more frequent rest periods and the close matching of grazing pressure to forage availability.

Discussion

The SDG treatment will be continued with the key principles applied adaptively, based on seasonal conditions and pasture response, allowing changes in land condition to be compared to the other simpler, more conventional management treatments on the trial site. Grazing exclosures within the SDG treatment will also allow the separate effects of complete rest and rest with managed grazing on recovery to be quantified.

One challenge will be assessing animal production in the SDG to enable a full assessment of the costs and benefits relative to other systems. An attempt is being made to assess weight gains using remote walk over weighing technology but given the very short grazing periods has not been successful. However, diet quality data combined with stock days per hectare may allow the profitability of the SDG system relative to other treatments to be modelled. Whatever the outcome, these results will be valuable in informing industry of the relative ability of different management techniques to accelerate recovery of paddocks in poor condition. We look forward to reporting this data as the project continues.

Legume establishment in challenging environments of northwest Queensland

Hay, KE*; Cox, KG*; Lemin, CD*; English, BH*; Dayes, SA*; Bambling, LR*

* Department of Primary Industries, Queensland.

Abstract

Establishing legumes on Mitchell Grass Downs country in northwest Queensland has the potential to reduce seasonal nutritional deficiencies, and subsequently increase animal performance within beef production systems. Legumes present an opportunity to increase crude protein (14 to18%) and metabolizable energy (8 to10 MJ/ME/kg DM) in the diet, as the nutritional quality of grass dominant native pastures declines markedly during the dry season (May to October).

Recent research initiated by the Queensland Government, with support from the Australian Government and Meat and Livestock Australia (MLA), has trialled establishment of deep-rooted and productive legumes (*Desmanthus, Stylosanthes*) on a property 80 km northeast of Julia Creek, Queensland.

This site is characterised by naturally treeless cracking clay soils, highly variable summer-dominant rainfall, (550 mm average annual rainfall, CV=0.43) and is highly susceptible to drought. The soil contains adequate Colwell phosphorus levels for legume growth (12mg/kg), however, sulphur (MCP) is low (4.6mg/kg). Rainfall variability, highly competitive adapted annual grass species and high summer temperatures (average maximum of 38ºC) make establishment of legumes difficult.

In January 2024, following 350mm of rain, uncoated *Stylosanthes seabrana* (Caatinga stylo, Primar) and scarified *Desmanthus* (Ray and Progardes) was broadcast onto cultivated strips (10 m wide) prior to further anticipated rainfall. No herbicide or fertiliser was applied. Assessment in March 2024 showed good seedling populations of desmanthus (~20/m^2) with fewer Caatinga stylo (~5/ m^2). In May 2024, the survival of seedling populations under a dense monoculture of Flinders grass (*Iseilema spp.)* was observed. Further measurements will be completed following the 2024/2025 wet season to confirm successful establishment of mature *Desmanthus* and *Stylosanthes* on this site. This research was initiated due to regional producer interest and will be utilised in extension efforts under the north Queensland Pasture Resilience Program (https://futurebeef.com.au/resources/qprp/).

Introduction

Queensland's beef cattle industry is the largest across all Australian states, with 10.7 million head (49% of the national herd) being recorded in Queensland (MLA 2022). The Northern Mitchell Grass Downs country in northwest Queensland has a semi-arid climate, with summer dominant rainfall typically from November to April. Wet season rainfall is reliant on the monsoon trough, and this is followed by a consistent and extended dry period from May to October. During this dry period, the quality of native perennial pastures, Mitchell grass (*Astrebla* spp.*)* and the highly competitive annual grass species Flinders grass (*Iseilema* spp.*),* declines significantly. This decline results in a nutritional deficit for beef cattle production, one of the area's main industries.

The production systems in the Northern Downs are predominantly extensive beef cattle grazing businesses on ‘unimproved’ rangelands native pastures (Chilcott, 2020). Desmanthus (*Desmanthus* spp.) and Caatinga stylos (*Stylosanthes seabrana*) are potentially useful legumes for the region due to their persistence on heavy clay soils in low rainfall environments under grazing, and high levels of seed production enabling them to recruit new plants for long-term pastures (Hall, 2005, Peck, 2012). Introducing legumes into the grazing environment provides an additional, readily-digestible feed source containing improved crude protein (14 to18%) and metabolizable energy (8 to10 MJ/ME/kg DM), mitigating the dry season nutritional shortfall. Compared to grass-only pastures, legume-grass pastures allow cattle to select a diet of higher quality and digestibility, often leading to increased intakes and improved animal production (live weight gain, reproduction) (Gardiner, 2016). Long term stocking rates for land in good condition vary from 10 to 15 ha for an Adult Equivalent animal (450 kg steer).

Northwest Queensland is considered a challenging environment for legume establishment due to its low annual average rainfall (550mm), high rainfall variability (CV=0.43), high summer temperatures (average maximum of 38ºC) and susceptibility to drought (Chilcott, 2020). Treeless cracking clay soils that are common in this area experience surface crusting that challenges seedling emergence if there has been rain after sowing and before seed germination. Soil phosphorus fertility is generally adequate for legume growth (Colwell 12mg/kg); however, sulphur is low (MCP 4.6mg/kg). Although responses to applied P and S are likely, application of fertiliser on extensive areas is costly and overall is not considered a viable option for legume pastures in this region.

Establishment of suitable legume strips into existing Mitchell and Flinders grass pastures has the potential to help to lessen the seasonal protein and energy shortages for grazing animals and support improved animal weight gain and production. The deep tap root of these legumes supports the production of green leaf well into autumn and winter. Additional benefits expected from introduction of legumes also include increased access to high quality forage, increased nitrogen fixation in the soil and thus improved soil fertility.

In response to regional grazier interest into methods to effectively establish pasture legumes in the region, a small on-property demonstration was developed by Queensland’s Department of Primary Industries with support from the Australian Government and Meat and Livestock Australia. This site will be utilised under the Queensland Pasture Resilience Program to demonstrate feasible options for establishing legumes in northwest Queensland under challenging environmental conditions.

Methods

Following 350mm of rain and prior to further anticipated rainfall, a 10-ha unfenced site within a larger paddock was directly sown into 6m x 1000m strips. Caatinga stylo (Primar) and desmanthus (Ray and Progardes*)* were tested for germination performance (8/16 hours, 20/35° Dark/Light) and treated for hard seed dormancy by mechanically scarifying seeds prior to planting. The site had previously contained dense Flinders grass that had been baled to reduced existing dry matter. Sowing rates were adjusted to account for low germination percentage (hardseed content) and are presented in Table 1. No herbicide was applied.

No fertiliser was applied to best replicate typical extensive beef production systems in the region and to determine viable options for legume establishment in existing soil conditions. The seed was oversown into the cultivated strips using a fertiliser spreader. Rainfall on the site (30mm) shortly after planting prohibited planned rolling from occurring. A further 130 mm of rainfall was recorded from planting until the first assessment. At the first assessment in March 2024, seedling populations were recorded based on frequencies per m^2. Observations in May 2024 confirmed seedling survival. Further population counts, and pasture yields will be taken at the end of the 2024/2025 wet season.

Table 1. Legume species and adjusted sowing rates used in the legume establishment trial

Species	Variety	Recommended sowing rate (kg/ha)	Acceptable germination %	Germination test %	Adjusted sowing rate (kg/ha)
Desmanthus	Ray and Progardes	2 kg/ha	70%	60%	2.3 kg/ha
Caatinga stylo	Primar	2 kg/ha	70%	40%	3.5kg/ha

Results and Discussion

Initial seedling establishment was successful for Desmanthus populations (~20/m^2), but fewer Caatinga stylo plants (~5/ m^2) were recorded in the trial strips. The seedlings were small (estimated 3 to10 cm in height) however, and under a dense monoculture of Flinders grass. Most of the seedlings survived until May when the Flinders grass began to senescence but would undoubtedly have suffered from competition for light and nutrients. The rapid establishment of Flinders grass seedings needs to be considered when using cultivated strip systems. Potential options could be staggered cultivations to kill Flinders grass seedlings before sowing, either by repeated cultivation or application of a suitable herbicide before or immediately after sowing, or the use of selective herbicides to control the grasses post-emergence.

Despite the competition from the Flinders grass, this small strip trial indicates potential for simple approaches to desmanthus and Caatinga stylo planting and establishment into northwest Queensland Mitchell Grass Downs pastures. If further yield measurements confirm successful establishment, it may pave the way for successful adoption of legumes into these environments, with a range of associated benefits for pasture quality, soil improvement and animal performance.

Institutional capacity building and co-design of novel management practice unlock greater potential in communal grazing lands in Sub-Saharan Africa

Sircely, J[1]

[1]Livestock, Climate and Environment, International Livestock Research Institute (ILRI), PO Box 30709 Nairobi 00100 Kenya

Key words: capacity building; grazing management; rangeland restoration; pastoralism; aridity

Abstract

In communal grazing lands in Sub-Saharan Africa, two immediate problems face pastoralists and other users of communal lands: (1) weak local institutional oversight of common pool resources in grazing lands; and (2) inadequate evidence for the cost-effectiveness of various grazing management and restoration practices, especially in arid and other non-equilibrium rangelands. In this synthesis of local capacity development and restoration work across multiple systems and locations, it is shown that there are significant commonalities in terms of how progress may be achieved, as well as a number of important differences. Specifically, shared commonalities include: capacity building of grazing management institutions improves local oversight; local or ‘traditional’ knowledge may be generally sufficient for grazing management, though can improve with appropriate integration of global or ‘expert’ knowledge; local knowledge may be generally insufficient for restoration, but has a strong role to play; implementing new grazing management or restoration practices requires fitting to local systems, plans, and goals; this fitting can be accomplished through pastoralist–expert co-design of grazing and restoration practices; and, as decades of development experience have shown, new grazing management or restoration practices that fit local conditions poorly are generally ineffective or unsustainable. Differences among systems and locations include aridity and associated equilibrium (more humid rangelands are less variable) and non-equilibrium (more arid rangelands are more variable) ecosystem behavior; degree of privatization; livelihood priorities (crops, livestock, or both) and management goals; scale of grazing lands and their institutions, and processes and rate of capacity development; degree of previous degradation and rate of change in range condition; and the technical practices applied. Not only are these commonalities and divergences useful for improving environmental performance including carbon storage, they are essential to supporting local pastoralist institutions to enhance resilient livelihoods.

Introduction

Communal grazing lands in Sub-Saharan Africa face two immediate challenges—the strength of local institutional oversight, and inadequate evidence for the cost-effectiveness of management practices. Local institutions responsible for management of common pool resources in grazing lands have become weakened (Reid et al. 2014) in many pastoralist rangelands around the world, partly due to weak security of land tenure, lack of investment and support, and policies that are inadequate or ill-fitting in communal rangelands. Where cohesive communal management does not exist at local level, weak oversight allows for chaotic and disorganized grazing patterns, a significant driver of rangeland degradation in combination with climate change-induced volatility in rainfall. Meanwhile, evidence for the relative cost-effectiveness of various grazing and restoration practices is generally inadequate (Mudau et al. 2022) or even absent, and most especially so in arid rangelands. While pastoralist local knowledge on grazing management is generally strong, local knowledge on restoration is often less developed and effective in addressing new challenges linked to climate change and other pressures upon rangeland systems. Experience in local capacity development, and in restoration co-design, across multiple systems and locations shows several commonalities among rangelands, as well as important differences that are often associated with variation in aridity.

Results

Commonalities among rangelands and regions

Capacity building of local institutions can significantly improve oversight of grazing management. Improvement in local institutional capacity to manage rangelands is a commonly noted initial result of CBRM approaches, time and again, from southern (Coppock et al. 2022) and East Africa (Reid et al. 2021, Waweru et al. 2021) to central Asia (Ulambayar and Fernández-Giménez 2019). Neither good nor poor management should be assumed, as in practice, rangelands with poorly functioning local institutions can be as common as those functioning well, generally speaking. The goal of practitioners supporting community range management should be helping local institutions to progressively and sequentially develop and intensify their system toward optimal livestock production and environmental performance. Introducing new grazing management or restoration practices requires fitting into local systems, plans, and goals (Bayer and Waters-Bayer 1989), and producer–practitioner–researcher co-design of grazing (Sircely and Seidou 2018) and restoration (Sircely and Seidou 2018, Sircely et al. 2022) practices can accomplish this fitting.

In many rangelands, local or traditional knowledge can be sufficient for reasonably sustainable pastoralist rangeland livestock production, with modest impacts on rangeland ecosystems, and high wildlife compatibility, often in spite of dramatic climatic volatility. Local or traditional knowledge is highly useful for grazing management (Reid et al. 2014, Sircely and Seidou 2018), yet appropriate and cost-effective integration of global or 'expert' knowledge may significantly benefit management through regenerative grazing techniques. However, it remains exceptionally difficult to prescribe grazing management practice that can deliver win-win pastoralist livelihoods and environmental conservation (Bayer and Waters-Bayer 1989, Ferguson 1990). Prior understanding of basic spatial patterns of local rangeland use through the seasons of the year is required before advising a certain community on a basic grazing plan, into which restorative or regenerative grazing techniques can be fitted (Robinson et al. 2020), as feasible given the various constraints they face. To ensure that novel grazing practices are successful, practitioners and researchers must first understand the basics of local systems, by mapping out the rangeland with pastoralists, and clarifying their formal or informal grazing plans and bylaws or other means for encouraging adherence to these grazing plans. Potentially effective and feasible means of improving the grazing plans can then be suggested by practitioners or researchers (Robinson et al. 2020). Most of the proposed options are likely to be rejected by pastoralists as infeasible. Any options that are not rejected can be considered further, or the proposed options can be modified to improve feasibility.

For rangeland restoration, local knowledge is useful—and often essential—although producer–expert co-design will generally produce better tailored, more effective, more sustainable, strategic rangeland investments. The degradation observed in most rangelands is historically a relatively new problem, one significantly attributable to erratic rainfall resulting from global climate change (Girvetz et al. 2019), along with other more recent trends such as conversion to farms or private lands that place great pressure on communal rangeland systems (Galvin et al. 2008). In rangelands, foresight for a decade or more ahead is an absolute requirement for effective restoration planning. To achieve this type of vision, the fusion of global scientific knowledge (if shallow or 'skin-deep') with highly local producer knowledge (yet deep over decades to millennia) may be considered fundamental. The role of researchers in producer–practitioner–researcher collaborative design infuses research with both internal and external validity (Sircely et al. 2022). Site selection and restoration technique targeting to specific sites serve as an excellent example—pastoralists sometimes wish to pursue more "modern", intensive techniques on severely degraded lands, at high cost per area and with a moderate or higher risk of failure. Alternatively, the same resources might be better invested in the restoration of much larger areas, through less intensive or more passive techniques in lands only moderately degraded, at low cost per area and with a low risk of failure. Benefit:cost analyses are desperately needed to quantify the cost-effectiveness of various restoration techniques across gradients of contextual factors in rangelands, especially aridity. Development of low-cost, 'light-touch', ecosystem-based techniques, enabling feasible restoration of very large rangeland areas, is needed to provide alternatives to costly measures with mixed success rates (Mudau et al. 2022). For restoration, experience shows that producer–practitioner–researcher co-design and testing of restoration techniques, combined with support on restoration planning, is an effective strategy to identify, plan, and implement rangeland restoration at scale.

Differences among rangelands linked to aridity

In arid desert and semi-desert zones (e.g., < 350 mm/yr in the tropics), an individual rangeland (or 'rangeland unit' managed by a particular local rangeland management institution) will generally be much larger than in semi-arid zones (in turn larger than in humid climates), much like private ranches. As a result, pastoralist institutions that oversee rangeland management operate at vastly different spatial scales, from < 100 km^2 in wetter semi-arid climates to > 5,000 km^2 in the most arid zones in East Africa, for example. As aridity increases, livelihood alternatives to livestock become much more limited, with rainfed cropping infeasible in arid areas and access to markets and services severely restricted by the remoteness of many desert areas. As livelihood priorities shift toward livestock, so too do land management objectives. In semi-arid regions, where rainfed cropping and non-mobile livestock production are often feasible, the rate and degree of privatization of communal land are often much greater than in arid zones. Each of these factors contributes to the lower populations in arid regions, as well as lower livestock densities. As scale increases, so too do transport and transaction costs for local institutions, along with the need for local institutions to communicate and coordinate with lower-level sub-units of a rangeland covering a vast area. These social constraints combine with the fundamental control of low and variable rainfall to determine the feasibility and cost-effectiveness of various rangeland management options along the gradient from semi-arid to arid rangelands.

Aridity has mixed costs and benefits for rangeland livestock production. Agro-ecologically, there are dramatic differences between wetter semi-arid savanna rangelands and arid desert and semi-desert rangelands. Low and extremely variable rainfall in arid rangelands requires people and livestock to be more mobile, enhancing the resilience of these rangelands to degradation in terms of woody encroachment and loss of grass cover, and enabling these rangelands to respond quickly to restoration. In more arid zones, non-equilibrium rangeland dynamics prevail (Ellis and Swift 1988), where extreme variability in rainfall makes prediction of spatial patterns of rainfall nearly impossible at the scales of rangeland management, and where carrying capacity rises and falls annually or seasonally depending on how much rain falls (Behnke and Scoones 1992, Campbell et al. 2006). Equilibrium rangeland dynamics, in which predictable rainfall enable more confident forecasting of carrying capacity, occur in more humid rangelands and in wetter semi-arid rangelands. Not only are non-equilibrium rangelands more variable, they are less susceptible to degradation (von Wehrden et al. 2012), and are often in a less degraded state than many semi-arid rangelands. Social factors that contribute to the lower vulnerability of arid rangelands to degradation include the the lower likelihood of receiving pastoralist visitors from elsewhere, both during the annual dry seasons and during major large-scale droughts, along with decreasing susceptibility to forcible invasion given that these areas dry out before semi-arid zones. Finally, lower rainfall and the infeasibility of rainfed cropping in most arid rangelands reduces their susceptibility to farm conversion and rangeland fragmentation, which often lead to further degradation of rangelands. Consequently, changes in rangeland condition in response to restoration or modified grazing management are generally much faster in arid than in semi-arid rangelands.

As a result, the technical practices applied by pastoralists often change with aridity—high rainfall variability often leading to more flexible, opportunistic management (Westoby et al. 1989). In arid areas, grazing management practices often become less reliant on predictable, pre-planned, prescribed resource use, and more reliant on the flexibility that allows tracking and utilization of rapidly changing resources in an opportunistic manner. Similarly, decision-making processes and the means for achieving community members' adherence to bylaws and management plans are often more flexible and less prescribed in advance, rather evolving in real-time as conditions change in these erratic environments. Restoration practices should generally differ (Sircely et al. 2022), with large arid rangelands requiring more low-cost, 'light-touch', ecosystem-reliant techniques as opposed to heavily input-reliant intensive restoration approaches that may cost more than they produce.

Discussion

The commonalities and aridity-linked divergences noted here may be practically useful in several ways to those seeking to support pastoralists to enhance resilient livelihoods. The uses may include, but are not limited to, approaches for capacity building of local pastoralist range management institutions, as well as enhancing the environmental performance of rangeland restoration in pastoralist areas. Aridity, scale, and remoteness arguably constrain almost all aspects of land management in communal pastoralist rangelands, firstly by limiting the production of forage and browse, livestock, and other ecosystem services. In arid zones, the long distances and low population density reduce market access, increase the cost of service delivery, and create large transaction costs for local institutions responsible for coordinating grazing management. Limited livelihood options in arid rangelands leads to greater livestock-dependence. Grazing practices generally differ along this aridity gradient, becoming more flexible and opportunistic, as do decision-making and means for achieving adherence to bylaws. Restoration practices should generally differ as well, with large arid rangelands requiring more ecosystem-reliant techniques as opposed to input-reliant approaches.

Greater emphasis should be placed on conducting basic research in truly arid systems, including validation of remote sensing and ecosystem simulation models, documentation of local or traditional management goals, practices and their effects, and integration of these to bring pastoralist rangeland management into the 21st century through co-design processes. The extreme variability and context-dependency of socio-ecological dynamics in arid rangelands most especially underscores the need for action research and co-design. In the meantime, the important aridity-related differences highlighted here, as well as the commonalities among pastoralist rangelands, provide significant information that can greatly inform the design of rangeland management and restoration approaches for communal pastoralist rangelands.

Abstract

Enteric methane emissions (eCH_4) from ruminants are the main source of greenhouse gas (GHG) from the livestock sector in sub-Saharan Africa (SSA). The SSA countries face significant challenges in assessing their climate commitments in the livestock sector, particularly in terms of mitigation measures due to the lack of accurate GHG data obtained through *in vivo* measurements. The objective of this study was to directly measure and analyze eCH_4 in pastoral and agropastoral systems using an advanced methodology: the GreenFeed® system. Different ruminant feeding strategies were tested with the aim to identify those that contribute to the reduction of absolute emissions, emission yield, and emission intensity. Cattle were fed natural rangeland fodder, cultivated forage (green and hay), and combinations of grass with main crop coproducts or legume tree forage. Data collection lasted 2.5 years and included 35 trials (diets). Each trial lasted 3 weeks and was split into 2 weeks of diet adaptation and 1 week of data collection. The dry matter (DM) intake in animals was 20±2.4 (12 to 29 g/kg of body weight per head), the DM digestibility, 48±4.6 (30 to 70 %), and the eCH_4 emissions, 70±17.8 (28 to 114 g/d per head). Green herbaceous forage and tanniferous forage, such as legume tree forage and legume crop co-products, showed good potential to increase livestock productivity and reduce eCH_4 emissions yield by up to 33%. These results will help policymakers promote clean technologies and sustainable livestock practices in SSA, and help implement the IPCC Tier 2 methodology to accurately estimate emission factors by cattle categories and breeds.

Introduction

In extensive livestock farming (pastoral and agropastoral) in Sub-Saharan Africa (SSA), animal productivity is low, resulting in higher emission intensities (mass per unit of product) and yields (mass per unit of intake). Depending on the type of ruminant livestock system, enteric methane (eCH_4) can contribute up to 61% of total carbon emissions from a livestock system (de Figueiredo et al. 2017). According to Gbenou et al. (2024a), the hot dry season has the greatest potential for eCH_4 mitigation because it is the period when eCH_4 yields are very high.

The low quantity and quality of feed resources during this season on rangeland that prevents the rumen from functioning optimally is one of the causes.

Feeding strategies suggested in the international literature on GHG mitigation, in particular eCH_4, are often not adapted to the SSA context because they involve costly inputs that are inaccessible locally. Furthermore, they sometimes are in competition with animal productivity and are technically complex to apply. In contrast to these literature strategies, SSA's livestock farmers have access to a variety of crop coproducts, tree legumes, and agro-industrial byproducts, which they use for feeding their animals in agropastoral systems (Gbenou et al., 2024b). The aim of this study was to test the eCH_4 mitigation potential of these locally available and accessible feed resources with the goal to promote low-carbon livestock system in SSA.

Methods

The study was carried out at an experimental station in South-Western Burkina Faso. The study involved ten Sudanese Fulani zebu steers of 2.7±0.1 years and 138.4±10.1 kg average, kept in a barn. Grasses, such as *Panicum maximum* C1 (hay and green), *Andropogon gayanus* (hay), and *Brachiaria ruziziensis* (hay), and rangeland fodder (hay or green), according to seasons were used to feed the steers. Cattle were also supplemented with the most commonly used livestock feed, selected from a survey of farmers: cereal coproducts (maize, sorghum, millet and rice straws), legume coproducts (cowpea and peanut haulms), and tree legumes (*Gliricidia sepium* and *Leucaena leucocephala* dry leaves). The animals were fed at an intake level of 3.2% or 2.3% of their body weight (BW) in dry matter (DM). The grasses and rangeland fodder were provided as stand-alone control diets (100%) or mixed with crop coproducts or LEGTREE legume in constant proportions (75:25 on a DM basis, experimental diets). Access to lick stone and water was *ad libitum*. Data collection lasted 2.5 years and included 35 trials (diets). Each trial corresponded to a diet and lasted 3 weeks split into 2 weeks of diet adaptation and 1 week of data collection. The diets were grouped into four categories: 1) grass diets (diets with 100% *P. maximum* C1, *A. gayanus*, *B. ruziziensis*, or rangeland fodder - GRASS), 2) cereal coproduct diets (mixed diets containing grass and cereal coproduct at 75:25 ratio - CEREAL), 3) legume coproduct diets (mixed diets containing grass and legume coproduct at 75:25 ratio - LEGUME), and 4) tree legume diets (mixed diets containing grass and leaves of tree legume at 75:25 ratio - LEGTREE).

Table 1: Average chemical composition of diets offered to Sudanese Fulani zebu steers.

Item	GRASS	CEREAL	LEGUME	LEGTREE	SEM	P-value
DM (g/kg diet)	96.1	92.2	92.5	94.6	0.01	0.074
OM (g/kg DM)	823.8 ^{B}	806.5 ^{D}	817.0 ^{C}	909.6 ^{A}	0.09	<0.001
CP (g/kg DM)	26.9 ^{C}	29.0 ^{C}	61.8 ^{B}	99.9 ^{A}	0.14	<0.001
NDF (g/kg DM)	689.7 ^{A}	645.9 ^{C}	598.5 ^{D}	658.5 ^{B}	0.35	<0.001
ADF (g/kg DM)	429.5 ^{A}	400.5 ^{C}	386.1 ^{D}	408.3 ^{B}	0.18	<0.001
GE (MJ/kg DM)	16.5	16.2	16.5	19.1	0.04	0.103

GRASS: diets with 100% *P. maximum* C1, *A. gayanus*, *B. ruziziensis*, or rangeland fodder; CEREAL: mixed diets containing grass and a cereal coproduct at 75:25 ratio; LEGUME: mixed diets containing grass and a legume coproduct at 75:25 ratio; LEGTREE: mixed diets containing grass and leaves of tree legume at 75:25 ratio; DM: dry matter; OM: organic matter; CP: crude protein; NDF: neutral detergent fiber; ADF: acid detergent fiber; ADL: acid detergent lignin; GE: gross energy

A,B,C Values within a row with different superscripts differ significantly at $P < 0.05$

Daily individual DM intake was calculated as the difference between the quantities offered and refused. Daily excreted faeces were collected from faecal bags fitted to each animal for apparent digestibility calculation. Individual representative samples of feed (offered and refused) and faeces were collected daily, and their chemical compositions were determined using NIRS (CIRAD laboratory, Baillarguet, France), as described by Gbenou et al. (2024a, 2024c). The eCH_4 emissions were measured using a GreenFeed® (GF) unit (ID: 252, C-Lock Inc., SD, USA). Measurement times were tailored to the feeding behaviour of the animals, with random access to the GF unit at 6:30 am (overnight fast), 10 am (immediately after feed intake), 2 pm (during rumination) and 6 pm (immediately after feed intake and at sunset). On the 7th day (last day) of each trial, an additional measurement was performed at 00:00 (during total rest). The total number of visits was 29 per animal per feeding condition, exceeding the minimum number of 20 visits recommended by Manafiazar et al. (2017). Each animal spent an average of 3 min±02s (2min20s to 4min15s) at the GF unit per visit.

All statistical analyses were performed using R software version 4.1.2. (R Core Team 2021). The DM intake, apparent digestibility, and eCH_4 emissions were analyzed using the general linear model (GLM) procedure. The least squares means and their SEM presented a table were compared using the duncan.test (de Mendiburu 2023) in the event of a significant difference (P<0.05). The statistical model used for the variance data analysis was $Y_{ij} = \mu + C_i + (1 \mid A_j) + \epsilon_{ij}$, where Y_{ij} = variable of interest; μ = overall average; C_i = fixed effect representing the different diet categories; A_j = random effect representing individual variations among animals; and ϵ_{ij} = residual error.

Results

Chemical composition of diet categories

The CP contents in LEGUME and LEGTREE were twice and three times those of GRASS or CEREAL, respectively (Table 1). Fiber content was lower in all categories of mixed diets (P<0.001).

Diet intake and digestibility

The highest intake was obtained with LEGUME and LEGTREE. No significant difference in DM digestibility was observed between diets (Table 2).

Enteric methane emissions

All supplemented diet's categories (CEREAL, LEGUME and LEGTREE) induced eCH_4 yield (g/kg DMI) mitigation from 19% to 47% compared with GRASS (Figure 1). The eCH_4 mitigation in %GEI followed the same patterns in diet's categories (Table 2).

Table 2: Dry matter intake, feed apparent digestibility, and eCH_4 emissions by Sudanese Fulani zebu steers fed different diet categories

Item	GRASS	CEREAL	LEGUME	LEGTREE	SEM	P-value
DMI (g/kg LW)	16.4 ^{B}	18.0 ^{B}	25.5 ^{A}	26.2 ^{A}	0.31	0.006
DMd (g/kg DMI)	46.0	48.1	49.7	48.8	0.00	0.092
eCH_4 (g/kg DMI)	30.6 ^{A}	24.8 ^{B}	22.3 ^{BC}	20.0 ^{C}	0.53	<0.001
eCH_4 (% GEI)	9.3 ^{A}	7.9 ^{B}	6.8 ^{BC}	5.8 ^{C}	0.17	<0.001

GRASS: diets with 100% *P. maximum* C1, *A. gayanus*, *B. ruziziensis*, or rangeland fodder; CEREAL: mixed diets containing grass and cereal coproduct at 75:25 ratio; LEGUME: mixed diets containing grass and legume coproduct at 75:25 ratio; LEGTREE: mixed diets containing grass and leaves of tree legume at 75:25 ratio; DMI: dry matter intake, DMd: dry matter digestibility; eCH_4: enteric methane, GEI: gross energy intake

Discussion and Conclusion

This study investigated local feeding practices with the aim of identifying mitigation options for low-carbon livestock systems in Sub-Saharan Africa (SSA). The feeding practices tested are among the most widely available in West Africa and the most commonly used by livestock farmers (FAO 2014; Sib et al. 2019). GRASS can provide sufficient quantities above the daily required CP (7% DM) recommended by NRC (2000) for ruminant maintenance. LEGUME and LEGTREE presented high nutritional quality (CP) compared with GRASS and CEREAL due to the nutritional quality of different resources used to supplement animals. In fact, legume crop coproducts are more nutritious than cereal crop coproducts (Jarial et al. 2020), and legume trees are more nutritious than legume crop coproducts (INRA 2018).

DMI varied according to diet categories. The highest intake obtained with LEGUME and LEGTREE was associated with their highest CP content (Gaviria-Uribe et al. 2020). There were no significant differences between GRASS and CEREAL intake, which hadsimilar nutritional qualities (CP, NDF and ADF). There was no significant difference in DMd between the four diet categories despite the intake improvement in LEGUME and LEGTREE, possibly due to the effect of anti-nutritional factors (Soltan et al. 2017).

This study's innovative feature is that it demonstrates how local feeding practices in a real-world setting can help design low-carbon livestock systems, specifically by using crop co-products and legume trees. The eCH_4 yield mitigation induced by mixed diet categories was 19, 33 and 47% for CEREAL, LEGUME, and LEGTREE, respectively, and could be explained by the tannin content in those diet categories. The mitigation rates induced by LEGUME and LEGTREE are higher than those obtained with the most promising feed additives (Red seaweed and 3-nitrooxypropanol - Bovaer®) in ruminants (EPLM 2024). However, the average eCH_4 yield (24.4 g/kg DMI) recorded across all diet categories (20 – 31 g/kg DMI) was similar to that reported by IPCC (2019) Tier 2 for SSA cattle. The rate of loss of GEI in the form of eCH_4 (Ym - 15 to 52%) that CEREAL, LEGUME, and LEGTREE prevent could be redirected in milk and meat production for improved food security in SSA.

In conclusion, compared with grass-exclusive diets, local feeding practices improve diet quality and influence intake and eCH_4 emissions in livestock. Diets based on cereal and legume co-products, and legume trees resulted in significant eCH_4 yield mitigation and consequently low-carbon livestock systems.

Comprehensive strategies for sustainable rangeland ecosystem restoration

Louhaichi, M [1,2]

[1]International Center for Agricultural Research in the Dry Areas, Tunis, Tunisia. Email: m.louhaichi@cgiar.org

[2]Department of Animal and Rangeland Sciences, 304 Snell Hall, Oregon State University, Corvallis, OR 97331, United States.

Key words: Rangeland health; rangeland governance; rangeland assessment; regenerative grazing; multi-stakeholder engagement.

Abstract

The development of a resilient and sustainable pastoral landscape is crucial for reversing degradation and ensuring long-term ecological health. Historically, unsustainable practices and climate change have severely degraded these landscapes. The context for restoration involves complex socio-economic, cultural, and ecological factors, necessitating a holistic approach. Key risks and drivers of change include climate variability, land tenure conflicts, and socio-economic pressures on land use. This paper presents comprehensive strategies for sustainable rangeland restoration, drawing on over two decades of experience in arid rangeland restoration and supported by relevant existing literature. Effective planning requires a deep understanding of socio-cultural dynamics, land tenure, and rights to access, rather than focusing solely on biophysical and technical aspects. Identifying target groups that are homogenous and less prone to conflict is essential to initiate restoration efforts effectively. Setting clear restoration priorities and targets, determining appropriate interventions, and understanding the specific uses of restored areas are critical components of the planning process. The basic steps for restoring a degraded ecosystem include agreeing on a common goal, establishing robust governance structures, and devising effective strategies. Removing sources of degradation or conflict is fundamental, followed by physical and biological restoration efforts. Patience is vital, as ecological restoration is a time-consuming process. Success factors include multi-stakeholder engagement, leveraging institutional collaborations to enhance resource utilization and efficiency, securing long-term investments and commitments, and supportive national and local policies. Utilizing local practices and knowledge, along with community empowerment, ensures ownership and sustainability of the restoration process. In summary, intervention strategies for restoring degraded pastoral landscapes are site-specific, requiring tailored approaches rather than a one-size-fits-all solution. Restoration efforts must be coupled with effective management to be successful, and inappropriate policies can exacerbate damage. Developing national institutions' capacity through new tools, monitoring, and grazing management is essential for sustained restoration and rehabilitation efforts.

Introduction

The degradation of pastoral landscapes, particularly in arid regions, is a pressing environmental concern that threatens ecological stability and the livelihoods of pastoral communities. Unsustainable land use practices, exacerbated by climate change, have contributed to the widespread decline of these landscapes, leading to reduced productivity and biodiversity (Zhang et al. 2023). In fact, restoring degraded pastoral landscapes requires a multifaceted / holistic approach that integrates ecological, socio-economic, and cultural practices of the communities involved. As such, the restoration process must be rooted in a thorough understanding of local contexts, which includes identifying key risks such as climate variability, socio-economic pressures, and land-use conflicts (Semplici and Campbell 2023; Birhanu et al. 2024).

In addition to understanding these contextual factors, the success of restoration efforts hinges on planning that prioritizes stakeholder engagement, governance, and long-term sustainability (Gann et al. 2019). It is crucial to set clear restoration goals, determine appropriate strategies, and ensure the involvement of all relevant stakeholders. A collaborative and inclusive approach, leveraging local knowledge and institutional support, can help guide efforts and ensure that the restoration process is both effective and sustainable (Slayi et al. 2024).

This paper presents practical approaches for reestablishing ecological health in pastoral landscapes, drawing on two decades of experience in arid rangeland ecosystems. By examining key drivers of change and the essential elements of successful restoration. Through a synthesis of literature and case studies, critical factors that contribute to successful restoration and rehabilitation will be highlighted, with a focus on ensuring the long-term viability of both ecosystems and the communities that depend on them.

Participatory methodologies and approaches

The International Center for Agricultural Research in the Dry Areas (ICARDA) and in collaboration with the International Union for Conservation of Nature (IUCN) have developed a toolkit (Fig.1) which advocates for holistic approach for addressing the socioecological aspects leading to more resilient pastoral systems (Louhaichi et al. 2022). The key elements of the approach are listed below:

Set up the governance structure and build partnerships: This process begins with understanding the socio-cultural context, land tenure systems, and rights to access. Targeting relatively homogenous groups with minimal conflicts can further support restoration efforts (Naylor et al. 2012) Collaborative partnerships among stakeholders foster shared responsibility, optimize resource allocation, and drive innovative solutions to complex challenges

Identify the root causes of degradation: Conducting a thorough site evaluation is essential to uncover the underlying causes of rangeland degradation. These may include factors such as overgrazing, agricultural encroachment, invasion by woody plants, or unsustainable land management practices. Identifying these root causes provides the foundation for developing targeted interventions to restore and sustain the health of the rangeland ecosystem (AbdelRahman, 2023).

Define the overall goal and specific objectives: Restoration goals should be specific, measurable, and time-bound, aiming to improve soil quality, enhance biodiversity, or increase livestock productivity. Prioritization is key, focusing on the most critical areas for restoration based on the severity of degradation and the ecological importance of the site. Setting clear restoration and rehabilitation priorities, along with specific targets, is essential. This includes determining the type of intervention required, where it should take place, how it will be implemented, and what intended use, ensuring that the approach is tailored to local needs and conditions (Holl and Aide 2011).

Planning and Design: Engaging local communities and stakeholders in the planning process is crucial, incorporating traditional land-use knowledge to inform decisions. Restoration strategies should be tailored to local conditions, including species selection, grazing management, and erosion control measures. Additionally, it is important to plan for future climate variability to ensure that restoration efforts are resilient in the long term.

Set up robust monitoring protocols: Establishing comprehensive monitoring protocols is crucial for understanding and managing rangeland health effectively. Begin by assessing the current condition of the rangeland to create a reliable baseline for future comparisons. This involves examining key indicators such as soil health, vegetation cover, biodiversity, and erosion levels. Regularly updating this data provides valuable insights to inform adaptive management strategies, enabling timely responses to emerging challenges and supporting the long-term sustainability and productivity of rangeland ecosystems (Eyre et al. 2011).

Use site specific tools and procedures: Two rules to keep in mind 1) No "one-size-fits-all" approach exists, and (2) it is crucial to fix the physical structure (e.g., erosion) before addressing the biota. For arid ecosystems, water-harvesting techniques such as building check dams or contour lines are essential for retaining moisture and improving the hydrological balance. Vegetation management involves reintroducing native plants and grasses suited to local conditions to stabilize the soil and boost biodiversity. Therefore, before planting the right species in the right place, it is essential to conduct a thorough needs assessment, drawing on indigenous knowledge. The selection process should involve local communities to ensure the choices align with local contexts. Prioritize multi-purpose plant species based on both socio-economic and environmental criteria, with a preference for indigenous and well-adapted species. It is also crucial to select species that require minimal care and protection, reducing demands on capital and labor. Emphasizing social fencing over physical fencing can further enhance sustainability and community ownership (Brancalion and Holl 2020).

Grazing management: Grazing is a critical factor in any restoration. Whether the restoration technique used (i.e.: reseeding, planting shrubs and trees), grazing remains essential. For instance, long term protection (no grazing) can lead to the collapse of the entire ecosystem. Therefore, careful consideration must be given to the timing, intensity, and duration of grazing. Recently, there has been increased emphasis on regenerative grazing, which prevents overgrazing and promotes vegetation recovery (Bartley et al. 2023).

The SRM toolkit has been successfully adopted by the HERD project, funded by GEF, in West Asia. More recently, it was applied to a silvopastoral site in semi-arid Tunisia, which was recognized last year as one of the 12 selected success stories worldwide at the FAO Global Conference on Sustainable Livestock Transformation.

Conclusions/Implications

This paper presented comprehensive strategies for sustainable rangeland ecosystem restoration. In summary the key elements to keep in mind include: 1) engaging multiple stakeholders and fostering institutional collaborations to leverage resources, share knowledge, and enhance efficiency; 2) securing long-term investments from financing agencies alongside sustained commitments from key actors; 3) establishing favorable and supportive national and local policy frameworks; 4) integrating local practices and traditional knowledge into implementation strategies; and 5) empowering communities to take ownership of the restoration process.

In which biome is the most degradation happening? The case of croplands, rangelands, forests, and irrigation water in Tunisia

Yigezu, YA[1]*; Louhaichi, M[2]; Annabi, M[3]; Bahri, H[3]; Worqlul, A[2]; Belgacem, AO[2]; Barbouchi, M[3]

Key words: Ecosystem services; combat resource degradation; valuation; inaction.

Abstract

This study estimated the quantities and monetary values of ecosystem services (ESS) lost due to in/inadequate action to control agricultural resource degradation in Tunisia. We used a combination of GIS, remote sensing, and data from publications and official statistics to generate estimates of total and percentage of crop lands, rangelands, and forests falling in one of three (low, moderate, and severe) degradation classes and the corresponding biomass yield (ton/ha). We used a combination of market and non-market valuation methods to estimate the value of ESS lost due to inaction. The estimates are provided for each biome x province combination.

Using extremely conservative assumptions, we estimated that in/inadequate action is causing Tunisia to lose at least 1.97 million tons of potential production of different food crops, 209 thousand tons of forest biomass, and 2.5 million tons of forage from rangelands, and at least 736 million cubic meters of irrigation water annually. In addition, Tunisia is losing at least 141.68 million tons of soil which is also associated with the release of at least 779 thousand tons of carbon into the atmosphere. Rangelands constitute 73.51% of the total national soil erosion out of which 67.7% is happening in the five Southern provinces where erosion rates as high as 52t/ha are recorded.

The monetary value of all the ecosystem services that Tunisia is losing annually in all biomes is estimated to be at least $2.17 billion (4.65% of GDP). The main cost of in/inadequate action in the country in monetary terms is related to crop lands which constitute 53.98% of this loss followed by irrigation water, and rangelands which contribute 28.19% and 12.09% of total cost of inaction, respectively. These estimates have generated much discussion among high officials in Tunisia on the need to solicit funds to control land degradation, especially in rangelands.

Introduction

Desertification induced by land degradation affects most of the dryland areas of the Tunisia and has the knock-on effect of contributing to climate change by releasing soil carbon into the atmosphere. The drylands of Tunisia, which are already challenging areas for food production are also experiencing loss of biodiversity and ecosystem services that support agrifood systems (Rosendahl, 2022). The impacts of degradation of agricultural resources in Tunisia is evident not only in terms of the growing difficulty for farmers to produce food, but also in terms of the growing gap between food demand and supply, leading to the country's growing dependence on imports, as well as the consistently increasing food prices which historically even led to popular uprisings. Loss of land productivity due to desertification and weather shocks is also a contributing factor to food and feed shortage and conflicts which are the major causes of forced migration of people, predominantly the youth, from dryland areas. Left unchecked, these challenges are expected to increase with time and put the inhabitants, particularly the farming communities, at greater risk.

Few studies were carried out in the past to estimate the extent and monetary value of resource degradation in the country. For example, a World Bank study covering all sectors (including agriculture, tourism, manufacturing, and transport) estimated the cost of environmental degradation in Tunisia in 1999 to be 2.1% of GDP (Sarraf et al., 2004). Another study was also conducted only for the Medninne province (Sghaier and Belgacem, 2011) which estimated the cost of land degradation in the province to be 36.4 million Tunisian Dinars. A more recent study (GIZ, 2023) covering the provinces of Béja, Siliana, Kairouan, and Kasserine (representing about 14% of the total national area) estimated that, at discount factors of 7% and 10%, every dollar invested to control land degradation will bring back 14 and 12 dollars, respectively – indicating that combating land degradation is not only a worthy effort in terms of its environmental benefits, but also a financially viable endeavour. On a positive note, Daly-Hassen (2017) reported that the country has made good progress in carrying out afforestation in many parts of the country leading to positive outcomes.

All the past studies are either old and hence less relevant, limited in terms of their geographic and agricultural biome coverage, and are lumpsum with no disaggregation by province and biome – making them less useful for policy makers. This study aimed at providing credible estimates of the costs of inaction in terms of the quantities and values of ecosystem services lost due to failure to intervene to control land degradation. The study covered the whole country, with disaggregation at provincial levels, and included the four main agricultural biomes, namely, crop lands, rangelands, forests, and water.

Methods

Most economic valuations of land degradation are based on comparisons with a counterfactual that refers to a scenario with no-land degradation. This implicitly assumes that after the interventions, land will be restored to 100% of its potential (Quillérou et al., 2016). We argue that these assumptions are not realistic as it is difficult, if not impossible, to know the land attributes if degradation would not have taken place (the counterfactual). Interventions may not restore land to its original state and, hence, the benefits of action and the costs of inaction may be overestimated.

In this study, we follow Gregersen et al. (1995) to classify the total value of land resource into two broad categories: Use and non-use values. Use values are further classified into direct and indirect use-values. Direct use values are again classified into consumptive and non-consumptive use-values. Consumptive use-values include ecosystem service values that are produced on the land for immediate consumption (such as grain and straw on crop fields, wood and timber on forest lands, hay and leafy biomass from pastures, etc.). Non-consumptive use-values refer to recreational, educational and research values. Indirect use values are classified into the following four categories: (i) Watershed, soil protection, and nutrient recycling; (ii) gas (carbon dioxide and oxygen) exchange, carbon storage and climate stabilization; (iii) habitat and protection of biodiversity and species; and (iv) aesthetic, cultural and spiritual values. As the Aralkum desert is far away from human settlements, for the on-site valuation, we focus only on the non-use values of land and trees, with focus on their potential to serve as a carbon sink. In general, non-use values of natural resource or environmental assets are classified into three broad categories: (i) Option values (values of the option of not using it in the present time); (ii) existential values (values of its mere existence); and (iii) bequest values (the amount of the ability to bequeath it to future generations). Following Yigezu et al. (2020), we use a combination of market and non-market valuation methods to monetize the ecosystem services lost and have used area weights to aggregate province-level estimates to generate national level estimates.

Results

The results showed that inaction to control degradation in natural capital in the agriculture sector (croplands, pasturelands, forests, and water) in Tunisia is causing the country to lose substantial amounts of ecosystem services (ESS). Using extremely conservative assumptions, we estimated that Tunisia is annually losing at least 1.97 million tons of potential production of different crops (cereals, legumes, vegetables, fruits, and others), which represents 22.41% of current production and the associated crop residues. Degradation also causes the loss of 209.25 thousand tons of forest biomass (0.53% of total forest biomass stock), and 2.5 million tons of forage (equivalent to 28.03% of current forage supply) from natural pastures. Moreover, due to inaction or inadequate action to conserve water and reduce losses, the country is losing at least 736 million cubic meters of irrigation water (28.78% of total irrigation water supply from surface and ground water sources). In addition, the country is losing 147 million cubic meters of rainwater (11.98% of total precipitation) due to surface runoff. Tunisia is also losing at least 141.68 million tons of soil (i.e., 13.14 ton/ha or 0.94% of total soil stock) every year due to erosion on crop, pasture, and forest lands, which is also associated with the release of at least 779 thousand tons of carbon into the atmosphere. This does not include the amount of soil eroded from the other land use types including urbanization, infrastructure, abandoned agricultural lands, etc. and the associated carbon emission. In addition to these losses, the country is suffering different kinds of harm (including health, infrastructure damages, extreme weather, water quality deterioration, soil salinity, etc.) related to degradation of the natural capitals in the agriculture, forest, and water sectors, some of which are not addressed and hence no detailed estimation is provided in this report.

The monetary value of all the ecosystem services that Tunisia is losing annually in all biomes is estimated to be at least $2.17 billion (4.65% of GDP). The main cost of inaction in the country in monetary terms is related to crop lands which constitute 53.98% of this loss followed by irrigation water, and rangelands which contribute 28.19% and 12.09% of total cost of inaction, respectively. Direct use values (including crop and biomass, forage, and forest biomass lost constitute 80.87% of the total loss while indirect use, including the value of soil eroded and the associated soil carbon emissions, constitute about 15.15%.

Discussion

It is noteworthy that despite the low current level of forage biomass production in the rangelands, the biomass loss in rangelands accounts for about 54% of total which is higher than the 36.6% share of rangelands in total agricultural land. Rangelands, especially those in Southern Tunisia, also constitute most of the areas with the highest erosion rates per unit area which go as high as 52t/ha. Only the five Southern provinces constitute about 82% of the total national soil erosion. Rangelands constitute 73.51% of total national soil erosion out of which 67.7% (i.e., 91.8% of total erosion in rangelands) is happening in the five Southern provinces which constitute 66.8% of total national rangeland area. This calls for concerted efforts between national and international research organization, the relevant departments within in the Ministry of Agriculture, national and international development organizations, and financing institutions in the voluntary carbon market to join forces in identifying packages of policy, institutional, and technological innovations that are believed to be effective in combatting resource degradation in each biome for each province. These packages will need to be refined through a series of consultations with panels of experts. Such efforts should give the utmost priority to rangelands where the extent of land degradation in the form of soil erosion is the highest.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Where will we be in 20 years?

Whyte, AW

Wyndham Station, Anabranch South, NSW, Australia

Key words: Respect; regionally specific; connection; diversity; resilient

Abstract

While we are local to our neighbours, very central to major cities, we are very remote from the politicians and decision makers, always a challenge to have our perspective heard, I reckon in 20 years that will change.

The year is 2045. This paper explores the author's insights looking forward into the future, revealing both key aspirations for Australia's rangeland communities and potential roadblocks. For pastoral Australia to thrive in the future, management based on landscape needs will be the norm. There will be greater populace and regional economic developments in our rangeland communities. The term remote will become a thing of the past, and national affections for the rangelands will be regarded highly by all stakeholders. Failure to reach these goals will be to the detriment of the rangelands and its people.

Introduction

We live in Far Western NSW, between Wentworth and Broken Hill, on the Anabranch River. With the combination of river floodplains and undulating sandy rises, there is naturally a lot of diversity in our landscape on our 31, 000 ha property that we manage. Diverse landscapes can be found across the rangelands of NSW, and indeed across all of Australia. The way we manage our landscapes is underpinned by our awareness of ecological health and biodiversity. Something as targeted as managing for increased ground cover or adjusting stock numbers according to seasonal conditions can go a long way for sustainable management of the land (Soils For Life 2024). Importantly, diverse landscapes should be respected and appreciated, as diversity is strength and ensures resilience, of which is so important in our variable climate.

The following paper is based on the author's own opinion of 2045, as seen from the perspective of an Australian pastoralist. Current realities are firstly addressed, followed by what '20 years from now' might look like with aspirational change.

Current Situation

Although Australia's rangeland area is vast, the proportion of Australia's population residing in the rangelands is low, around 2% (Nielsen et al. 2020). This provides a huge challenge for the rangelands, with limited capacity to care for our rangelands and support and endorse healthy rangelands. Looking 20 years into the future, one can't help but consider the changes needed to secure a prosperous future for Australia's rangelands communities.

Some see the opportunities of renewable energy as providing a secure future of rangeland populations, unfortunately we haven't learnt how to value the land when building energy infrastructure. Others see the best option for the future as being large areas turned into National Parks, this decision comes with its own problems of shifting increased costs onto existing land owners, biosecurity, pest plants and animals as well as increasing fire risk, potentially risking biodiversity.

There is very little knowledge about rangelands and their management in the state and federal Government offices and too often decisions are either not made or blanket decisions are made across large areas, suited to some, not others. There is no question that certainly some decisions around National Parks, appear to be more about buying urban vote, than landscape health. No question that for most voters they genuinely want to make good decisions for the future of our wonderful environment, not many really know what that is and are open to options presented by politicians via media, "game changers". Without the support of those living and working in the Rangelands, these decisions only succeed in increasing the divide between urban and rural areas.

State boundaries can cause divisions in communities, with different legislation around livestock (e.g. SA doesn't allow goat enterprises on pastoral leases), stocking rates (some states cap stocking rates), clearing (how regrowth is defined) and services (electricity and roads). While state Govts enjoy the income in the form of royalties, leases and taxes, that return is very quickly gobbled up by large capital cities that are very demanding.

Enterprise diversity is really important in an arid/variable environment, the current depressed state of the wool industry will impact regions ability to maintain economic viability if it continues, reducing diversity. With the costs increasing much faster than the price received for products, this encourages increasing scale, reducing the number of people and thus reducing the amount of care that the land receives, that is the cycle we are in.

Technology for the rangelands brings great opportunity, while also trepidation. With some looking for the "silver bullet", the tool that will make managing the land and livestock simple, can be mostly done from home via a screen. While quality land managers are slowly adopting tools that help them improve their connection with the land and livestock and/or improve communication amongst the management team.

Some parts of the Rangelands have been seen as "carbon mines", areas that have been targeted for carbon projects to offset emissions from remote places (urban areas). While this has seen a large influx of capital into those regions, a gold rush, there will be a significant hangover, a legacy of fixed land management that will continue for generations. Land management in these areas needs to change as new information becomes available, they need to be the best managed patches of land in those regions.

20 years from now

Looking forward into 2045, I am optimistic for a new status quo, as describe by the following. The year 2045 will be a turning point for pastoral Australia, as it will be the start of management based on landscape needs, and while land tenure is still held by the state, management based on outcomes will override archaic legislation.

Many other aspects of life in the rangelands are coordinated by regional systems, rather than state based, such as health, education, housing and infrastructure. This has seen a real change in the population spread, where moving to the rangelands is quite common now.

With the acknowledgement and respect of the many ecosystem services that land managers can provide in the Rangelands, this has bought many more people to call the rangelands home and show their love of the land.

Although technological advancements still occur, it is not technology that has taken over the management of the environment. Humans still have a key role to play, such as managing livestock and use of fire. Being able to become involved in rangeland management is now a sought-after role.

There is much more balance to the discussion about carbon emissions, than there was 20 years ago. Take Rangeland livestock for example, where methane emissions are easily offset by biodiversity credits, improved water infiltration and the "platinum badge" for healthy eating.

While for many the renewable energy boom in the 20's and 30's was a great income support, now with the understanding of there being no such thing as "low value land", renewable energy projects and transmission lines are planned with that in mind. This has seen a large reduction in transmission lines and renewable energy sites are rarely visible in the landscape, such is the sensitivity of the new planning guidelines.

Conclusion

For Australia to secure a prosperous future for its rangelands, it will be important that changes are made in line with fostering thriving communities of diverse landscapes. It is hoped that this paper ignites a fire inside you and challenges you to examine the future. Some questions to ponder: "What value do we place on our unique and wild Outback and those that choose to live there?"; "Is our society so busy *putting out fires* in urban areas to even think about those that live in remote Australia?"; and "Do we accept *Geographical Narcissism* as discrimination, while having zero tolerance for racism, sexism?".

Visions for 2045: A pastoralist's perspective on advocacy with purpose

Price, BA

Price Cattle Company Pty Ltd

Key words: Land use; accountability; technology; natural capital; biodiversity

Abstract

Visitors to my home in the Arcadia Valley north of Injune in Central Queensland remark at the breathtaking beauty that surrounds us. Framed by the sandstone cliffs of the Expedition and Carnarvon Ranges, beef cattle graze on a diverse pasture comprising dense perennial pastures and mixed legume species. Looking forward 20 years from now, I envisage I will be looking out over my paddocks with an immense sense of pride knowing that in 2045 the land continues to reward generational stewardship and advocacy. However, this reality will require ongoing commitment to sustainable practices, as well as business agility, as new markets emerge, and unforeseen challenges arise. In this paper, I present my own firsthand experience of business advocacy with purpose directed at environmental stewardship and accountability. I then present a case for concern on the legacy impacts of coal seam gas extraction in the rangelands, as an example of competing land use challenges. The system designed to protect the interests of all stakeholders cannot be compromised for short term financial gain, as this will only lead to increased risks of adverse longer-term environmental impacts, production losses and psychosocial trauma. I will end with future expectations relevant to all rangeland users and policy makers.

Introduction

I live in the "Arcadia Valley" region located north of Injune in Central Queensland, Australia. Here, my husband and I and our three children (Price Cattle Company Pty Ltd) produce organically certified, grass-fed beef in the Brigalow Belt Bioregion (DES 2018). This region, characterised by brigalow (*Acacia harpophylla*), a native woodland (DCCEEW 2024), is home for many of thousands of years to the Traditional Owners, the Iman Aboriginal People (DESI 2019). This bioregion is also a known biodiversity hotspot, given the high historical rates of land clearing that has occurred (Thornton and Elledge 2022) and subsequent ecological communities reported as being threatened (CSIRO 2022).

Since European settlement, clearing of the brigalow bioregion of Queensland and New South Wales has made way for agriculture. In the last decade, the Arcadia Valley and Darling Downs regions of Queensland have been identified and targeted for development of the coal seam gas (CSG) reserves under prime agricultural land (Dougall 2024). The production of CSG, also known as coal bed methane, sourced from underground well extraction has become an integral part of the gas industry. A major driver was a decision in 2000 by the Queensland Government to boost the contribution of gas to the State's power supply (Commonwealth of Australia 2014), with 1996 seeing the commencement of Queensland's domestic CSG production (Towler et al. 2016). The expanding activities of the CSG industry in Queensland's rural, agricultural areas has come with public scrutiny, particularly with regards to environmental and social impacts, and as a result, government regulation has been evolving, including amendments to the land access framework (Towler et al. 2016).

Our firsthand experience of confronting such competing land use challenges confirmed the rules that govern such mandatory "land access" considers only that, i.e., accessing our private land. This single dimension does not address the multiple dimensions of impacts that hosting a gas production and processing facility has (e.g., see Dougall 2024), such as on our business, our values and our common rangeland commitments.

With growing local and global concerns about loss of biodiversity and environmental degradation, and the need to maintain a social license to operate and address climate change risk, means land users in the rangelands must prioritise better environmental outcomes. Advocacy with purpose, at all levels, I believe, will be key to reaching this goal. This includes advocating your own business and commitment to land management, paving the way for others through proactive leadership, advocating collaboration and adoption of technologies to better inform policy, and advocating for equity and accountability from all rangeland users.

The following paper presents our own business advocacy in the rangelands, provides a case for concern about competing land use challenges, and ends with visions for 20 years from now.

Our systematic approach to advocacy

Land settlement and agricultural developments: An historical directive for the Fitzroy Basin

Broadscale clearing of Brigalow in central Queensland was directed by the state under the Land Development Fitzroy Basin Scheme initiated in 1962 (Thornton and Elledge 2022). My husband's father was 19 when he drew a ballot block that was part of the 1962 land development scheme (e.g., see Cowie et al. 2007 after Donohue 1984 and State Library of Queensland 2019). He was directed to broadscale clear the standing brigalow scrub, erect fences, plant improved pastures and build infrastructure on the land. Today, the Fitzroy Basin carries the largest cattle herd in any natural resource management region in Australia, making up a quarter of Queensland's herd (Thornton and Elledge 2022).

Some of the challenges we face today as pastoralists is pasture condition decline. In the Fitzroy, pasture rundown and dieback are particularly concerning (Bowen and Chudleigh 2017) and something we have had to deal with ourselves. We partnered up with the Department of Primary Industries and established new pasture plantings (grass and legumes) and adopted grazing practices aided by technologies (see next section).

Advocacy & leadership: Embracing technologies, backing yourself and paving the way for others

Since transitioning to a certified organic production system in 2014 and establishing our Fullblood Wagyu herd, we have ensured access to an exclusive beef market for our cattle that allows us to achieve premium market returns for our beef. Our land and herd management practices are targeted towards improving animal production while also protecting biodiversity and natural resources. This is done through the adoption of agribusiness-based technologies to improve decision making, such as using Optiweigh (remote walk over weighing) and CiboLabs Pty Ltd (pasture imagery service), to give us the frequent data capture required to forward plan and make more informed decisions on holding and selling of stock (DPI 2022).

We are firm believers of "healthy food starts with healthy farms". It is possible to grow production animals and look after the natural resources they depend on, providing there are sound decisions being made, such as adjusting stocking rates according to seasonal conditions. Through our participation in industry programs, we are more aware of innovations and methods to improve our efficiencies and reduce our carbon footprint. As further examples of industry best practice, we have used satellite derived estimates of food on offer and ground cover to not only inform stock movements to manage pasture utilisation, but to also identify low cover areas needing attention (e.g., either more rest from grazing or mechanical intervention required). We have also developed our water infrastructure so that cattle grazing distribution and evenness of grazing can be better managed. A spin-off from this has been improved calving rates and weaning weights (DPI 2022), where cattle spend less time walking to water (i.e., reduced energy expenditure).

We (Price Cattle Company) are serious about and committed to responsible, professional pastoral practices, and we have been recognised for this and acknowledged as industry role models. Our varied industry related activities have included hosting field days on pasture dieback, hosting a property tour during the internationally recognised Beef Week 2024, speaking on panels, being interviewed for agricultural publications on topics ranging from succession to technological advancements, through to providing a recipe and article for a Workplace Health and Safety cookbook.

In 2022, we received a prestigious Farm Biosecurity Producer of the Year award, that acknowledged our professionalism towards farm biosecurity, innovation, technology, record-keeping, environmental sustainability, and business transparency (Farm Biosecurity 2022). Business transparency is particularly important to us as we know from our own experiences that industry compliance can be overwhelming. This prompted us to use social media as a platform to help others and share with other pastoral businesses our own farm biosecurity plans.

Issues of competing land use: Changing legislation to create equity in advocacy

We have firsthand experience with competing land use challenges. We were taken to the Land Court of Queensland by a fossil fuel mining company because they wanted to be granted approval to drill more CSG mining wells on our land, in accordance with their legal right. In response, we initiated proceedings against the mining company for breaches of the existing Conduct & Compensation Agreement (CCA) that for five years the mining company ignored requests to address. They did not keep their word and act in accordance with their public statement that they only accessed land where they were welcome and when questioned as to why they were pursuing access, the response was a changed narrative that they were now choosing to gain access in accordance with their legislated rights.

We had previously invested significant resources and time into negotiating an agreement with the mining company, to which they did not honour. When the company wanted to drill more wells without addressing ongoing breaches, we choose to fight. Our response was strategic and wide ranging. The mining company had been threatening our family with legal action for many years and we planned our response to prepare for this worst-case scenario.

Most pastoralists are so busy on their farm they do not spend much time away from it. In our case we had to be proactive in raising our profile as best practice operators. The threat to commence court action materialised when new lawyers were engaged. We were in mediation with the CSG mining company and notice was given that the mining company was withdrawing from the negotiation process and immediately commenced Land Court proceedings.

We learnt this threat of legal action was a tactic to force us into signing a new CCA. The attitude of the CSG mining company was if they can't comply with the agreed CCA they would just have a new one written that did not contain any of the previous clauses.

Going to court is very expensive and this multinational company expected us to back down to avoid court. They did not expect us to fight and provide documented evidence of their operating practices. We had drone footage evidence of vehicles traversing unauthorised access roads, photographs of mining infrastructure that created animal welfare risks, reports from experts outlining the land degradation caused by unrehabilitated land disturbed by the mining company and five years' worth of correspondence that demonstrated the tactics of the mining company towards our family.

During the time since 2018 when the CCA had been signed and then breached we were ensuring all avenues for landholder complaints were being exhausted and extensive evidence was being collated to demonstrate the non-compliant conduct of the mining company. When the actions of mining company staff resulted in hundreds of organically certified cattle losing their organic status and corrective action notices being issued by our organic certifier, the mining company further compromised our certification by ignoring deadlines for stockproof fencing to be erected. We followed the regulatory process and lodged complaints with the various Government Departments, the Queensland Gasfields Commission and the Queensland Land Access Ombudsman. The process took years, and we learnt the legislative system creates a situation whereby the Government and the resource company, as the Authority Holder, exclude the landholder from their interactions. While we were told there was confirmation of Environmental Authority breaches that correlated with our lodged complaint, we learnt the system we expected to protect the rights of the landholder and the environment worked slowly and secretively.

Although disappointed by the lack of transparency in resources governance and procedural fairness, we did not lose focus. In choosing to be active participants and advocate with purpose we broadened our knowledge, network and experience. Often the skillset associated with the business of farming is underestimated. Successful pastoral operations understand the importance of working both “on” and “in” their business. Working parallel with the legal process we looked at the tactics employed by the mining company and ensured our small family business was not only credible but formally acknowledged as industry leaders. We did not target the mining company; we instead became advocacy generalists. When asked for our commentary on any issue relating to our business and operating environment we provided it.

We took the position that if mining fossil fuels is necessary for the economy and would continue to expand its footprint, then transparency and accountability must occur. Agreements between other landholders and mining companies were not our concern and we make no judgement of landholders who embrace mining on their pastoral land. Unlike the mining company, we do not have shareholders wanting high financial returns on their investments. Price Cattle Company stakeholders are the future generations of our family who will make their assessment of our performance using different key performance indicators. The battle in the court was therefore only one aspect of our strategy. It was important to provide an inside-out perspective of the legislative and regulatory system involving mining leases on pastoral land. We chose to engage with the individuals, organisations and departments tasked with a component of the system, no matter how small their contribution. We documented, questioned and held everyone to account.

Visions for 2045: The role of pastoralists and standards for all rangeland users

A shared vision of caring for our rangelands sits forefront in my mind. For me, as a pastoralist, experiencing moments when nature is communicating with you, often at daylight or dusk, is a reminder that we are part of something greater than ourselves, and that is something worth protecting. Only after we have, over many years, challenged ourselves to engage, understand and adapt to the changing environment, can we become empowered enough to step outside of our comfort zone and start making real, transformative change.

As land users of the rangelands, it is important that we embrace our role as guardians of the ecosystem. It is hoped that in 2045, rangeland monitoring technologies will be well evolved that they are not only used to aid decision making but also used to demonstrate on-ground validation of environmental stewardship. For pastoralists this might include ecosystem services payments. By then it is hoped pastoralists won’t have to fight for third parties to treat the land respectfully. The systems will be transparent with enforceable actions that prioritise environmental sustainability over corporate agendas and mining royalty payments.

The International Year of Rangelands and Pastoralists commencing in 2026 provides a unique opportunity for Australia. Using the year to establish a shared, documented vision for the rangelands could create a blueprint for their future management. All stakeholders should operate within the same base rules of conduct when it comes to environmental outcomes. Pastoralists have a great opportunity to share their stories in 2026 and embrace a narrative that demonstrates their environmental stewardship credentials. Often the public only hear the well scripted, well resourced, non-substantiated attacks on Australian farmers and their farming practices. As environmental offset programs and transitioning land use for carbon projects in Australia creates ripple effects in the rangelands, the need for standardised environmental assessments will become increasingly important.

Conclusion

From my own perspective as a pastoralist managing the land, I accept I work with nature as well as in it. I also believe that advocacy with purpose will be key for improving the future protection and management of the rangelands. The reality of competing land use challenges needs strong advocacy to ensure systems in place designed to protect the land are accountable, impartial and effective. Pastoralists also need to be actively raising their business profile and public visibility, embracing scientific innovations and celebrating generational wisdom. Established credibility is essential when questioning the frameworks, regulations and legislations of other industries operating in the rangelands. In 2045, it is hoped that rangeland communities will be vibrant, and the next generation of land managers will be in tune with nature, tech savvy, strong advocators of conservation, and are able to thrive under changing environmental, social and economic conditions.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Challa Station in 2045

Dowden, DLA

Challa Pastoral Pty Ltd

Key words: Future vision; technology; carbon farming; natural capital; biodiversity

Abstract

Sometimes it's good to look at what we are doing now and imagine what we will have achieved in the future. It gives us hope and encouragement to continue.

This paper, set in 2045, explores the research projects conducted at Challa Station, with a focus on carbon management, biodiversity conservation, and sustainable grazing land practices. The author reflects on what the future might look like in 20 years, suggesting that current research efforts provide a promising preview of what could be achieved. By 2045, Challa Station, through Australian-led rangeland innovations, has become a flourishing landscape despite increasingly variable rainfall patterns. This success has been made possible by advancements in understanding and monitoring landscape function and soil health, as well as the ability of land managers to make more objective, rapid decisions and implement precision grazing strategies.

The United Nations' proclamation of the International Year of Rangelands and Pastoralists in 2026 gave us hope that all aspects of rangelands would be promoted and supported in the future. By 2045, pastoralists are recognized for their contributions to society, particularly in mitigating the impacts of climate change through carbon sequestration and the protection of natural capital. Australian rangelands pastoralists also understand that carbon is only one aspect of sustainability. A thriving, robust ecosystem has become the true measure of value. In 2045, our natural landscapes function effectively, our human communities are resilient, and rural regions remain wonderful places to live.

Introduction

In Australia, pasture-raised beef accounts for 78% of the country's red meat ruminant livestock methane emissions (Mayberry et al. 2018). To achieve carbon neutrality by 2030 (CN30), grazing management has focused on promoting carbon storage (MLA, 2020). For instance, restoring soil carbon through improved grazing pressure management—preventing animals from selectively overgrazing—and using mechanical interventions to rehabilitate bare areas helps reduce soil erosion and biodiversity loss by restoring ground cover and pasture biomass. Additionally, revegetation offers rangeland managers an opportunity to address and mitigate climate change risks effectively.

Challa Station is our family run red meat operation that spans 206,000 hectares in the southern rangelands of Western Australia. Through participating in an Australian Government carbon project coined 'Human Induced Regeneration' (HIR) (Clean Energy Regulator 2024) – being the focus of regeneration of native forests, we were able to gain a deeper understanding of critical biodiversity habitat and carbon sequestration. This not only led to changes in how we manage the land and our livestock but has also provided us with new visions for the future.

This paper explores our journey of adopting research and development on Challa Station and where we ultimately would like to be in 20 years' time.

Restoration and revegetation: improving land condition through adaptive grazing management

The Challa Human Induced Regeneration (HIR) carbon project, initiated in 2019, became the catalyst for embracing new research in biodiversity, conservation, and livestock management. Initially, so little work had been conducted in our region that we began discovering previously unknown species in the rangelands, such as *Baeckea sp. 'London Bridge'*, a shrub identified on Challa Station in 2000. This discovery motivated us to implement measures to trap and reduce goat numbers, thereby alleviating grazing pressures on the landscape. Scientists have since identified and named many more plant species and developed a clearer understanding of the grazing thresholds necessary to avoid suppressing or adversely impacting the growth of native flora, including species like *Baeckea* and *Canthium*.

In 2019, the HIR carbon project changed the way we managed our station. It provided the opportunity to be rewarded for managing our herd in a way that discouraged grazing on native Mulga (*Acacia aneura*) forests, allowing for regeneration and carbon sequestration. This initiative provided financial input through carbon credits, enabling us to improve how we managed our property. These improvements included reducing herd size by 30% whilst simultaneously improving the quality and productivity of the cattle. We invested in new water infrastructure to better distribute grazing pressure evenly across the landscape. Each of the watering points had a set of Total Grazing Management yards built to allow better control of our herd and feral herbivores. We built fences to protect the regrowing native forest and other sensitive areas. These changes not only supported environmental goals but also enhanced the sustainability of our business operations.

Satellite-based technologies: Adopting innovations that improve efficiencies and reduce our carbon footprint

Challa Station has been in the Dowden family since 1888, with five generations contributing to a deep understanding of the property. Over the years, the red meat enterprise on Challa Station has evolved, transitioning from small ruminants (sheep and goats) to large ruminants (cattle) and adapting cattle genetics, shifting from Droughtmaster to Santa Gertrudis breeds. The move away from sheep, beginning in 2008, was driven by the need to mitigate the impact of dingo attacks.

Challa Station has always been quick to embrace technological advancements to improve efficiencies and reduce its carbon footprint. One notable example was the implementation of satellite water monitoring devices back in 2015. This innovation allowed us to remotely monitor water tank levels from our home office, reducing the need to drive hundreds of kilometres to conduct physical water checks. Previously conducted every four days, these checks are now carried out every ten days. This change not only significantly reduces fuel consumption for vehicle-based mill runs (water checks) but also frees up valuable time for other essential management tasks.

Technological advancements have significantly improved our understanding of cattle behaviour and their movement across the landscape. For example, satellite tracking ear tags (Ceres Tag; CSIRO, 2020) have revealed areas preferentially grazed by cattle, such as alluvial plains (Vercoe and Durmic 2024). These tags have also enabled us to locate cattle more efficiently, including heifers (young female cows yet to calve) that might otherwise miss mustering because they had not yet established their home territory.

The potential of precision agriculture in the rangelands is vast. Tracking and monitoring livestock location is just one application. Advanced technology, such as accelerometer-equipped ear tags, can also link ear movements to behavioural cues. With the development and validation of specific algorithms, these devices can predict activities like grazing, ruminating, and even calving (Hu et al. 2024; Trotter et al. 2018). This precision enhances both livestock management and our understanding of animal behaviour in the rangelands.

Furthermore, the advent of plant DNA analysis from animal dung provided us with new awareness of the plants on offer and selected by our cattle. This is explored in the next section.

Diet ID project: UWA BeefLinks

The Diet ID project (Vercoe and Durmic 2024), which was run with Meat & Livestock Australia and the University of Western Australia, used DNA metabarcoding of plant DNA detected in animal dung to determine the animal's dietary botanical composition (i.e., which plant species were being ingested). This information was assessed together with information on animal whereabouts (previous section) and the nutritional value of plant species (see Vercoe and Durmic 2024). Although the dung sampling was limited to a snapshot in time rather than continuous sampling over a year or across seasons, it did however reveal interesting results on animal diet selection. Firstly, there were more plant species making up cattle diets revealed by DNA metabarcoding than was perceived or easily observed closer to water. Secondly, differences in diet selection between individual cattle was apparent, and thirdly, plant species frequently ingested by cattle could be ascertained (e.g., native shrub species *Eremophila* and *Maireana*).

Biodiversity monitoring: manual and automated monitoring sites and application

Biodiversity monitoring technology was installed on Challa Station in collaboration with AxisTech Pty Ltd. To-date this has included four automated 'prototype' monitoring sites and a mobile monitoring unit. In brief, the close monitoring of environmental conditions (atmospheric and soil condition monitoring using weather stations and carbon soil probes, respectively) and above ground species diversity (flora and fauna monitoring using fixed cameras) is providing data for machine learning on how the landscape is performing. Challa Station also had 48 manual monitoring sites, which were established in the year 2000 (photo monitoring and plant counts). This new data on species richness and landscape function will help direct and validate grazing management decisions.

Future aspirations: moving cattle in response to pasture condition

In 2045, we reflect upon our achievements. At Challa Station, we have successfully integrated technologies that enable rapid, whole-system monitoring—including plants, landscape function, animal production, and nutrient availability—facilitating real-time decision-making. Precision agriculture, such as satellite monitoring and geo-referenced animal sensors, has optimized our grazing systems, improving both animal production and land condition outcomes.

A key innovation has been the adoption of virtual fencing technology, which was in its infancy in 2024 (Durmic et al. 2024) but now functions seamlessly in the rangelands. This technology allows us to precisely control the location, timing, and duration of grazing pressure. By implementing adaptive grazing strategies, we can now ensure that livestock remain productive while preventing overutilization of vegetation, enabling regeneration and enhancing resilience to climate change risks. It has made shifting cattle to different areas remarkably easy, allowing us to simply adjust the virtual fence line on our computer to create a new grazing inclusion zone. This flexibility enables us to respond quickly to localized rainfall events and protect sensitive areas undergoing regrowth. This approach not only enhances grazing efficiency but also supports better land stewardship and resource management.

Today, the benefits are evident across the landscape. An abundant understorey of white, gold, and pink wildflowers, primarily everlasting daisies (*Xerochrysum viscosum*), now flourishes during winter, showcasing the harmony between sustainable livestock management and ecological health.

In addition to mitigating the risk of landscape and biodiversity degradation, understanding the diet selection of our cattle opens up opportunities to access provenance markets—markets that value red meat produced in rangelands with recognized and valued plant species. For instance, cattle on Challa Station selectively graze on potential anti-methanogenic species such as *Eremophila* sp. Research has documented the anti-methanogenic properties of this genus, including *Eremophila glabra* (Li et al. 2014). This insight not only enhances the environmental credentials of our production system but also creates avenues to meet the growing demand for sustainable and environmentally conscious meat products.

In 2045, we manage cattle movements with unprecedented precision, responding to pasture conditions with far greater accuracy than ever before. Advancements in ecosystem and biodiversity monitoring have transformed how we assess land health. Using rapid data capture via handheld devices, we can simply wave our mobile phones over a section of land to instantly receive accurate, quantitative data on pasture condition, eliminating the guesswork from rangeland management.

We now also have a deep understanding of the nutritional value of plants and the specific anti-methanogenic species that cattle reliably graze. Rangelands cattle are celebrated for their carbon-negative status, and high-quality red meat from these regions has become synonymous with sound environmental stewardship and the preservation of biodiversity values. These advancements not only enhance production but also solidify the role of sustainable rangeland management in combating climate change and maintaining ecosystem health.

By 2045, the rangelands will provide a multitude of benefits that extend far beyond supporting numerous families in marginal areas and producing red meat to feed a growing population. Pastoralists will be widely acknowledged for the ecosystem services we deliver, playing a vital role in enhancing and safeguarding natural capital for the benefit of the entire community.

Additionally, the rangelands will be valued for contributions that cannot be measured economically, such as the resilience of our communities and the deep trust and strong friendships that are the backbone of rural life. These intangible but essential values underscore the enduring importance of the rangelands, not just as a source of production but as a foundation for social and environmental well-being.

The strong global foundation and momentum generated by the United Nations' proclamation of the International Year of Rangelands and Pastoralists helped shift the narrative about the rangelands. By 2045, we can confidently celebrate a bright future for Australia's rangelands, recognizing their vital role in sustainable agriculture, ecosystem health, and community resilience.

Conclusion

Adopting innovations to enable greater efficiencies and better-informed decision making is important to livestock grazing enterprises paving a path to carbon neutrality. One way for rangeland managers to combat climate change is to improve ground cover. In doing so, this reduces the risks of soil erosion, where increases in pasture biomass will allow for improved soil carbon and biodiversity. In addition, Natural Capital Accounting is expected to assume even greater importance in the future. This will increase the demand for sophisticated monitoring of ecosystems and landscape function, so that rangeland managers can demonstrate they are sustainable. For this reality, science advancements will need to continue to ensure the required monitoring technologies are available and practical to implement in the rangelands.

Key words: cattle comfort; heat stress; chill, forecast; temperature

Abstract

The highly variable weather and climate of northern Australia can pose a significant threat to cattle and other livestock, with prolonged heat waves and sudden chill conditions known to increase mortality risk. For example, the compounding impact of high temperatures, high humidity and calm conditions led to significant cattle heat stress and dozens of animal deaths in southern Queensland in late January 2024. Conversely, the combination of flooding, low temperatures, and high winds associated with a tropical low caused thousands of cattle deaths in northern Queensland in February 2019.

Currently, the Australian Bureau of Meteorology issues national sheep graziers' alerts for potential risk of chill Test and exposure, however there are no such equivalent chill (or heat) warnings for cattle. A key objective of the Northern Australian Climate Program (NACP) is to develop prototype forecast products of thermal stress that can be utilised by livestock producers to help manage the risks posed by extreme weather and climate events.

In this research, we describe NACP's latest prototype forecast maps of the Heat Load Index (HLI) and Cattle Comfort Index (CCI), derived from the Bureau's numerical weather prediction system - ACCESS-G3. These forecasts display the predicted chill and heat conditions across Australia out to 7 days. We also assess how well the predictions of CCI performed for a extreme heat event in southern Queensland in January 2024.

Introduction

According to the Australian Bureau of Statistics in 2021, there were approximately 24.4 million dairy and beef cattle in northern Australia, with 44% (10.7 million) and 7% (1.7 million) in Queensland and the Northern Territory, respectively[16]. Cattle in Australia's far northern tropics typically encounter hot and humid wet seasons (October to April), often punctuated by monsoon bursts (Berry & Reeder, 2016). Further south, in the arid regions,

[16] https://www.mla.com.au/news-and-events/industry-news/herd-and-flock-numbers-for-each-region-released/

cattle experience hot, dry summers and cold winters. As such, Australian cattle are highly susceptible to thermal stress risk from both chill (Cowan et al., 2022) and heat stress events (Lees et al., 2019). For example, a humid-heat wave event in southern Queensland and northern New South Wales across late January 2024 (during the Australia-day long weekend) culminated in cattle deaths in feedlots across the western Darling Downs, southern Darling Downs and South Burnett regions (Condon, 2024).

The Australian Bureau of Meteorology (hereafter, the Bureau) currently provides sheep graziers' warnings for chill risk in its forecast districts (Nixon-Smith, 1972) and, during the warmer months, an Australia-wide gridded 3-day heatwave forecast service for people (Bureau of Meteorology, 2024). However, the Bureau does not officially provide gridded thermal stress forecasts for livestock. Based on an anonymous survey conducted in June 2022 with 76 beef producers across northern Australia, more than 60% of respondents expressed a desire for a cattle heat stress forecast map (Cowan et al., 2024).

As part of the Northern Australia Climate Program (NACP), researchers are developing gridded thermal stress forecast products for cattle. The NACP is funded by the red meat sector to develop innovative forecast tools to help graziers better manage drought and climate risk (Lavender et al., 2022). In this study, the first objective is to introduce the latest prototype cattle thermal stress forecasts, like the Cattle Comfort Index and Heat Load Index, developed in collaboration with the Bureau, using their deterministic 7-day numerical weather prediction system, ACCESS-G3 (Australian Community Climate and Earth-System Simulator, Global – v3). The second objective is to assess the performance of forecasts for thermal stress during the late January 2024 heatwave event in southern Queensland.

Methods

Thermal Stress Metrics

The HLI is a dimensionless measure of the instantaneous heat load in cattle, derived from the black globe temperature (which includes solar irradiance and temperature), relative humidity and wind speed (derivation in Gaughan et al., 2008). Hourly data is required to calculate the HLI, from which the Accumulated Heat Load Unit (AHLU) can be derived. When the HLI exceeds a given critical threshold value (e.g., 86 for Angus cattle, 96 for Brahman), cattle begin accumulating heat (McCarthy & Fitzmaurice, 2016). When the HLI < 77, the animals will shed their heat load, whilst the AHLU remains constant if the HLI is between 77 and the critical threshold.

The CCI covers both cold and heat extremes, describing an adjustment to the temperature due to changes in the relative humidity, solar irradiance and wind speed (see derivation in Wang et al., 2018). For temperatures warmer than 25°C, increases in relative humidity lead to an enhanced warming, whereas higher wind speeds will act to cool the CCI. Increased solar irradiance produces a warming effect but has less of an influence as humidity increases.

ACCESS-G3 Numerical Weather Prediction System

The Bureau's deterministic ACCESS-G3 model has a N1024 (~12 km) horizontal resolution with 70 vertical levels reaching a height of 80 km. It assimilates satellite measurements and surface observations (including 0.25° daily sea surface temperatures) at a N320 (~40 km) resolution (Bureau of Meteorology, 2019). We utilise forecasts of screen temperature and relative humidity, 10-metre winds and downwards shortwave radiation at the surface – these forecasts are generated by ACCESS-G3 at four daily initialisation UTC times: 00, 06, 12, and 18z (Zulu time) (10, 16, 22, and 04 Australian Eastern Standard Time [AEST]). For the prototype forecasts maps, we display only the 12z initialised forecasts at 3-hourly intervals, extending up to 9 days, starting from 10 AEST. In addition to CCI and HLI forecasts, we also produce forecasts for the Temperature Humidity Index (THI; a combination of temperature and dewpoint temperature; Wang et al., 2018) and AHLU, the latter calculated for five different HLI thresholds, representing different cattle breeds (e.g., 86→Angus, 96→Brahman)(Gaughan et al., 2008).

To verify these forecasts, we use observations from a network of Bureau operated Automatic Weather Stations[17]. These stations record temperature, wind speed and relative humidity. For solar irradiance observations, we rely on daily global solar exposure, derived from visible radiation measurements from geostationary satellites (Poulsen & Majewski, 2022).

Results

Gridded Thermal Stress Forecasts

An example CCI forecast for 10am AEST on 29 October 2024, is shown in Figure 1. For this forecast product, we have deliberately separated the dark reds to maroon colours (indicating heat) from the blues (indicating chill) with more neutral bland colours (indicating normal conditions). Additionally, we are currently trialling an email alert system for the THI across the northern Western Australian and Queensland Local Government Areas, as well as Northern Territory pastoral regions. The alerts are designed to notify our regional NACP extension officers (called Climate Mates) about the likelihood of extreme THI conditions over the next 1 to 5 days in their regions. The Climate Mates can then pass that information onto their network of local producers and stakeholders.

Verification of the southern Queensland heat stress event in January 2024

Next, we assess how well the ACCESS-G3 forecasts performed during a real-world cattle thermal stress event, specifically the heat conditions in southern Queensland in late January 2024, which led to reported cattle deaths across numerous feedlots (Condon, 2024). We focus on the town of Dalby in the Western Downs Region of Queensland.

It is apparent that the ACCESS-G3 forecasts did not predict the heat event at a 7–10 day lead time, as the CCI and THI were well underpredicted (Figure 2).

Closer to the event, we see the 3-5 lead time forecasts captured the diurnal cycle of the CCI and THI, however the model tended to overpredict the intensity of the heat. The reason for this is the model under-predicted the rain event on 27 January, leading to an overestimate in the solar irradiance (and underestimate in relative humidity) contribution to the CCI.

[17] http://www.bom.gov.au/climate/data/stations/about-weather-station-data.shtml

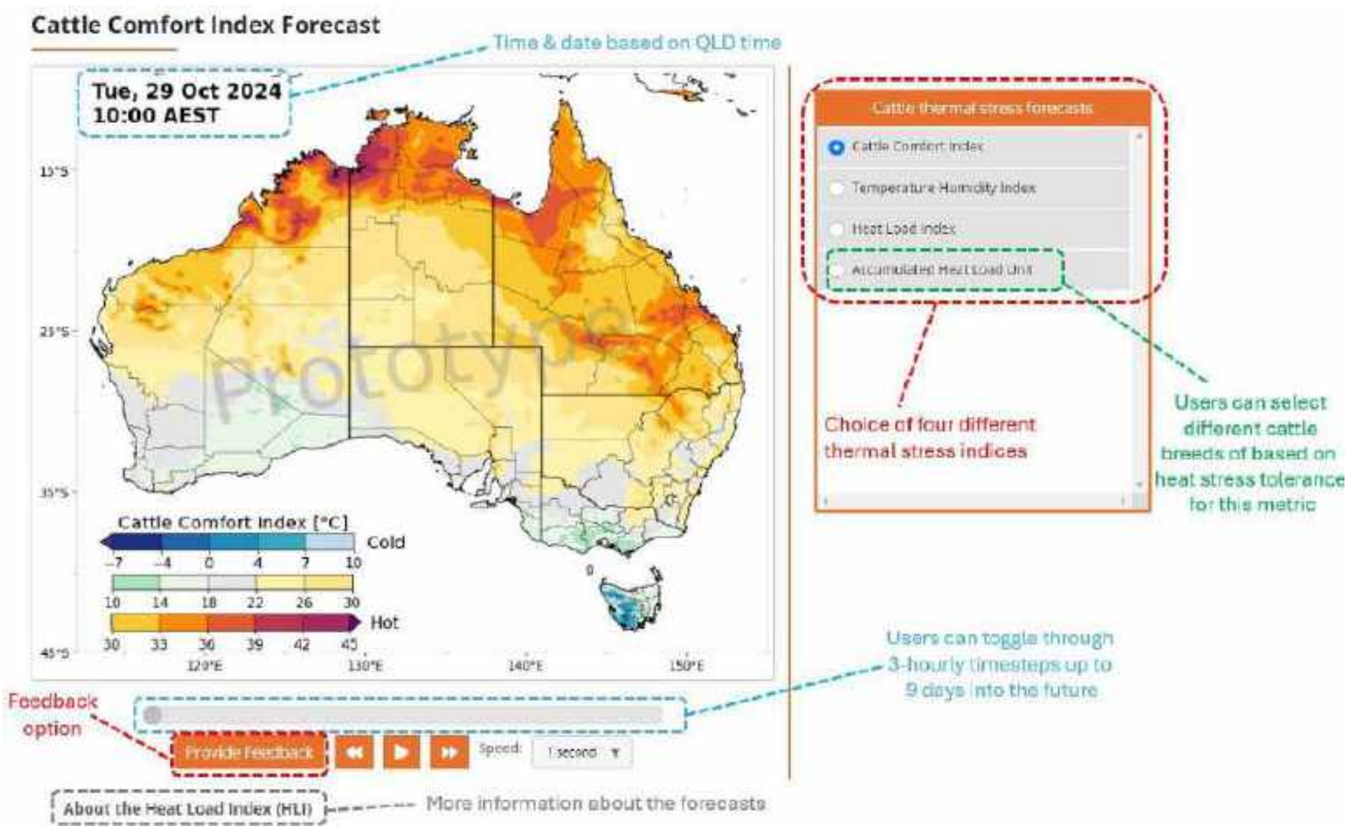

Figure 1: Example of a Cattle Comfort Index (CCI) forecast map from the Bureau's ACCESS-G3 numerical weather prediction system. This forecast is taken from https://nacp.org.au/cattle_thermal_stress_forecasts.

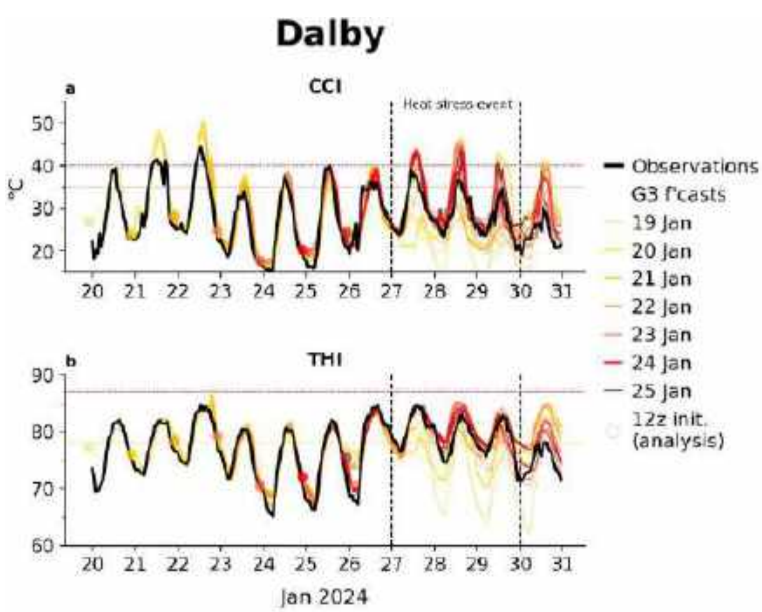

Figure 2: Observed heat stress event (black lines) in Dalby, Queensland (27.16°S, 151.26°E) in late January 2024, as indicated by (a) the Cattle Comfort Index (CCI) and the Temperature Humidity Index (THI). The coloured lines (yellow to red) show the ACCESS-G3 forecasts from 19-25 January. Circles indicate the model forecast initialisation at 12z each day (e.g., 10pm local time).

Discussion

This paper has introduced a suite of cattle thermal stress forecast products, based off the Bureau's deterministic numerical weather prediction model, ACCESS-G3. Initial verification results suggest that forecast skill is relatively good up to 5 days, however beyond that lead time, wind and relative humidity become harder to predict, and hence, Cattle Comfort and Heat Load indices show greater divergence from observations. There is scope to expand these forecast products to include other indices such as the Livestock Chill index, which would be of value for sheep/wool producers in central/northern Queensland. Other improvements could include using higher resolution modelling, such as the Bureau's ACCESS-City models, that are centred over metro regions at a 1.5 km horizontal resolution. The NACP team are also exploring ways to enhance forecast visualisations on the product website, including the potential for users to zoom in on a region of interest. This would improve the accessibility and utility of forecasts. Future NACP research will target the defining of heat and chill thresholds for cattle under Australian climate conditions, noting that temperatures in the cooler months are not as severe as in Europe or North America, however cattle can still be significantly impacted.

Northern Australia's Green Break of Season (GBOS) dates and their relationship with pasture

Naha, R[1, 2]; Cowan, T[1, 2]; Wheeler, MC[2]; Owens, J[1]; Cobon, D[1]; O'Reagain, P[3]

Key words: Green Break of Season (GBOS); Green Date (GD); Pasture Growth; Northern Rainfall Onset (NRO); Northern Australian Climate.

Abstract
Across northern Australia's rangelands, livestock production depends heavily on rain-fed pastures that rely primarily on rainfall during the wet season months of October to April. Planning for the onset of pasture growth (called green cover onset) after the dry season enables graziers to set appropriate stocking rates based on the available fodder at the end of the previous growing season. This reduces costs and alleviates the strain on existing livestock. This study focuses on the 'green break of season' (GBOS) date, defined as the first occurrence of meaningful rainfall over a 3-day period after the dry season, and its relationship to the green cover onset. By utilising robust model-derived estimates and satellite observations of pasture growth at representative locations, we examine the relationship between the green cover onset and GBOS for various rainfall thresholds and find a strong linear relationship. Additionally, we investigate the historical or long-term 'green date', at which the GBOS reliably occurs in 70% of all years. We analyse the spatial distribution of green dates over northern Australia and examine how these dates are influenced by the phase of the El Niño-Southern Oscillation. Ultimately, our findings aim to assist producers and graziers in determining their "decision date" for better management of livestock and resources.

Introduction
Australia is the world's third-largest exporter of beef (Meat & Livestock Australia, 2022) and relies heavily on pasture to feed cattle in its northern regions. Pasture growth and cattle liveweight gains in northern Australia are closely linked to October-April wet season rain, which accounts for over 90% of the area's annual rainfall (Lisonbee et al., 2022). Northern Australia also experiences substantial seasonal and interannual rainfall variability, sometimes resulting in droughts and floods (Thi Tran et al, 2016; Johnson et al. 2016). These conditions affect cattle enterprise management and livestock production (Cobon et al., 2019), creating challenges in balancing forage supply with herd sizes (Cobon et al., 2020b) and significant financial risks.

There are various rainfall-based definitions to help estimate the timing of new pasture growth for grazing management, such as the “green season” (McCown, 1981), “green break of season” (Balston and English, 2009), and Northern Rainfall Onset (NRO) (Cowan et al., 2020; Drosdowsky and Wheeler, 2014). These definitions highlight the complexity of identifying a singular onset date for productive green pastures. In this study, we define the Green Break of Season (GBOS) as the first day after 1 September when 50 mm of rainfall accumulates over three consecutive days. The GBOS signals the anticipated start of pasture growth, initiating green cover and supporting liveweight gain in stock (Balston and English, 2009). We then examine the Green Date (GD), commonly used in the grazing industry (FutureBeef, 2021), defined as the date representing 70% of GBOS dates across all historical years. By combining the GD with an estimated end of growing season date, producers can set an appropriate dry season stocking rate, crucial for maintaining land and pasture condition (O’Reagain et al. 2009). Understanding the GD helps graziers ensure sufficient feed for livestock and maintain adequate groundcover in most years (FutureBeef, 2021, Meat & Livestock Australia, 2018). The aim of this paper is to 1) evaluate the capability of short-term rainfall accumulations to predict the onset of pasture growth at a representative location in northern Australia and compare this approach with the NRO; and 2) investigate the distribution of GDs across northern Australia with respect to ENSO phases.

Methods

Our study investigates the effectiveness of a 3-day rainfall accumulation as a measure for defining the GBOS across northern Australia (10°S-29°S, 112°E-154°E). Using historical rainfall observations, we evaluate the capability of short-term rainfall accumulations to represent the onset of pasture growth and compare this approach with the Northern Rainfall Onset (NRO).

We use gridded daily rainfall observations (1900–2023) from the Scientific Information for Land Owners (SILO) database (Jeffrey et al., 2001) to calculate GBOS, NRO and GD, and the grass production biophysical model GRASP (Rickert et al., 2000) to estimate daily pasture growth (1990–2020), based on long-term grazing trials at Wambiana Station (20° 34’ S, 146° 07’ E) in northern Australia (O’Reagain et al. 2009).

We define the GBOS as the first occurrence of a 3-day rolling sum of 50 mm rainfall between September 1 and April 30 (with additional thresholds ranging from 10-80 mm also tested). The GD is defined as the date on which 70% of all historical GBOS events occur. During El Niño and La Niña years, we identify the reliable GBOS using a 70^{th} percentile threshold for GBOS in those years, based on average Southern Oscillation Index (SOI) values exceeding ±5 from June to November (Allan et al., 1996). A Student’s t-test is applied to assess significant differences between the reliable GBOS during ENSO years and the GD for all years.

We use the green cover variability dataset (1990–2020) from Wambiana, to calculate the Green Cover Onset (GCO), which is defined as the date when green pasture cover reaches and sustains a minimum of 5% after 1 October. The relationship between GBOS and GCO is evaluated using statistical regression analysis, with confidence intervals calculated at the 95% level.

Results

The Green Date (GD)

Figure 1 illustrates the GD at Longreach (23.45°S, 144.25°E; central Queensland) which occurs significantly earlier during La Niña years and later during El Niño years compared to all years. This timing is consistent with the ENSO-driven rainfall patterns in northern Australia (Cowan et al., 2020). The overall 50 mm threshold GD spatial pattern for northern Australia, demonstrates early onsets in the north and northeast regions, with later GDs in central and interior regions (not shown here but refer to Fig. 3 in Naha et al., unpublished manuscript/pers. comm.).

Green Cover Onset (GCO) at Wambiana and its relationship with GBOS and NRO

The analysis of GCO at Wambiana highlights instances of false starts and false dry periods, demonstrating cases where early pasture growth fails initially due to insufficient follow-up rainfall (Figure 2a), or exceeds a certain threshold value (e.g., 2.5%) and maintains a marginal green cover during the cooler months (e.g., July-August; Figure 2b). Thus, careful identification of sustained green cover is essential.

The regression analysis between the GCO and GBOS shows a strong correlation between the two variables, particularly at a 50 mm threshold (Figure 3), explaining about 94% of GCO variability with respect to any change in GBOS. This suggests 50 mm as an optimal threshold for predicting GCO at Wambiana. Furthermore, the analysis comparing the NRO and GBOS (Figure 3) reveals a stronger correlation between GBOS and GCO (R^2 = 0.94) than that between NRO and GCO (R^2 = 0.62), suggesting that GBOS, which reflects short bursts of rainfall, is more effective than NRO for determining the onset of pasture growth at Wambiana.

Discussion

Our study investigates the timing and reliability of the GBOS, a rainfall-based metric aimed at marking the onset of new pasture growth in Australia's northern tropics. By examining the correlation between GCO and GBOS, calculated using various rainfall thresholds (not shown), at a representative location in northern Australia (Wambiana), our research highlights that 50 mm over three days offers the most ideal threshold in determining the relationship between GCO and GBOS at this location, with an explained variance being greater than 94%. At this threshold, the GCO demonstrates a stronger correlation with GBOS than with the NRO, providing the first clear evidence that pasture growth is more related to short bursts of rainfall, than the slower accumulation of rainfall (as observed for Wambiana). This suggests that GBOS may be a more effective indicator for determining the onset of productive pasture. The study also examines the historical GD, representing the start of the pasture growing season and the climatological GBOS across northern Australia. This analysis reveals significant shifts during La Niña years, which tend to advance the onset of pasture growth through earlier effective rainfall. The findings have practical implications for graziers, enabling them to better estimate pasture availability and prepare for stocking and feeding through the dry season. By understanding regional GD patterns and the influence of ENSO phases, graziers can plan ahead for livestock needs, optimising decisions on calving/lambing and stocking rates.

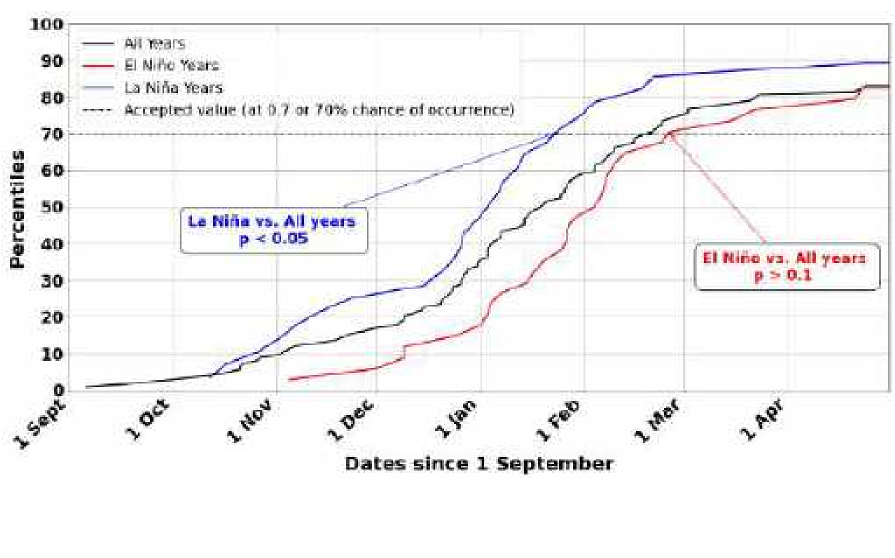

Figure 1: Percentiles of GBOS for Longreach (23.45°S, 144.25°E) from 1900 to 2023, determined using a 50 mm threshold over 3 days. The black dashed horizontal line indicates the 70th percentile, which defines the GD. The solid black, red, and blue curves represent the GBOS percentiles for all years, El Niño years, and La Niña years, respectively. P-values shown are from a Student's t-test comparing the reliable GBOS during ENSO years with the GD for all years.

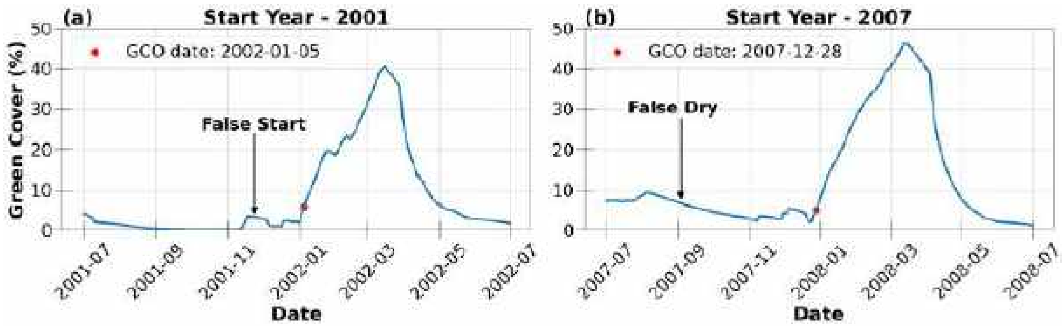

Figure 2: Examples of (a) a 'False start' in green cover onset (2001), and (b) a 'False dry' in green cover (2007).

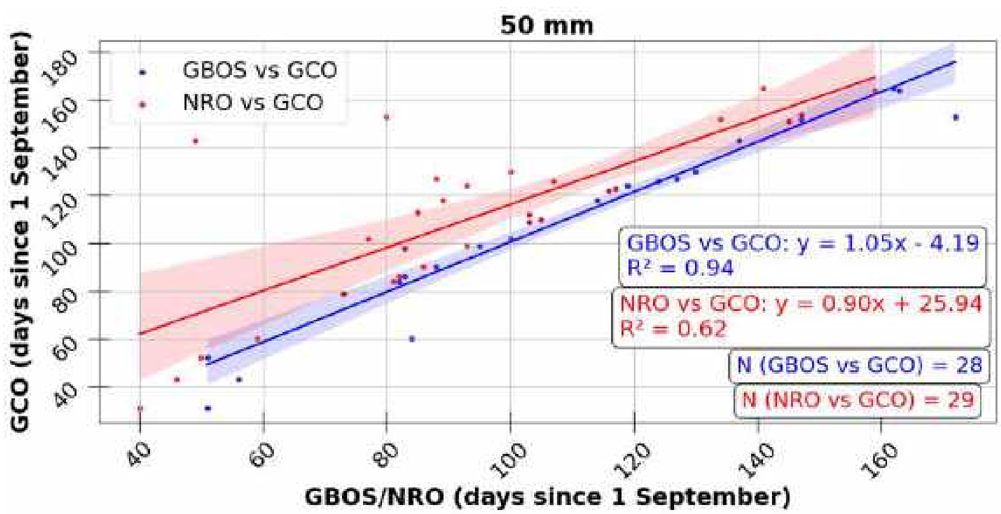

Fig. 3: Linear relationship between GBOS versus GCO and NRO versus GCO at Wambiana Station for a rainfall threshold of 50 mm from 1990 to 2020. The blue shading in the background represents the 95% confidence intervals. The letter 'N' denotes the number of data points included in each regression analysis.

Brush, burn, return: maintaining rangeland health following catastrophic fires

Larson, S[1]; Becchetti, T[2]

[1]University of California Cooperative Extension, Santa Rosa, CA, USA (slarson@ucanr.edu)

[2]University of California Cooperative Extension, Modesto, CA, USA

Key words: fuel treatments; shrubland management; prescribed livestock grazing

Abstract

Rangeland vegetation in California has evolved with a long history of fire. Reports from early Spanish explorers provide insight into Native American use of fire to maintain grasslands for hunting, oak tree germination and acorn production. Lightning also ignited natural fires, and the combination of the two created a mosaic of different age classes of brush with grasslands intermixed, creating natural fire breaks to minimize the spread of wildfire. Brush control by fire ceased in the 1980's due to a range of factors including administrative barriers (permitting), environmental impact, and costs.

While California's Mediterranean shrublands are ecologically adapted to periodic fire, identifying and adopting strategies to reduce the impacts of severe wildfires in shrublands is now key to reducing their destructive impact. One strategy is livestock grazing, an extensive land use (occurring on roughly 33% of land area statewide) that is also frequently adopted by State and local agencies as a fuel management practice. Shrubland ecosystems accounted for approximately 38% of California's burned areas from 2000-2020 but there is relatively little research into long-term management strategies to mitigate the impacts of shrubland fires. Livestock have been documented to browse on resprouts and slow the spread of shrubs; a management strategy that could reduce shrub encroachment.

To understand shrublands' influence on fire intensity, we analyzed changes in land cover type resulting from major fires (based on hectares and structures lost). Results indicated that with no management, and depending on time and climate, shrublands quickly recovered, becoming the dominant vegetation type. However, while shrublands and grasslands fluctuate in extent, results indicated that forests are not recovering. Every fire footprint had similar changes, indicating that these vegetation patterns are not a feature of the most devastating fires only, but occur following any fire in land cover types that contain shrublands and forests.

Introduction

California has a long history of fire with most of our vegetation evolving with it. Stories from early Spanish explores provide insight to Native American use of fire to maintain grasslands for hunting, oak tree germination and acorn production. Lightning strikes have been a natural ignition of fire and the combination of the two created a mosaic of different age classes of brush with grasslands intermixed, forming natural fire breaks to minimize wildfire spread. With settlers and ranching, control of brush to maintain grasslands for livestock became a common practice (Murphy and Leonard, 1974). Roughly in the 1980's most of the brush control came to a stop. The knowledge of ecosystem functions was lost and the understanding of how grazing keeps a system functioning. With the increase in catastrophic fires experienced in California over the past 20 years, there's a growing interest to manage range and forest lands to lessening wildfire severity. We explore if shrublands (brush) management could be a key to having a resilient community and healthy rangelands.

Methods

While California's Mediterranean shrublands are ecologically adapted to periodic fire, identifying, and adopting strategies to reduce the severity of severe wildfires in shrublands is key to reducing their destructive impact. Even if fine fuels are controlled, the management of shrublands is forgotten. Shrubland ecosystems account for approximately 38% of California's burned areas from 2000-2020 (Calhoun et al. 2022) but there is relatively little research into management strategies to mitigate fire impacts in shrublands.

To better understand the influence of shrublands' regrowth, we examined vegetation types before and after fires occurred. We assessed impacts from the largest California fires, we selected the largest in size (hectares) and most damaging structurally (houses, buildings), according to California Department of Forestry and Fire Protection (Cal Fire) data from 2001 to 2021, a twenty-year span, (Table 1).

We identified twenty-five fires as our sample data point to analyze. Year and season of each fire was entered, and the land cover characterized utilizing National Land Cover Dataset (NLCD) to identify six classes across the footprint of each fire: deciduous forest, evergreen forest, mixed forest, scrub/shrub, herbaceous, and other (developed land). From these six, three basic functional groups were created: forest, shrubland, herbaceous. We used Python 3 and PANDA Python Package to calculate within each fire footprint the percent of the three land cover classifications over time.

Each of the twenty-five wildfires was graphed to show the percent area of each classification (y-axis) and years (x-axis). This allowed changes in each classification before and after the wildfire to be apparent. Wildfires were then grouped into three categories based on the length of time since the fire occurred, or the length of recovery post fire for the vegetation data. In ARCGIS, a web application was created to map all historic fires to 1950. Predictions were made based on the trends observed for vegetation patterns for the fire footprints in the "pre-recovery" fires.

Results

Wildfires distributed across California represent a mix of public and private landowners under a variety of management and idle (no use) land. In all fires examined the same pattern was observed. Forest and shrubland covers decrease immediately post fire and herbaceous layers experience a dramatic increase in cover. After fires, herbaceous cover plummets and shrubland's cover increases, levels well above the pre-fire percentages. The length of time this vegetation shift lasts varies, but within five years, the grassland layer is back to pre-wildfire levels or lower, and the shrubland layer is either at or above pre-wildfire levels. The forest layer drops and even in the longest "recovery" classified wildfires, never seem to recover to pre-fire levels, appearing to be replaced by the shrub layer (Fig. 1).

The Cedar fire started in October 2003, in San Diego County, burning for two weeks, burning 2,232 homes, and killing 15 people. It cost at least $1.331 billion (2003 US).

Table 1. Twenty-five wildfires included in analysis, year occurred, season started, hectares and number of structures destroyed (Cal Fire data).

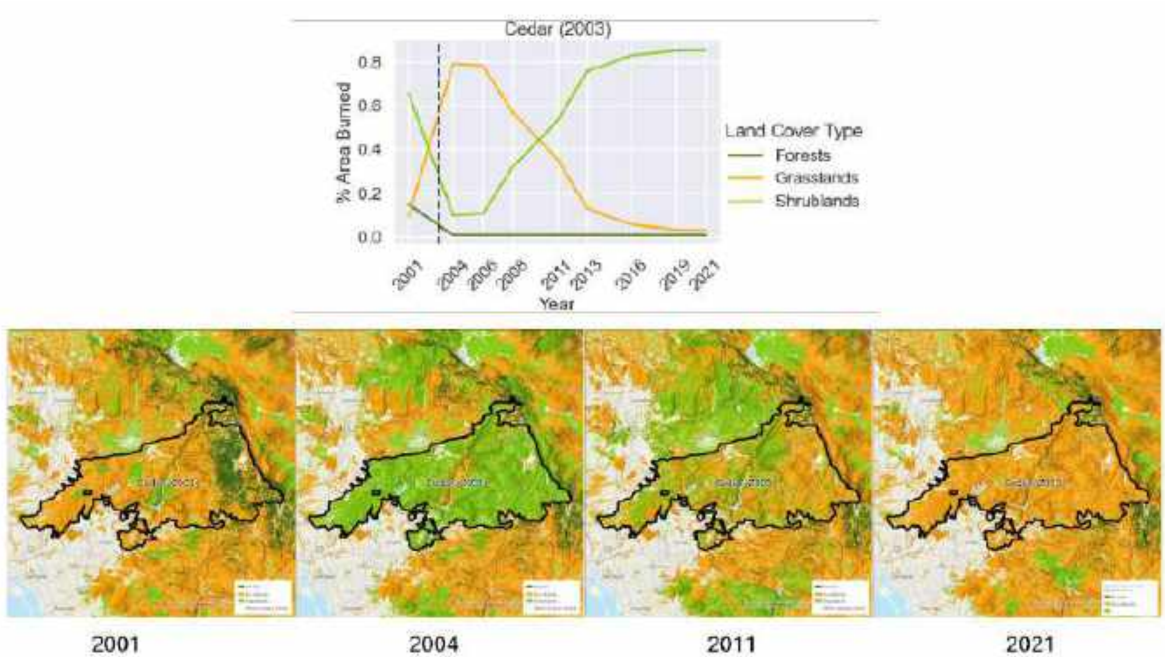

Figure 1. Cedar Fire, October 2003, 110,579 hectares.

Discussion, Conclusions & Implications

Research showed that wildfires are making large vegetation changes to ecosystems with the most drastic changes predominantly in shrublands, both in the short term and long term. Without interventions to maintain shrublands at the pre-fire levels, and steps to reforest fire footprints, there will be continuing shifts in species. Species that rely on forested land cover will either need to adapt to shrubland habitat, relocate, or will disappear completely. Vegetation pattern changes also raise questions about post-wildfire management. Livestock as well as wildlife have been documented to browse on resprouts and slow the spread of shrubs (Rouet-Leduc et. al., 2021). Our data shows that choosing no post fire fuel treatments will result in a decrease in forested landscapes and an increase in shrublands. Fires can destroy permanent fencing on rangelands but with temporary electric fences or even virtual fencing areas could be targeted for vegetation management using ruminants.

Our findings document that some form of fuel treatment is needed following a catastrophic wildfire to assist rangeland health. Fuel treatments can alter fuel conditions so that wildfire is easier to control and less destructive (Reinhardt et. al., 2008). The costs of fuel treatments vary widely, yet the relative cost and success must be considered as opposed to doing nothing and having the fuel loads return (Strand et. al., 2014). Potential benefits of fuel treatments such as reduced wildfire risk, reduced fire suppression costs, and reduced structural losses will be site-specific. Thus, a site-specific analysis must account for the cumulative cost of fuel treatments, the likelihood of wildfire return, with or without treatments, and the overall health of the rangeland. Grazing with cattle, sheep, and goats can support post-wildfire recovery to extend the return interval of the shrubland, and therefore lengthening the fire return interval, mimicking what was naturally occurring before European settlers. Grazing for fuel reduction has the potential to offer a low cost, landscape-level fuel treatment (Germano et. al., 2012). With fire hazard increasing as fuels go untreated, management after catastrophic fires will become more critical to maintain rangeland health.

Research indicated that with no management, after a period, depending on climate, shrublands become the dominant vegetation. While shrublands and grasslands fluctuate, the data indicated forests are not recovering. Other fires assessed had similar vegetation (land cover changes), indicating this pattern is not a factor of the most devastating fires only, but any fires that occur in land cover types containing shrublands and forests. More active prescribed grazing post-wildfire is needed to manage the abundance of herbaceous and re-sprouting shrubs. Prescribed grazing can manage the height and structure of herbaceous growth, result in changes in fire behavior and the decrease of catastrophic fires on the landscape.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Enhancing climate resilience through the NACP extension service

Marshall, AG.[1,2]; Hinds, EM[1]; Cobon, D[1]

[1] Centre for Applied Climate Sciences, University of Southern Queensland, Toowoomba, Australia.

[2] Bureau of Meteorology, Hobart, Australia.

Key words: Climate, resilience, extension, adoption

Abstract

The Northern Australian Climate Program (NACP) extension service delivers workshops, field day talks, property visits, and webinars to provide the support and confidence for regional producers to use weather and climate information in decision making. This service helps producers to make more informed assessments of climate forecasts and understand the factors that can influence their specific region in the days, weeks, and months ahead.

Integration between research, development and extension allows for the most relevant and up-to-date climate information to be used in the field to meet end-user needs, and for industry feedback to further inform the program's activities for the benefit of agricultural communities. This iterative model has proven very successful in Australia, as evidenced by the industry funding of the third NACP program (NACP3). One of the main measurements of the success of the program and its impact on producers is meeting Category C goals, which describe the number of practice changes (189 to date) resulting from timely and effective use of the NACP extension and adoption service.

We highlight how the NACP extension service is helping the grazing industry to manage drought and climate risk in northern Australia by improving weather and climate awareness, improving knowledge and skills, providing support and confidence to use this in decision making, and delivering practice change to reduce climate risk and drive positive financial, environmental and social outcomes.

Introduction

The Northern Australia Climate Program (NACP) delivers innovative climate research, product development and targeted extension outcomes to improve the capacity of the red meat industry in managing drought and climate risk across northern Australia. NACP extension and adoption activities are undertaken by regionally located extension officers called Climate Mates, who are leaders in their local community with extensive networks and knowledge of the local industries. Climate Mates are selected for their capacity to communicate with industry and community, and thus they have a unique role to improve the use of weather and climate forecasts through training and engaging with agricultural producers, natural resource managers, advisors and supporting the broader extension teams in the regions. Supported by climatological experts to understand contemporaneous climate forecasting for use within the NACP extension program, Climate Mates take feedback received from clients and communicate it to project partners at the University of Southern Queensland and Bureau of Meteorology to aid in the focus of research and development tools.

Methods

The NACP extension and adoption service integrates and embeds climate forecast information into industry and community networks to improve resilience to weather-climate variability, extremes and change. The program works to:

- Deliver a climate service to producers and graziers across northern Australia
- Facilitate practice change and related decision making by working with stakeholders one-on-one
- Document practice change by providing metrics that meet a triple bottom line (economic, environment, social)
- Facilitate two-way communication with researchers to improve both the relevance of research-driven products and the uptake of forecast information by industry and community
- Seek industry advice on climate needs and product development
- Develop linkages between agriculture producers, natural resource managers, advisers and key supply chain stakeholders to drive adoption of best practice weather/climate management strategies

NACP extension and adoption is modelled on the 'staircase of engagement' (Figure 1; Hewitt et al. 2017, Lavender et al. 2022), which provides a valuable framework for planning, implementing and evaluating the extension activities. Through this, Climate Mates are tasked with achieving key performance indicator targets relating to delivery of awareness (Category A), change in knowledge, attitude, skills, aspirations (KASA; Category B), change in practice (Category C) and demonstrating impact (Category D). Awareness is achieved through passive engagement by providing information, usually through quick presentations, newsletters, websites and tools, and a change in KASA comes through providing dialogue-based activities often in interactive groups such as workshops. A change in practice (e.g. adoption of climate forecasts to inform decision-making) necessitates active engagement with tailored and targeted discussions and focused relationships, often through face-to-face interaction between Climate Mates and producers. Climate Mates record each Category A, B and C outcome using a Customer Relationship Management platform, which enables results to be tallied around the engagement of producers with our educational resources and regional climate information.

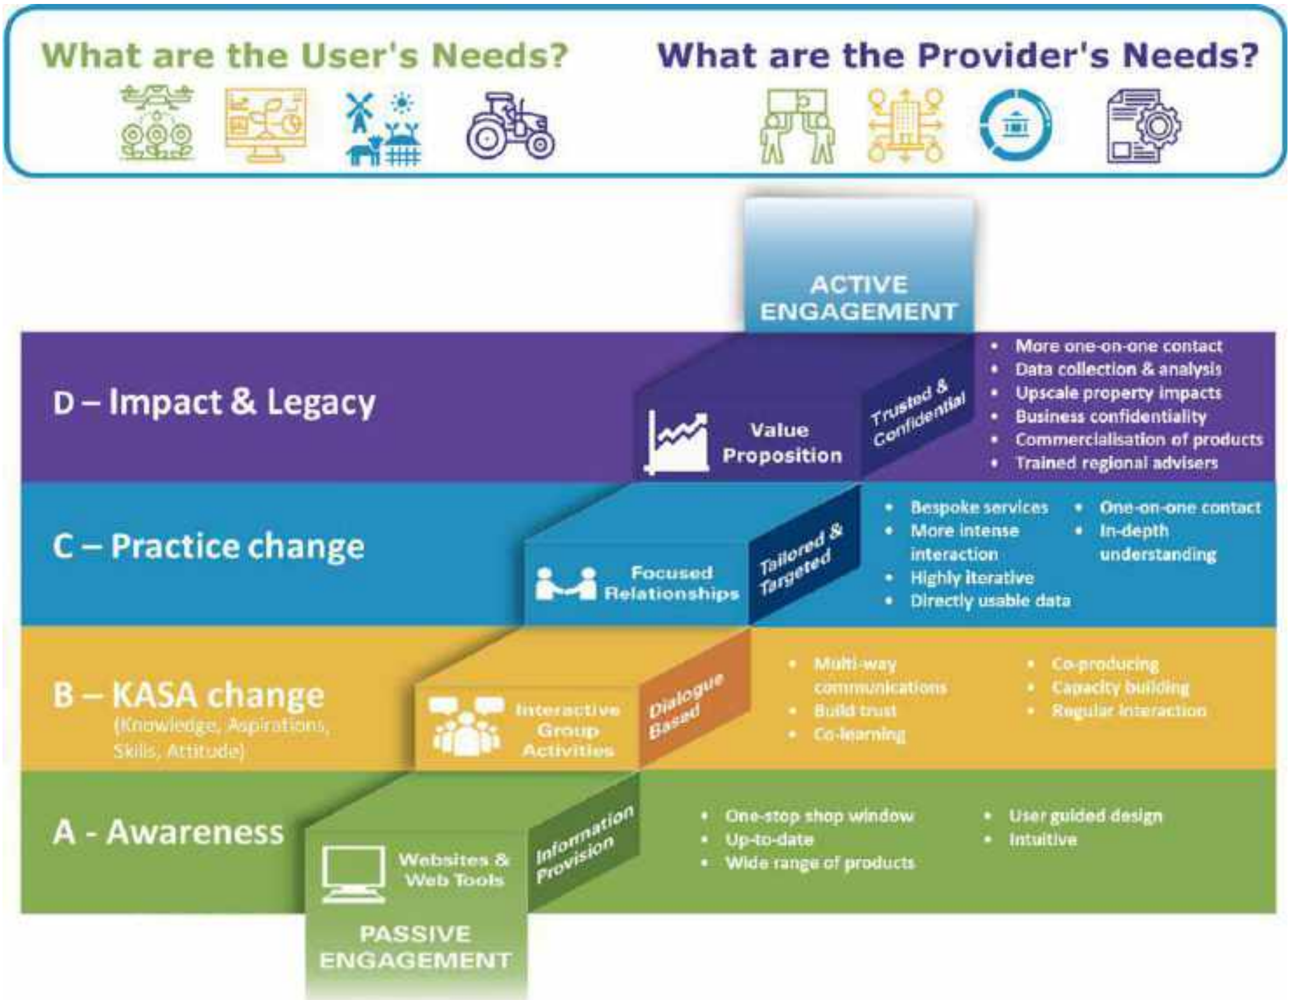

Figure 1: Schematic of four broad categories of NACP engagement with primary producers, adapted with permission from Hewitt et al. (2017).

Results

NACP incorporates robust monitoring, evaluation, and learning activities with tailored extension and adoption services that have been built around:

Category A goals: Producers have improved awareness of NACP, its aims and benefits for Australian agricultural industries, commodities, and stakeholders through the provision of web-based drought information and tools.

Category B goals: Producers have improved knowledge, aspirations, skills and attitudes in the use of forecast products and tailored information for effective decision making.

- Climate Mates have provided ongoing training to producers in interpreting drought and climate forecasts and information demonstrating climate resilience.
- Regular communication between stakeholders and Climate Mates has built knowledge, confidence, and trust around forecasts tools, and the capacity of producers and graziers to use that knowledge to maximise climate resilience. This has led to increased uptake and improved interpretation of forecast products, and improved trust and confidence in Bureau of Meteorology forecasts and services.

- The NACP extension and adoption service, tailored to each region, has been dialogue based and built around interactive group activities; workshops, field days, training sessions, online demonstrations, property visits, agricultural shows, and regular email updates. This direct engagement has fostered transformational change across various levels (property, community, regional) and enhanced the integration, coordination, and sustainability of climate resilience practices.

Category C goals: Practice change has resulted from timely, effective use of the extension and adoption service.

- Personalised and focussed one-on-one interactions between producers and Climate Mates have led to effective uptake of climate products in operational and strategic decision-making and improved economic, environmental, and social outcomes.
- Measures of practice change have also included the extent to which stakeholders and industry are incorporating the NACP extension and adoption service in their decision-making, and the observed strategic changes in enterprises that arise from the service.

Category D goals (in progress): Impact and Legacy

- Centred on the core principles of confidence and trust in climate knowledge and forecast information, this is measuring the improved capacity of producers to be resilient, sustainable, productive, and profitable by using the NACP extension and adoption service in decision making.
- Case studies are providing a comprehensive understanding of how informed decision-making impacts natural resource management on properties, enhancing climate resilience, and improving the project's overall capacity.

All Category data has been managed using a Customer Relationship Management platform to capture, manage, and report on producer engagement, adoption, practice change, and project milestones. To date, NACP3 (2022-present) has delivered 11,941 Category A, 4,291 Category B, and 189 Category C outcomes for producers, exceeding those achieved in NACP2 (2018-2022; Lavender et al. 2022). Importantly, Category C outcomes in three years of NACP3 are already 126% of those achieved in the four years of NACP2 (150 Category C outcomes), demonstrating growth and interest in the use of the program across northern Australia.

Category A, B, C, and D outcomes are assessed through feedback from community, industry, and advisors via emails, reports, surveys, and stakeholder interviews. This monitoring, evaluation, and learning framework has demonstrated its capacity to drive significant behavioural changes and foster greater trust and confidence in climate forecasts among producers.

The NACP website highlights several case studies that illustrate how on-property decision making has benefitted from the use of climate information delivered through the program's extension service (https://nacp.org.au/outreaches/case_studies). For example, producers in Batchelor NT (south of Darwin) have gained a greater understanding, confidence and trust in forecast information from participating in face-to-face training sessions with the regional Climate Mate and extension program coordinator. This has resulted in lower stress, more informed decision making, and better outcomes that include improving the land through revegetation works, weed and erosion control (Category C). This is helping to balance social, economic, and environmental considerations for their business (Category D).

Conclusions

Delivered across northern Australia, the NACP extension and adoption service provides region-specific information through Climate Mates; extension officers with local knowledge, landscape management expertise, and commodity-specific connections.

NACP incorporates robust monitoring, evaluation, and learning activities with tailored extension and adoption services that are built around awareness (Category A), change in KASA (Category B), practice change (Category C) and demonstrating impact (Category D).

The tailored extension and adoption service is utilising existing monitoring and forecast products to help the northern Australian red meat industry make proactive decisions to minimise the economic, social, and environmental losses associated with climate variability and extremes in the days, weeks, and months ahead.

Drawing on the success of the program, future directions may include adapting the NACP model to other farming regions and commodities in livestock and horticulture, with a key focus on planning and preparedness for building drought and climate resilience across Australia.

Enhancing climate resilience as a NACP Climate Mate

Hinds, EM

Centre for Applied Climate Sciences, University of Southern Queensland, Toowoomba, Australia.

Key words: extension services; climate literacy; decision support.

Abstract

The Northern Australia Climate Program (NACP) is improving the capacity of the red meat industry to manage drought and climate risk across northern Australia. NACP runs an extension and adoption service that enables producers to better understand the main climate and weather influences in their region, interpret forecast information from days to seasons ahead, and make better informed decisions on property, particularly in the management of pastures for production (Lavender et al. 2022).

Undertaken by regionally located extension officers called Climate Mates, the NACP extension and adoption service includes one-on-one property visits, field day talks, newsletters, workshops, webinars and monthly mailouts. Climate Mates come into the role with existing community networks, and a sound knowledge of local industries. However, most have limited knowledge of weather and climate to begin with, and so with help from peers and researchers at the Bureau of Meteorology, Climate Mates quickly develop an understanding of concepts such as tropical convection, climate drivers, and seasonal variability.

Introduction

Climate Mates are part-time outreach advisers also known as extension officers or agents, who bridge the gap between researchers and pastoral producers by delivering tailored climate and weather information that is accessible and relevant to the needs of northern Australia. The NACP's use of Climate Mates as extension advisers is crucial for improving the uptake of climate information and enhancing the resilience of pastoral industries in northern Australia (Cobon et al. 2021). The program's success depends on the clear communication of complex climate data (observations and forecasts) in ways that are practical and understandable for local producers.

Climate Mates are employed to service one or several pastoral districts of northern Australia from their state or Territory. The focus of this paper is to highlight the experiences from the role of Climate Mates, and how satisfying and successful the work has proven to be.

Figure 1 The NACP extension team, NACP conference, Darwin NT, November 2021.

Methods

On employment, the Climate Mates are not expected to have qualifications in climate science, with employment criteria focussing on the ability to exchange information clearly, as well as having existing connections to the pastoral industry. This ensured that those employed in the roles were active stakeholders of the industry and held a vested interest in the program benefiting their industry. Many of the Climate Mates are beef producers, or work in affiliated industries, such as cattle transport, carbon mitigation, animal nutrition, pasture production, and natural resource management.

Most Climate Mates are located in agricultural communities. Climate Mates are employed on a part-time basis, which could be considered a hindrance to the employment of potential candidates seeking full time work, however this provides benefits to those employed in the pastoral industry to complement their existing work. This local knowledge of pastoral production systems and the beef supply chain, along with established industry networks in their regions, make them trusted intermediaries between researchers and pastoralists.

Unfortunately for many of the Climate Mates, their employment began during COVID in 2020-2021, resulting in the climate literacy training being delivered online. Delivery of content was via videos and power point presentations from colleagues at the University of Southern Queensland's Centre for Applied Climate Science (UniSQ CACS), and program researchers employed by the Australian Bureau of Meteorology. The Climate Mates found benefit in being able to watch training content over again to gain understanding but felt disadvantaged in being unable to ask questions amongst new colleagues that they had yet to establish working relationships with. "I didn't want to appear stupid or be the only person asking the question" pers comms. N. Pilcher, September 2021.

Results

The initial intake of Climate Mates in 2018, completed their climate literacy training in-person, onsite at the University of Queensland's Toowoomba campus, during 20-21 August 2018.

These sessions were delivered by a team of senior climate researchers to the newly appointed Climate Mates. According to Climate Mate, A. Huey, the training was poorly designed, "the climate mates were a group of practical, no nonsense, mostly extroverts, who had been plucked straight out of northern Australia and into the middle of a southern winter, presented complex graphs, and an onslaught of acronyms over a short time". Several of the climate mates present at that initial training agreed that the "training content and delivery was unrelatable, and high level" and it was suggested that one of the newly recruited Climate Mates was so overwhelmed with the content and quantity of information presented, that they left the program as a result. While a disappointing outcome, ironically, this outlines the exact need for extension services at the core of NACP, to ensure clear communication and education of complex climate and weather information to primary producers and land managers, in a practical and relatable way.

The Climate Mates employed in the program, regardless of their initial training design have all now gained a solid understanding of influential climate and weather systems, as it relates to their regions. This has been achieved through regular group updates, mentoring, conference attendances, workshops, roadshows with Bureau of Meteorology research staff, online meetings, self development and their own research. According to Climate Mate V. Mayne, the improved understanding can be attributed to the relationship between the Climate Mates and the researchers employed in the NACP from the Bureau of Meteorology and the UK Met Office. V. Mayne says "having access to experts over the phone and in person" provides valuable knowledge and explanations of the climate systems, and forecasting models that Climate Mates can then provide in their conversations with producers. "It gave us a lot of confidence in what we were delivering, gave our producers a chance to ask tricky questions that we didn't have an answer for, and gave the Bureau of Meteorology a face and a person to relate to" (V. Mayne, pers. comms.). At workshops or property visits, V. Mayne says that "having the Bureau there was great. It was a two-way relationship. Producers would get firsthand explanations of the forecasts, and our research team would learn about beef production and really get an understanding of the lives of our producers".

Several of the NACP climate researchers have participated in climate road shows. These are multi week trips through the remote pastoral districts of northern Australia accompanied by the local Climate Mate and/or natural resource management officer to visit cattle stations to deliver climate literacy workshops. Long distances, heat and cold, flies, roadhouse food, station accommodation or swags under the stars, these trips have been exhausting at times but highly rewarding for all involved. These researchers can now include pregnancy testing amongst their skill sets, along with the knowledge of cattle breeds, cattle genetics, pasture production, bottle feeding calves, weighing cattle, changing flat tyres, and a valuable early lesson that running cattle in a distant paddock are not going to attack you. NACP researchers have stated that these trips are some of the highlights of their careers, "being able to demonstrate your research work, and to see it being used and appreciated, and how it applies in their world, it's just so satisfying", pers comms T. Cowan October 2024.

Personal interactions with producers allow the Climate Mates to provide insights to NACP researchers, highlighting information gaps and possible tools that could be used by agricultural land managers, one example is the development of the Bureau of Meteorology's Chance of three-day totals forecast maps. These maps, show the chance of receiving at least a particular rainfall total, over three consecutive days in the forecast period. This was particularly important for agriculture to plan work activities such as windows for crop planting, expectations around pasture response and grazing times, and consider access issues to paddocks and infrastructure. After the development of this tool, many of NACP's engaged producers, have used it to plan the preparation of paddocks and the date of cotton planting, organised fuel and food delivery to the station before road access becomes an issue, and in understanding the likely response of pasture growth. An important, but less discussed value of our extension service, is in the trust and confidence that land managers gain from their involvement. With increased understanding of the forecast products, producers make informed decisions about grazing management, removing some of the risk of land degradation, economical hardship, and emotional stress. Climate mate A.Huey, says that one of the highlights of her role is "the value of giving people the info and skills to filter out all the white noise and media hype that can cause a lot of undue stress if you just read a headline". This was recorded in a producer interaction from central Australia, where a station manager Z. Groves, attended a NACP climate literacy workshop in 2021, after two years earlier, experiencing drought and hardship in the 2018-2019 season. She shared in group feedback discussion, that if she had known this information prior to this time, that it would have "saved a lot of stress". She recalls that they were "hoping for rain", rather than following trusted information with confidence. She said "it wouldn't have changed the drought but it would have meant there were no surprises, and that they were better prepared". As Climate mate J. McLaughlin states, "considering climate has an influence on every part of life in the bush, to be able to review what the climate is likely to do in the months ahead is pretty powerful. The return on investment is huge".

Discussion

A legacy of the extension and adoption service is the production of Rain Gauge, a Profitable Grazing Systems (PGS) training course through Meat and Livestock Australia. This course embeds climate literacy into grazing production systems across Australia. This contextualised knowledge will be available nationally to producers for future use. It also offers the Climate Mates of NACP, continuity in delivering tailored climate and weather information after finalisation of NACP. Since its commencement in 2018, NACP has engaged with over ten thousand red meat producers, extension officers, government agency staff and industry stakeholders, across northern Australia (Cobon.D. 2024).

From personal experience, the rewards of delivering climate extension services across northern Australia are many. From being able to visit and explore the vast rangeland landscapes of the NT and showing graziers the tools to use to interpret the forecasts, through to utilisation of these tools in decision making. I am convinced that the information and education I provide, is helping people to make decisions that will benefit the rangelands environment. We forewarn of drier or wetter than normal conditions, and promote herd management decisions, such as reducing grazing numbers, or spelling paddocks. Other benefits are the personal relationships formed through continued extension and contact, I count many of the producers I have engaged with as friends now, and I'm always rewarded at a visit with a station meal and beef to take home. Once just an avid rain radar watcher, and appreciator of intense tropical storms, four years into the role, I now understand and speak confidently about the seasonal drivers and influences of northern Australia's climate.

Livestock grazing systems: a problem or a solution for our planet?

Blanfort, V[1] ; Corniaux, C[1] ; Alary, V[1] ; Duteurtre, G[1]

Key words: Livestock grazing system; climate change; controversies; metrics

Abstract

Within the context of global change, livestock production is undergoing major restructuring. For several decades, demand for animal products has been rising sharply. This “livestock revolution”, together with expansion of land cultivated for food and feed, has exacerbated human pressure on land and natural resources. Ruminant livestock farming is one of the most heavily criticised sectors, notably for its significant contribution to greenhouse gas (GHG) emissions (12% of total emissions) and its role in degrading sensitive environments (desertification in the Sahel, deforestation in Amazonia). In addition to being a simple factor in reducing the environmental impact of food systems and, in particular, in adjusting GHG emissions, the productive purposes of livestock grazing systems and agro-pastoral systems are now being widely revisited. It is no longer just a question of ensuring food security, but of considering the many services provided by this activity, which is also heavily impacted by climate change. It is a complex question, and we need to go beyond simplistic visions and solutions. To contribute to the debate, we examine the major developments in the various types of livestock sector over the last few decades, particularly the ruminant sector, and their impacts on climate change. Then we propose to debate the controversies linked to the need to reduce emissions, which have made livestock farming a particularly problematic environmental and social issue. What are the options for sustainable grazing systems, combining adaptation to climate change with mitigation? What is the future of grazing livestock under the influence of intensifying and accelerating climate change? In order to facilitate transformation of the livestock sector, it is essential to reconsider the evaluation metrics used to assess the sector's impact on nature and its sources. This will enable a more comprehensive and detailed understanding of this sector, which will in turn inform its future development.

Introduction

According to a recent FAO (2023) assessment, livestock production accounts for 12% of anthropogenic greenhouse gas (GHG) emissions, or 40% of total emissions from the agrifood system. Critics point to its role in deforestation in the Amazon, desertification in the Sahel, competition between animal feed and human food, and concerns about the impact of meat consumption on human health and animal welfare. However, these generalisations fail to take into account the diversity of livestock farming systems, species, production methods and consumption patterns. Livestock farming fulfils important environmental, social and economic functions beyond its impact on GHGs, and it is therefore unwise to consider solely an emission reduction target. Effective assessment of livestock’s contribution to climate change requires context-specific approaches, improved evaluation methods and consideration of its multiple and interdependent agro-ecological and socio-economic dimensions, particularly in developing countries where data on livestock GHG emissions are limited. Given significant transformations in the sector in recent decades, this paper reviews briefly livestock's impact on climate change and explores options for sustainable systems. It also addresses controversies that make livestock farming a contentious societal and political issue. We hypothesise that appropriate assessment methods can help to better address the trade-offs between environmental, economic and social functions, towards sustainable livestock systems.

How does livestock farming contribute to climate change?
Global livestock production has grown faster than the human population (except for beef), intensifying its environmental impact (Gerber et al. 2013, FAO 2023). Over the past few decades, this growth has led to the expansion of land cultivated for food and feed, significantly increasing the ecological footprint of the livestock sector, which is now a major contributor to agricultural GHG emissions.

According to the FAO (2023), livestock systems account for 12% of anthropogenic emissions, with methane as the primary contributor (54%), followed by carbon dioxide (31%) and nitrous oxide (15%). GHG emissions vary widely across regions and are not strictly tied to production volumes. Ruminants contribute 70% of livestock emissions, but grass-fed livestock systems account for just 20% (Gerber et al. 2013). Regions like sub-Saharan Africa, with low productivity, and Latin America, where forests are converted to pastures and feed crops, exhibit the highest emissions per kilogram of carcass produced (70 kg eqCO2/kg).

These figures are still the subject of debate within the scientific community. In particular, the contribution of livestock farming to emissions linked to land-use change and carbon sequestration has not yet been properly assessed. However, references on the specific contribution of livestock systems in southern countries to GHG emissions are insufficient and often based on data from developed countries. Besides in developed countries, livestock remains an important component of mitigation and adaptative strategies to climate changes through mobility, rangeland biodiversity preservation and source of income (see Alary et al. 2021).

What are the options for sustainable food systems?
Over the past 40 years, the rapid growth of livestock farming has certainly considerably increased GHG emissions. However, a more nuanced, context-specific approach (Blanfort et al. 2023) is essential to ensure that global solutions do not undermine rural communities and agro-pastoral systems, which often contribute to sustainable development. According to the United Nations, to feed nearly 10 billion people by 2050, livestock production should continue to grow, particularly in regions such as sub-Saharan Africa, India and South-East Asia, where populations are increasing rapidly and consumption of animal products remains low. To meet this demand, three options can be considered: i) increasing the number of livestock, ii) intensifying production or iii) importing animal products. These three options do not have the same impact on GHG emissions, respectively on: i) the increase in GHG emissions, ii) the reduction in GHG emissions per kg of product due to the increase in productivity but reduction in carbon storage in livestock farming systems, and iii) the carbon footprint linked to transport and imported deforestation (the direct or indirect deforestation caused by the production of raw materials or processed products outside the consumer's national territory).

Reconciling growth in the supply of animal products with global GHG emission reductions remains a major challenge. While alternatives advocate reducing meat and dairy consumption, particularly in the developed world, they often rely on industrialised models. A more viable approach, particularly in pastoral systems, is to minimise losses and waste throughout the animal product chain in pastoral systems: the circular bio-economy. This offers significant potential to reconcile sustainable economic development with global challenges such as food security, climate change and resource management (Vayssières 2011). Livestock systems that use grazed and harvested resources are also characterised by a capacity to store carbon in soils, which is highly effective in controlling carbon fluxes According to Gerber et al. (2013), soil management offers the greatest potential for reducing agricultural emissions. This approach is becoming increasingly integrated into sustainable development plans for the livestock sector. However, the current metrics and methods of assessment may prove inadequate for evaluating grazed ecosystems, particularly in tropical regions, where the potential for carbon sequestration is significant due to the extensive land area involved.

Better assessment methods to address controversies in the livestock sector and facilitate its transition

In recent decades, livestock production has generated controversies over its role in meeting the world's demand for protein and its impact on the environment, particularly in relation to climate change. Addressing these challenges requires integrating both aspects to steer agriculture towards sustainable food systems.

The report ‘Livestock's long shadow’ (Steinfeld et al. 2006) highlighted the significant negative impacts of livestock on land use and climate. Meanwhile, livestock issues are increasingly central to climate negotiations, such as the methane pledge at the 26th Conference of Parties in the United Nations Framework Convention on Climate Change (UNFCCC COP26) in 2021, and broader mitigation. Soil organic carbon (SOC) now plays a key role in climate regulation, accounting for 47% of agriculture's mitigation potential (Bossio et al. 2020), with most SOC stored in forests (30%) and grasslands (30–35%, Lal et al. 2012). Maintaining or increasing these stocks is one of the few options identified by the Intergovernmental Panel on Climate Change (IPCC 2019) that can simultaneously mitigate climate change, combat land degradation and biodiversity loss, and improve food security. These synergies inspired the international initiative 4 for 1000: soil for food security and climate, launched at UNFCCC COP21 in 2015. The positions and narratives on livestock thus vary across political, scientific and social spheres, influencing each other. Understanding the actors behind these diverse narratives and metrics helps clarify the current view of livestock and its impact on policies.

Some metrics persist unchallenged, shaping pro- and anti-livestock discourse. Questioning these metrics (on their nature and sources) on today's agricultural trends should allow a more objective and nuanced view of the livestock sector. However, measuring the role of livestock farming in global change is complex and requires new, contextualised evaluation methods to accurately assess carbon flows. These assessments are crucial for designing mitigation actions: i) reducing GHG emissions and ii) promoting carbon transfer and storage from the atmosphere to terrestrial compartments. Several cases of field research on livestock grazing systems in emblematic tropical areas reveal effective mechanisms for soil carbon sequestration and methane emission reduction by cattle. In Amazonia, in areas where farmers have stopped deforestation, research is supporting a low-carbon development path. The renewable resources in these regions (solar radiation, rainfall, soil) can efficiently support productive grazing systems that store carbon in the soil (Blanfort 2023), as shown by research in the French Amazon (Stahl et al. 2016, 2017). In Senegal, despite livestock's reputation for high GHG emissions per unit of product, research shows that pastoral areas can be carbon neutral by using an ecosystem assessment method that considers the entire use of the territory (Blanfort et al. 2023).

Conclusion

Livestock farming plays a complex role in climate change and food security, with its environmental impact varying across regions and production systems. While livestock contributes significantly to global GHG emissions, particularly methane, the environmental footprint is not uniform. A nuanced approach to evaluating these impacts is needed, considering diverse farming practices and the socio-economic functions of livestock.

Therefore, future research should focus on developing more refined and regionally tailored assessment methods to better understand the full scope of livestock's environmental impacts. In particular, it is necessary to produce more integrative measures and evaluation methods to better grasp the complex interactions between livestock farming and environmental factors, while integrating the multifunctional dimensions of livestock farming.

The aim is to contribute to science-based policies, right up to the international governance levels of the COPS of the UNFCCC and the United Nations Convention to Combat Desertification (UNCCD). The challenge for the future is to develop policies that support livestock farmers in the face of climate challenges, while guaranteeing food security and sustainable resource management.

The International Year of Rangelands and Pastoralists (IYRP), to be held in 2026, offers a tremendous opportunity to work towards these goals, to effectively integrate these issues into international commitments and climate financing. This will help to better integrate the role of pastoral systems in mitigation, adaptation and sustainable land management – aspects often underestimated in climate negotiations.

Realising the opportunities and potential for pastoralist youth in rangelands

Ruto, C[1]; Lekaitogo, J[2]; Finca, A[3]

[1]Kansas State University; [2]African Youth Pastoralist Initiative; [3]Agricultural Research Council, South Africa

Key words: pastoralist youth; rangelands; rangeland management; economic opportunities

Abstract

As pastoralist communities face a multitude of challenges that threaten their sustainability, engaging with youth in rangeland management is becoming increasingly important. This paper explores the opportunities that rangelands offer young people and the potential benefits of youth involvement in pastoralism. Drawing on existing cases and examples, we examine how youth participation in rangeland management contributes to socioeconomic development and ecological conservation. Pastoralist youth bring innovative approaches to traditional practices and integrate modern technologies with indigenous knowledge. Their adaptability and openness to new ideas can lead to more resilient pastoral systems and better rangeland management.

However, challenges remain in attracting and retaining youth in pastoral livelihoods. Addressing challenges such as land access, conversion and privatisation, and high entry barriers is essential for the viability of pastoral economies. Improving working conditions, strengthening labour rights, and ensuring succession planning and governance transition from elder pastoralists to the younger generation can attract more youth to pastoralism. We discuss potential strategies to overcome these barriers, including education programmes, policy support and economic incentives that recognise the multifunctional value of rangelands. Rangelands provide diverse opportunities for youth beyond herding along the value chain, including agribusiness ventures, eco-tourism and social protection projects. These opportunities present chances for young people to generate income, create jobs and contribute to the local and national economies. The greatest opportunities for change in pastoralist societies lie with the youth, who are often better formally educated and more in touch with emerging technologies and trends. By valuing and recognising the contributions of young pastoralists, we can explore innovative ideas and unlock the potential of rangelands in fostering sustainable development.

Introduction

Pastoralist communities are crucial in sustaining rangelands, encompassing over half of the Earth's terrestrial ecosystems (ILRI et al. 2021). These ecosystems sustain millions of people globally, particularly pastoralist communities, who depend on them for livestock grazing and cultural preservation. The livestock sector, predominantly supported by rangelands, accounts for over 50% of agricultural GDP in many African countries and provides critical sustenance and income for millions (FAO 2018). However, rangelands face significant challenges, including climate change-induced degradation, socioeconomic exclusion, and political and policy marginalisation (Briske et al. 2023). Pastoralist communities are at the heart of sustainable rangeland management, contributing significantly to local and national economies, and youth within these communities hold the key to their sustainability.

Youth represent a demographic group with the potential to integrate traditional practices with modern innovations and emerging technologies, fostering ecological balance and socioeconomic progress. However, these potential contributions are at risk as youth increasingly move away from pastoralism on account of limited economic opportunities, poor working conditions, and lack of access to education and land rights (Ancey et al. 2020). The disengagement of youth threatens the generational continuity of pastoralism, leading to the potential degradation of these ecosystems due to mismanagement and abandonment. Engaging youth in rangeland management offers a path to address these challenges in rangeland ecosystems by leveraging their adaptability, education and familiarity with emerging technologies. As rangelands play a crucial role in global food security, biodiversity conservation and carbon sequestration, empowering youth to re-engage with and innovate in rangeland management is urgently important (Holechek et al. 2020). This paper argues that addressing these socioeconomic and structural barriers is essential for realising the untapped potential of pastoralist youth to sustain and enhance the value of rangelands.

Methods

This study employed a literature review approach to investigate the role and potential opportunities for pastoralist youth in rangeland management. The review was conducted in several steps to ensure comprehensiveness and replicability. First, relevant sources were identified by searching academic databases, institutional repositories and online libraries. However, the review process revealed a significant scarcity of comprehensive, peer-reviewed studies and reports specifically addressing the role and contributions of pastoralist youth. This limitation necessitated reliance on grey literature, organisational reports and case studies. Specific journals, including *Rangeland Ecology & Management*, *The Rangeland Journal,* and *Rangelands*, were prioritised for their focus on rangeland ecology and pastoralism. Keywords such as "pastoralist youth," "youth," "rangeland management," "sustainable pastoralism," "youth empowerment," and "rangeland opportunities" were used during database searches, and only publications from the last two decades that explicitly addressed youth engagement in pastoralism, rangeland management strategies, or socioeconomic and policy dimensions were considered. Global, regional and local case studies and examples of youth engagement were selected. The selected studies were reviewed to extract data related to the research themes. The extracted data were categorised into economic diversification, technological integration and socio-political challenges affecting youth participation. A synthesis approach was applied to integrate findings across disciplines, providing a comprehensive understanding of the topic. Previously established review methodologies were referenced to ensure consistency and rigour, following guidelines outlined in earlier studies on pastoralism and rangeland sustainability (Turner et al. 2019, Scoones et al. 2013). This structured approach ensures that the findings are robust and grounded in diverse, high-quality sources.

Results

Rangelands offer a diverse range of opportunities for pastoralist youth. Beyond traditional herding, young pastoralists are increasingly engaging in agribusinesses, eco-tourism and value-chain activities like animal product processing and marketing. However, the findings indicate that they face significant opportunities and barriers in rangeland management. Key opportunities include diversification into agribusiness, where youth-led ventures such as dairy production, fodder cultivation and meat processing have demonstrated economic viability (FAO 2024). Ecotourism offers another avenue, particularly in biodiversity-rich rangelands. Initiatives such as community-run wildlife conservancies in Namibia have enabled young pastoralists to generate income while contributing to conservation efforts (Naidoo et al. 2016, Schiffer 2004). Youth can integrate ecotourism and biodiversity conservation with pastoral livelihoods by guiding tourists and conducting educational programmes about pastoralist practices, which generate income and foster cultural preservation and environmental awareness.

In Mongolia, young pastoralists are increasingly adopting digital tools to manage livestock and grazing patterns in response to overgrazing and climate change challenges. For example, herders use mobile phones for weather forecasts, livestock market prices and emergency alerts (Baival et al. 2012). Digital platforms such as the AfriScout app provide geospatial data to optimise grazing routes, while mobile banking services facilitate financial inclusion for young herders (SPARC 2013). Young pastoralists have also been instrumental in reviving community-based herding systems, known as *Nukhurlul*, which promote equitable resource sharing and sustainable grazing (Upton 2008). Educational initiatives, such as the Pastoralist Field Schools supported by the FAO, equip youth with skills to manage rangelands sustainably (Khisa et al. 2013). In the arid rangelands of Australia, Aboriginal youth are engaging in land stewardship programmes, and the Ranger Programs employ youth to manage invasive species, conduct controlled burns and monitor biodiversity, demonstrating the effectiveness of blending Indigenous and modern practices (Altman et al. 2012, Department of Climate Change, Energy, the Environment and Water 2021, Young et al. 2008). Thus, indigenous youth can actively participate in sustainable grazing and landscape restoration initiatives while raising awareness about their way of life. In Europe, shepherd and shepherdess schools are important for preserving pastoralism and herding traditions while equipping a new generation of herders with skills for extensive livestock farming (Bindi 2024, Escuela de Pastoras 2024). These institutions provide comprehensive training that integrates traditional herding and contemporary practices, empowering rural communities with extensive livestock farming and providing solutions to climate change as guardians of the ecosystems and managers of landscapes.

Despite these opportunities, systemic challenges persist. Limited access to land and insecure tenure rights disproportionately affect youth, reducing their ability to sustain livelihoods and engage with pastoralism, primarily due to land privatisation and encroachment (Archambault 2014). Additionally, the high costs of land and infrastructure limit entry into pastoralism. Climate variability exacerbates these challenges, increasing vulnerability to droughts and resource scarcity. A lack of reliable data and information on pastoralist youth further exacerbates this issue, making it difficult to design targeted interventions and support mechanisms. Youth engagement in pastoralist activities significantly contributes to the economic sustainability of rangeland-dependent communities. Young pastoralists bring diversification to traditional livelihoods, creating new revenue streams and job opportunities.

Discussion

The role of pastoralist youth is pivotal to the future of rangeland management. Their capacity to merge indigenous knowledge with modern technologies creates opportunities for innovation and resilience. However, enabling this requires targeted interventions, such as securing land rights through legal frameworks and community governance models that can reduce marginalisation. Educational reforms and initiatives that include technical training and indigenous knowledge systems can prepare youth for leadership roles in rangeland management.

Pastoralist youth have a unique ability to innovate within traditional systems, positioning them as drivers of sustainable development in rangelands. By integrating indigenous knowledge with modern technologies, youth can enhance resource-use efficiency and ecological resilience. The role of education and programmes like FAO's Pastoralist Field Schools and Spain's shepherding schools have built the technical and managerial capacity of young herders, enabling them to adopt climate-smart practices and engage in governance (Escuela de Pastoras 2024, FAO 2017, Khisa et al. 2013). Securing land rights through inclusive tenure policies and policy interventions is fundamental to addressing the barriers to youth participation and empowering youth engagement in pastoralism. Economic incentives, such as microcredit schemes and cooperatives tailored for livestock production and animal product price regulation, can lower financial barriers and create market access. Collaborative governance models that include youth in decision-making ensure that their voices shape the future of rangelands.

Enhancing land-tenure security is fundamental to advancing youth participation in pastoralist livelihoods and ensuring sustainable rangeland management. Secure land rights empower youth by providing stable access to grazing areas, reducing resource-use conflicts, creating space for infrastructure and value chain activities, and lowering entry barriers for new pastoralists. Policies formalising community land ownership, such as the Community Land Act in Kenya, offer a replicable framework for addressing tenure insecurity among pastoralist youth (Government of Kenya 2016). Integrating participatory governance models, where youth take active part in land management decisions, can further enhance tenure security. International organisations like the International Land Coalition advocate for inclusive land-tenure policies that combine customary practices with legal recognition to accommodate the unique needs of pastoralist communities. Financial incentives, such as subsidies for land registration and microcredit programmes for land development, can also reduce economic barriers to land ownership. By prioritising these policies, governments and development partners can unlock the potential of youth to contribute to sustainable rangeland management, ensuring the long-term viability of pastoral systems.

While the role of pastoralist youth is gaining recognition, a significant gap remains in the availability of data and information about their contributions and challenges. This lack of accessible, comprehensive research and online resources has hindered the development of targeted policies and interventions for pastoralist youth. However, efforts such as the International Year of Rangelands and Pastoralists (IYRP) have begun to spotlight these issues, catalysing global attention and dialogue on youth and other emerging issues. Despite this momentum, the scarcity of detailed data on pastoralists including the youth remains frustrating, as it limits the ability of stakeholders to understand and support their transformative potential in rangeland management fully. To bridge this gap, participatory and transdisciplinary research involving pastoralist youth is essential. Such approaches would ensure that the voices and experiences of youth are directly integrated into data collection and analysis, leading to more effective, evidence-based interventions and policies.

The potential for pastoralist youth extends beyond economic contributions. Their involvement in governance, education and technology development can drive systemic change, ensuring that rangelands remain productive and resilient. Communities and policymakers can secure these critical ecosystems' ecological and socioeconomic sustainability by investing in their capacities. The future resilience of rangelands is intrinsically linked to youth engagement. Their innovative spirit and technological fluency can maintain pastoralism as a viable and sustainable livelihood, balancing ecological conservation with economic development.

Acknowledgements
This paper acknowledges the invaluable contributions of the International Livestock Research Institute (ILRI) and the Food and Agriculture Organization (FAO) for providing information and insights. Additional thanks are due to the local pastoralist communities whose experiences informed this study.

Pastoralist women's initiatives in self-organisation and co-innovation for a sustainable future

Ghotge, NS[1]; Waters-Bayer, A[2]; Quiroga Mendiola, M[3]; Pasetti F[4]

Key words: women herders; endogenous development; local knowledge; transdisciplinary research

Abstract

On rangelands, which cover over half the Earth's land surface, pastoralists produce food and other products from livestock. Not only have rangelands and pastoralists received less investment in research and development; often, women's critical roles in pastoral systems are overlooked or undermined by development interventions. There are only a few examples where herdswomen and rangeland scientists have worked together to jointly understand the rangelands and possible futures.

The United Nations declared 2026 as the International Year of Rangelands and Pastoralists (IYRP). This paper draws on own experiences of members of the IYRP Working Group on Pastoralism and Gender (WG)[18] in their work with pastoralist women as well as from a desk study, which is underway, of publications and grey literature related to pastoralist women's initiatives in endogenous development and co-innovation, in self-organisation to have more influence in public spheres, and in the women's collaboration with scientists.

The paper brings some findings from this desk study, here specifically related to experiences in Argentina, Hungary, India, Eastern Africa and Spain, which will be used in the lead-up to and during the IYRP2026 to raise awareness globally about the strengths and potentials of pastoralist women. The findings will also feed into a global gathering of women pastoralists and researchers, designed to bring together their respective knowledge systems and intensify transdisciplinary collaboration in research and development in the rangelands.

Introduction

On rangelands covering over half the Earth's land surface, pastoralists produce food and other products from livestock (UNCCD 2024). About half of the pastoralists can be assumed to be women and girls. Not only have rangelands and pastoralists received less investment in research and development (Johnsen et al. 2019); often, women's critical roles in pastoral systems are overlooked or undermined by development interventions (Hodgson

[18] The Working Group on Pastoralism & Gender is one of several Working Groups of the IYRP Global Alliance.

2000, Wangui 2008, Yurco 2024). Despite having been highlighted for decades in development cooperation, gender issues are still often overlooked in rangeland and pastoralist development interventions.

The United Nations has declared 2026 as the International Year of Rangelands and Pastoralists (IYRP). In the lead-up to 2026, the IYRP Working Group on Pastoralism & Gender (WG) seeks to generate better understanding of gender issues related to rangelands and pastoralism, to advance gender equity regarding access to resources and inclusion in decision-making about pastoral management and governance issues, and to give greater visibility and voice to pastoralist women and girls at subnational, national, regional and global level. It also seeks to bring together knowledge systems of women pastoralists and scientists and to intensify transdisciplinary collaboration in research and development in the rangelands.

In all pastoralist societies, women play crucial roles in livestock husbandry and rangeland management. Their knowledge, expertise and labour related to animals, plants and water are essential to pastoralism, as is their work caring for homes and families and cultivating good social relationships within and between communities (e.g. Fernández-Giménez et al. 2024). Their roles in building social capital and ensuring the sustainable use and sharing of resources within the family and community help to maintain social cohesion and to navigate potential crises for pastoralists' survival. Pastoralist women are also keepers of the cultural heritage of pastoralism, ensuring that this vital knowledge, including ethnoveterinary knowledge, is shared in the community – particularly from women to women and girls – and thus passed on to younger generations.

Pastoralist societies throughout the world differ as to who can purchase, inherit or otherwise gain access to livestock; who decides about livestock management; who sells animals and their products; and who controls the income from sales. Most pastoralist women do not have the same opportunity as men to gain access to production resources such as livestock, land, credit, technologies and services.

In decision-making processes above the family level, pastoralist women often have only indirect ways of influencing decisions through male members of the community, instead of participating directly and meaningfully in decision-making entities themselves. Development initiatives and community governance institutions are often designed in ways that constrain pastoralist women from taking active part in addition to their productive (e.g. livestock care) and reproductive (e.g. childbearing and childcare, homemaking, care of the elderly) labour. These continuing obstructions to equity restrict women's potential and critically important contributions to development.

However, in many areas, pastoralist women are taking their own initiatives to deal with new problems and opportunities. For example, in Isiolo County in northern Kenya, some Somali women who were trading individually in camel milk formed the Anolei Women's Camel Dairy Cooperative for collecting, processing and selling the milk. They expanded local sales of dairy products into larger and further-reaching operations, as far as Nairobi 270 km away. Development agencies then provided support to these women by strengthening their business analytical capacities and helping them to reduce milk wastage and to add value to the milk products through joint market research and consumer-awareness activities (Po et al. 2023). Research in Eastern Africa showed that pastoralist women are more willing than men to experiment with options for commercial enterprises and diversification and are more likely to form groups to reduce risk and increase profits, although they have greater difficulties than men to access credit and assets (Stites 2024).

Methods

The almost 60 members of the WG, who come from various countries across the world, are collecting and analysing examples where pastoralist women have taken initiatives to form their own groups at national and regional level so as to improve their social, economic and political status. Likewise, the WG members are collecting and analysing examples of pastoralist women's own socio-economic initiatives on an individual or community basis and their collaboration with scientists in processes of transdisciplinary research and development, building on the women's initiatives. The examples are related mainly to the knowledge and innovation of pastoralist women in livestock production, animal healthcare, managing natural resources and governance of rangelands. These examples are drawn from the WG members' own experiences working with pastoralist women as well as from the above-mentioned inventory, which is still underway, of publications and grey literature related to pastoralist women's initiatives. These examples are to be used in the lead-up to and during the IYRP in 2026 to raise awareness globally about the strengths and potentials of pastoralist women. Further analysis will reveal how local initiatives can be supported and pastoralist women can exert more influence on decisions about research and development in the rangelands.

Results

The examples gathered from the different countries and pastoralist communities are diverse. Thus far, there are only a few examples where herdswomen and rangeland scientists have worked together to jointly understand the rangelands and possible futures. In the Argentine Puna, pastoralist women have collaborated with scientists to explore "mutual breeding" that integrates animals, people and the rangelands (Quiroga et al 2018). In India, the Van Gujjar, and Dhangar communities are working with ecologists and other scientists to understand better how rangelands function and are threatened and what needs to be done for their sustainable management (Anthra 2024). Some herdswomen are forming organisations to make their voices heard in policy dialogue and public events, also about research, and engaging in transdisciplinary research, e.g.in Hungary and Spain (Lelea etc 2024).

In 2010, about 100 women from over 30 countries met in Mera village in Gujarat State, India, in a Global Gathering of Women Pastoralist (IYRP). In their Mera Declaration, they called for recognition of their professionalism as women pastoralists and of pastoral mobility as a basic right. They demanded better access to land and other productive resources, markets, technologies, information and services, and incorporation of their expertise in interventions aimed at sustainable rangeland management. The Pastoral Women's Alliance that emerged from this event now includes about 3000 women. Another global gathering, Mera+15, is planned in 2025 to assess what has changed since the 2010 gathering.

Also in other countries, pastoralist women have taken initiatives to form national or subnational networks, such as the Pastoral Women's Council in Tanzania (PWC) and *Ganaderas en Red* (GER / Women Pastoralists Network) in Spain, with 200 members. In 2021, *Nők a pásztorságban* (Women in Pastoralism) was formed in Hungary with the aim of mutual help and knowledge sharing. Its members (now over 60 in number) also take part in festivals, events and international conferences. The women in such networks meet in person and virtually, exchange knowledge and learn from each other. This helps them overcome social isolation, nurtures pride in their identity and empowers them to work together towards sustainable development of their communities (Lelea et al. 2024).

In Argentina in 2006, the "Gender Area" of *Red Puna* (an Indigenous higher-level organisation in northwest Argentina) was formed to improve women's self-care and influence, combat domestic violence and help women achieve greater economic independence, e.g. through producing handicrafts made of llama fibre. For this purpose, the Indigenous women formed a subgroup *Las Artesanas* (Women Artisans). Women technicians, extensionists and researchers supported the entire process. The *Las Artesanas* members (now 120 women and 5 men) share their experiences and opportunities with new members and other women's organisations (Martínez 2013). Also in the Argentine Puna, pastoralist women and researchers share knowledge on grazing management and "mutual breeding" based on integrating animals, people and the environment. This work valorises women's knowledge and skills in managing herds and the relationships between livestock, pasture and the watershed, seeking to strengthen sustainability of the entire ecosystem (Quiroga Mendiola et al. 2018).

Amongst several pastoralist communities in India, when men left the community to seek jobs outside of pastoralism, the women dealt with this change by starting to manage the herds themselves, in addition to their regular tasks of caring for offspring and processing milk into different products for sale (Ghotge 2020). The *Van*

Gujjar Yuva Sanghatan (VGYS / Van Gujjar Youth Movement) – a group of young male and female Van Gujjar buffalo herders in the lower Himalayas – came together to address the challenges they face. The young women in this group have realised that formal education is needed to be able to navigate a future for themselves and their animals. Further south in Maharashtra State, women from the Dhangar pastoralist community are working with the team at the Indian NGO Anthra to understand the rapid changes in their ecosystems and the impact of climate change on their livestock and their livelihoods (Anthra 2024).

Women pastoralists in Europe, Africa and Asia are also using their networks to raise wider awareness in the general public and to influence policymakers by creatively conveying their messages through various media, including song and film, also participatory video (e.g. Maasai women in Tanzania: https://www.youtube.com/watch?v=BRvRRxoDggQ).

Pastoralism, especially highly mobile forms of it, makes collective action, organisation and even meetings difficult; however, modern technology in the form of mobile phones and apps have facilitated sharing and exchange. For example, in Spain, GER members use a communication tool called Slack, a free app installed on their mobile phones, to communicate and share knowledge. This group also brought out a cookbook of local recipes and uses songs, podcasts, films and social media to share messages about themselves and the work they do (cf. *Ganaderas en Red*).

Discussion and implications

There are many examples around the world that pastoralist women are organising themselves and innovating, also in collaboration with other research and development actors. The examples underline that cooperation and coexistence are important elements for pastoralist livelihoods, whether it be with the rangeland vegetation and landscape, with wildlife, with other communities living in and using the same natural resources, with research and development actors or with the State.

Women pastoralists have shown themselves to be passionate advocates for rangelands and pastoralism, defending pastoralists' mobility and land rights in the face of rangeland appropriation, commodification and conversion to other uses. Lack of formal education, health and social services suited for mobile pastoralists disproportionately impacts on the women and girls. Governments often justify initiatives to settle pastoralists with arguments about providing better services, yet pastoralists know that staying in one place reduces livestock productivity, degrades rangelands and water-points, and raises vulnerability to climate extremes, thus increasing poverty and compromising sustainability. Women pastoralists therefore call for services adapted to their mobile lifestyles.

Many of the women's organisations have given women a chance to develop new skills, take pride in their role as pastoralists and gain confidence to reach for their dreams. It is necessary to reinforce pastoralist women's efforts to advocate at all governance levels by supporting women-only and women-led groups to further strengthen women's confidence and capacities, educating women leaders and creating leadership opportunities for them, and funding their participation in international policy processes. Support is needed for pastoralist women's networks and international gatherings and for incorporating these networks into all initiatives related to rangelands and pastoralism, including those related to the IYRP 2026. It is also important to integrate pastoralist women into transdisciplinary action research and to build their capacities to carry out their own research on pastoralism and rangeland issues, building on their own specific knowledge, innovations and initiatives.

Pastoral animal husbandry, far from becoming obsolete in the face of industrial food systems, continues to thrive worldwide and is gradually becoming recognised as a more sustainable alternative to interventions in rangeland areas that require high levels of inputs based on fossil fuels. The knowledge-intensive practices of mobile pastoralists – men and women – make use of spatially and temporally variable vegetation and hold promise for a climate-friendly future. Pastoralist women's tasks are changing, largely due to their initiatives to address emerging problems and opportunities. The women are making deliberate efforts to increase their voice and influence also beyond their communities. It is time to make their vital traditional and new roles more visible so that they are better recognised in their own countries and globally and can contribute even more to wellbeing.

There is much to be learned from pastoralist women about their ability and determination to care for their animals, their families and the land that supports them; about their ability to face adversity and come together in innovative ways to face new challenges and grasp new opportunities; about their contribution to peace-keeping among multiple stakeholders in land use; and about their desire to continue as pastoralists and advocate for their way of life within their country and globally. These and more examples will be used in the lead-up to and during the IYRP in 2026 to raise awareness about the strengths and potentials of pastoralist women. Further analysis of pastoralist women's initiatives will reveal ways in which these can be meaningfully supported and ways in which pastoralist women can exert more influence on decisions regarding research and development in the rangelands.

The adaptive systemic approach: equitable co-design and partnerships for sustainable multi-use rangelands in Tanzania, Ethiopia, and South Africa

Palmer, CG[1]; Senga, MA[2]; Woldu, Z[3]; Bantider, A[4]; Gusha, B[1]; Norbert, J[5]; Tanner, JL[1]

[1] Institute for Water Research, ARUA Water Centre of Excellence, Rhodes University, South Africa; [2]Department of Sociology and Anthropology, University of Dar es Salaam, Tanzania, ARUA Water CoE; [3]Department of Botany, Addis Ababa University, ARUA Water CoE; [4]Land and Water Resources Centre, Addis Ababa University, ARUA Water CoE; [5]Institute of Resource Assessment, University of Dar es Salaam, Tanzania, ARUA Water CoE.

Key words: complex social-ecological systems; rangeland co-operation; strategic adaptive management.

Abstract

Building effective equitable partnerships and implementing co-designed projects and/or interventions to sustain multi-use rangelands, takes time, sustained commitment, and resources. There are pitfalls. Teams in three African countries used the collaboratively developed Adaptive Systemic Approach (ASA) to navigate these processes. We present a summary of the ASA and findings from its application. Key ASA strengths included: partnership building; enabling co-design; and capacity building through transformative social learning (explicitly respecting and integrating different knowledge forms: academic, practice-based, indigenous). We identify pitfalls: inadequate capacity building across academic disciplines, patchy facilitation skills, process discontinuities (e.g. changing representative participants), inattention to language and translation, power imbalances, and experiences of disrespect. We present adaptations to mitigate pitfalls. In all three contexts we aimed to move towards increased capacity for participatory governance, and an increased likelihood of improved rangeland condition and sustainable livelihoods. 1) The Great Ruaha River catchment (Tanzania), exemplifies challenges related to unequal water resources sharing, and ongoing contestation among competing water users, including communal livestock farmers, crop farmers and other community members. ASA engagements included these marginalised groups, addressed longstanding power imbalances, and set the groundwork for future collaborations. 2) Current vegetation cover in the Upper Blue Nile River basin (Ethiopia) reflects a complex interplay of human activities including grazing, cultivation, and selective fodder cutting; interwoven with the influences of climate, soil, and geology. A long-term restoration initiative in the Aba Gerima and Debre Yaqob catchments focusses on managing vegetation cover and the balance of woody plants and grasses. Using the ASA, communities in the two catchments co-developed strategies for rangeland and livelihood sustainability. 3) In the Tsitsa River catchment (South Africa) the appointment of eco-rangers, and early steps towards agreements for rotational grazing of multi-owned herds, in the degraded free-range communal rangeland, emerged from participatory ASA processes.

Introduction

Across Africa, rangelands are used by people with livestock for cultural, economic and food production purposes (Homewood 2004). As competition for rangeland use increases, contestation emerges (Samuels et al. 2021). It takes time, sustained commitment, and resources to build effective equitable partnerships and implement co-designed projects and/or interventions that catalyse change towards social justice and ecological sustainability - social-ecological justice (Wolff et al. 2019). There are pitfalls. We consider contexts in three African countries, two where livestock grazing has impacted vegetation cover, rangeland health and livelihoods, and one where livestock owners are scapegoated for water scarcity problems. In each context we applied the Adaptive Systemic Approach (ASA)(Palmer et al. 2023, Palmer and Tanner 2024). We qualitatively evaluated the indicators: partnership building; enabling co-design; effective communication; and developing participatory governance capacity and capabilities through transformative social learning. We discuss the implications of practising the ASA in rangeland management and restoration.

Methods

The Adaptive Systemic Approach (Palmer et al. 2023) (Figure 1) emerged from the literature on Adaptive Management (Allen and Garmestani 2015), the emergence of Strategic Adaptive Management (SAM) (Rogers and Luton 2011), and practice in the Tsitsa River catchment (Cockburn et al, 2018) - that included participatory monitoring, evaluation, reflection, and learning (Rosenberg and Kotschy 2020).

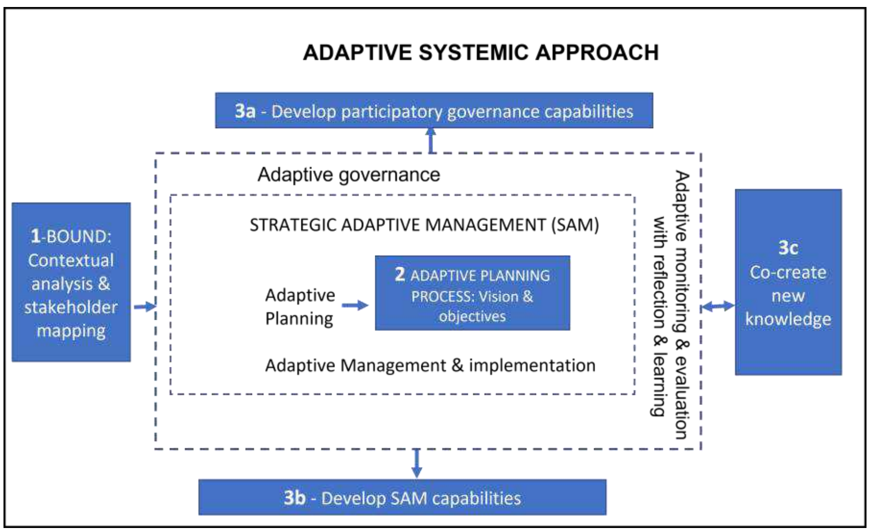

Figure 1. The Adaptive Systemic Approach (ASA) (1-3) begins with a contextual analysis termed “Bound” because systems have porous boundaries, influencing and being influenced by neighbouring systems. The Bound phase **(1)** includes early stakeholder mapping and engagement. Strategic Adaptive Management (SAM) was built on the tradition of adaptive management, with strategy conferred by an Adaptive Planning Process (APP) **(2)**. When the ASA was developed, SAM did not include governance, or monitoring and evaluation with reflection and learning. The first participatory ASA event is a facilitated SAM Adaptive Planning Process (APP) workshop **(2)**, where stakeholders experience participation, and begin a journey of participatory governance capability development **(3a)**. The APP gives rise to an objectives hierarchy – the blueprint for strategically and adaptively managing a system. SAM can be used to manage a problem being faced collectively by stakeholders, and also in the management of their home institutions. The ASA initiates the development of SAM capabilities **(3b)**. Concurrently, additional research into the collective problem may be undertaken, and in all participatory engagement stakeholders learn from each other (transformative social learning) – fostering the ongoing co-creation of new knowledge **(3c)**. Adaptive monitoring and evaluation, with reflection and learning is applied in each of the ASA activities, including facilitation planning and debriefing.

The full ASA was applied in Tanzania and Ethiopia. In South Africa, it was applied in the earlier Tsitsa River catchment forum (Cockburn et al. 2018). Detailed engagement data are curated at the Institute for Water Research, Rhodes University, South Africa. Here, we qualitatively assessed the key features of ASA practice claimed by Palmer et al. (2023): *Partnership building, Developing participatory governance capacity and capabilities, Transformative social learning and Enabling co-design;* in the three country-based case studies. Outcome achievement was judged as 1) minimal, 2) moderate, or 3) substantive.

Results

Tanzania: Ruaha River catchment in the Rufiji River basin

The Ruaha River catchment, Tanzania, is characterised by inequitable water sharing, and ongoing conflict among competing water users that include expanding towns, large- and small-scale farmers in the Usangu plains; pastoralists and fisherfolk in seasonal wetlands and in the Ihefu permanent swamps; and the wildlife ecosystems of the Ruaha National Park. The Ruaha River also sustains electricity production at the Mtera and Kidatu hydropower plants, with new hydropower development planned. Among these, small-holder irrigation and mobile pastoralists were blamed for reduced streamflow.

Partnership building, Developing participatory governance capacity and capabilities, and Transformative social learning were moderate among the wide spectrum of participating stakeholders. Analysis of participant reflections indicated intractable power differences despite evident co-learning and knowledge exchange among stakeholders. Continued application of the ASA would aim for slow trust-building, and data sharing to demonstrate the level of inequity, and the low level of threat from smaller resource users, in comparison to large-scale agriculture and hydropower. In the Ruaha, water-use conflict is more intense than rangeland-use conflict for livestock owners, and delinking grazing impact from water use would be helpful. *Enabling co-design* was minimal in the timeframe of the research engagement.

Ethiopia: Aba Gerima and Debre Yacob sub-catchments in the Upper Nile River basin

Landscape restoration activities, with restricted grazing and delivery of rangeland forage by "cut and carry" enabled livestock production and rangeland recovery (Feoli et al. 2002). Restoration practices were more rigorously maintained in Aba Gerima. The ASA Adaptive Planning Process workshop enabled the two catchment communities to meet, collaborate and learn from each other. They co-developed a vision and objectives that included a renewed commitment to cut and carry, to support livestock and rangeland improvement in both sub-catchments.

Partnership building, Developing participatory governance capacity and capabilities, Transformative social learning and Enabling co-design were all substantive at the scale of communities in the two sub-catchments interacting with each other and with researchers. These indicators were progressed in the preparation for, and facilitation of the Adaptive Planning Process workshop. Clear objectives for community livestock and landscape restoration and sustainable management were agreed. Progress in all these indicators was minimal at the scale of community-government engagement. The most immediate reason was the civil conflict in the region. However, researcher-government engagement was slow, and deepening research-government relationships, and extending these to include communities, would have required more extensive trust-building and communities travelling to the capital, Addis Ababa, for a "learning words" process prior to government engagement (Palmer et al. 2022, Palmer and Tanner 2024).

In engaged, transdisciplinary sustainability research, time frames are crucial (Palmer and Tanner 2024). Aba Gerima and Debre Yacob catchment had been the focus of Ethiopian research engagement over decades, and the success of landscape restoration was already evident (Feoli et al. 2002). The three-year ASA project came in as a facilitated intervention to encourage and renew sustainable pastoral grazing when cut and carry efforts had flagged in one of the catchments. It effectively catalysed renewed sustainability practice.

South Africa: Tsitsa River catchment in the Mzimvubu River basin

The Tsitsa River catchment is a strategic water resource in South Africa. However, historical land-use practice has resulted in extensive erosion and vegetation cover loss which threaten the effectiveness of any dam development (Powell et al. 2018). Water resource development needs motivated investment in landscape restoration. The seven-year Tsitsa Project (Cockburn et al. 2018) constellated many of the ASA elements and the Tsitsa River catchment was a learning catchment for the Tanzanian and Ethiopian cases.

Partnership building, Developing participatory governance capacity and capabilities (Palmer et al 2022), Transformative social learning (Weaver et al. 2023) and Enabling co-design (Fry et al 2024) were substantive. The research had time to facilitate the development of community livelihoods, with a focus establishing nurseries to grow the plants used in landscape restoration, and the employment of eco-rangers to control free-range livestock movement. This is an alternative to the "cut and carry" methods used in Ethiopia. The timeframe of the Tsitsa catchment intervention was not long enough to measure vegetation cover increases, so the appointment of the eco-rangers was the measurable impact on the rangeland of the engaged research.

Discussion

The ASA provides natural and social scientists with the conceptual and practice tools to effectively engage with natural resource users (like pastoralists) and managers, civil society, powerful private enterprise, and government agencies, with the purpose of moving rangelands towards social-ecological justice and sustainability. However, the reality of engaged transdisciplinary work is hard (Palmer and Tanner 2024). As we advocate for rangeland researchers, managers, and governments to use the ASA, we highlight one lesson from all our experience: the fundamental importance of epistemic justice – fairness in relation to knowing. The two core aspects of epistemic justice in transdisciplinary participatory engagements are, that all participants i) experience being equally and well respected, and ii) have sufficient understanding and vocabulary to both understand and contribute to participatory knowledge exchange. Engagement planning and facilitation style are key in achieving this. Early engagement in the Tsitsa River catchment revealed that while facilitation skills such as eliciting input from participants randomly (rather than preferencing those with higher perceived status or power) and writing participant input on sheets that everyone could see, in exactly the words used, resulted in experiences of being respected. It was harder to build equitable knowledge and vocabulary, and respect for a range of knowledge forms. Knowledge was unevenly held and respected. In the Ruaha and Tsitsa River catchments formally educated participants were impatient, and discounted the value of local knowledge, while local communities needed time, were sensitive to disrespect and could be easily silenced. It was hard to overcome entrenched gender and racial prejudice. The development of the Learning Words processes in the Tsitsa project (Palmer et al. 2022) was crucial: stakeholder participants who are residents in the landscape meet with researchers the day before a general stakeholder workshop. Their local knowledge is elicited, and they are exposed to how deep their knowledge is, and that other stakeholders know far less. They are encouraged to share their knowledge in the engagement to come. Researchers then introduce any specialist vocabulary likely to be used the following day. Very often residents understand the concept – but may have a different set of words – for example not all languages have a direct word for "catchment" or "landscape. Learning Words workshops need to be routinely incorporated into the ASA process. In all our case studies engagement with local communities was undertaken in their local language, with translation for participants who only spoke English. (A sound colonialism push-back.) Adaptation to the pitfalls of practising the ASA included working to expose both specialist natural and social scientists to foundational ASA concepts such as complex social-ecological systems, transdisciplinarity and transformative social learning. We exposed the depth of gap between the social and natural sciences and the need for work on conceptual similarities with different vocabulary, methodological differences, and engendering sufficient respect for researchers to take the time collaborate effectively. We exposed the need for training in epistemic justice-sensitive facilitation.

Inclusion of epistemic justice, the methods of Learning Words, and the wider framework of the ASA can contribute to several *IYRP themes*: The ASA provides a purposeful mechanism for *connectivity* and building social-ecological *resilience.* The ASA focuses on building a shared fair, sustainable future and supports *biodiversity* retention of the *ecosystem services* related to *soils, water and land-use*. Learning Words workshops forefront *indigenous and local knowledge,* and ASA facilitation methods enable fair inclusion of *women and youth*. It is vital to understand that sustainable rangeland restoration and management involves respectful engagement. Above all, to recognise that engagement processes take time, and that respect and trust building are the foundational levels of transformation.

Respectful publication of traditional herders' ecological knowledge

Sáfián, L[1]; Sáfiánné, I[2]; Molnár, Zs [3]

[1] traditional shepherd, Hajdúsámson, Hungary; [2] traditional shepherdess, Hajdúsámson, Hungary; [3] HUN-REN Centre for Ecological Research, Institute of Ecology and Botany, Vácrátót, Hungary

Key words: collaboration, participatory research, knowledge co-production, traditional grazing, traditional herders, publication ethics

Abstract

Knowledge partnership between traditional herders/pastoralists and researchers is vital for adapting to rapid socio-ecological changes. Respect can efficiently help these partnerships as we need trust, time and dedication to bridge scientific and traditional knowledge systems. The three authors of this contribution have been closely working together since 2009, and beyond co-producing scientific papers and media articles they are experimenting with various other adequate and respectful types of ”publications” to share herders' traditional ecological knowledge with scientists, diverse stakeholders and the wide public. In this paper, we share some of the experiences of our long-term collaboration and motivate others to experiment with and prepare diverse types of publications.

Introduction

Indigenous, traditional and local ecological knowledge is increasingly respected and collaborations between traditional knowledge holders (TKHs) and scientists are now widespread. Scientists usually publish their research results in scientific papers and, in the case of social sciences, often in scientific books. But do we know who read these publications? And what readers get and understand from the traditional knowledge of TKHs documented in these publications? Will they bring the desired change, especially improvement, in the life of TKHs?

Experience shows that scientific papers and books do have, but only a limited power to change people's behaviour. Alternative ways of publications are needed to reach more people and more efficiently.

In this paper we aimed to summarize the experiences of a herder family and an academic researcher about the benefits and challenges of alternative ways of publishing (sharing, teaching) traditional ecological knowledge.

Positionality

László Sáfián is a traditional herder coming from a seven-generation herder family. He has been working with Zsolt Molnár since 2009, teaching each other and testing diverse ways of collaborations, and co-production of knowledge and publications. Ibolya Sáfiánné is a traditional shepherdess, born into a herder family. She is the leader of the Hungarian Women Herders Group. Zsolt Molnár is a botanist, ethnoecologist working with traditional herders and farmers in Central Europe since 2000, and in Mongolia, Iran and Kenya since 2016. He was not born into a herder family.

Methods
This work is based on 15 years of collaboration between a herder family and a scientist. All data and conclusions below are based on our own experiences. The paper was designed and prepared together by the three authors, first in Hungarian (the mother tongue of the authors) and then translated into English. Many of the mentioned publications are also available in English, because one of the aims of the knowledge co-production between the authors was to share herders' traditional knowledge abroad, to put Hungarian herders on the global map of science on pastoralism.

Results
In most cases the design and the preparation of publications was led by the scientist (or outsiders, like journalists and film makers). Partly because the publications appeared in the scientific sphere, especially at the beginning. The TKH partners were not experienced on how to work in these unfamiliar settings. However, with time, the design turned more and more into co-design, and the preparation became also increasingly a co-production. Recently, publications were led by the herders themselves (see Sáfiánné et al. 2024, and journal and radio reports).

Our experience shows that many herders simply hate, as they express it, or at least feel very uncomfortable, being interviewed by journalists, participating in scientific works, but even they feel and know the benefits of these '*tortures*': "*People see and understand our life much better.*" Herders tend to be patient even in situations that are far beyond their comfort zone, especially if they experience reciprocal patience and respect from the other side.

Table 1 Various forms of publication of herders' traditional ecological knowledge for traditional knowledge holders (TKHs) themselves, for scientists and the wider public based on the experiences of the authors of this paper

Scientific publications	**Films, media and conferences**		**Exhibitions and other**
Scientific papers (high-ranked, English)	Short documentary films (English)	Media articles (English)	Exhibitions (photo)
Other non-local language papers, book chapters	Short documentary films (local language)	Media articles (local language)	Exhibitions (complex)
Books (English, multi-lingual)	Slow films (English)	Agricultural journal articles	Field discussions at the knowledge holder's place
Books (local language)	Slow films (local language)	Conference presentations (local language)	Field discussions at other knowledge holders' places
Local language scientific papers	Radio reports	Conference presentations in English/abroad	Facebook pages
Reports (e.g. IPBES, CBD, IYRP)	Podcasts	Online discussions (long presentations)	Teaching course (in person)
	Short TV reports		
	Talk shows		

- High-ranked papers can bring high respect for TKHs, especially when later they meet readers (academics, professors) at international conferences. Real co-authorship in scientific papers was achieved first by co-producing the results and discussion sections of the papers, and later by co-designing the whole research process.
- Short films, radio and TV reports prepared by outsiders can be challenging (even frustrating) for herders because uncareful journalists can strengthen misleading and unrespectful stereotypes and

misunderstanding. We found that experienced TKHs can help journalists to learn respectful and decolonial behaviours and approaches, slow down the preparation of the product and give a chance to TKHs to check the product for technical correctness and respectfulness before the publication. The success of these deep and respectful reports and articles can be unexpectedly big.

- Longer films and content rich, colourful books increase the chances of sharing traditional knowledge and can lead to respectful and adequate inclusion of local TEK in policies but also in cross-cultural scientific reviews. When TKHs see themselves in films and books, this increases their self-confidence, and they become aware of the value of their knowledge. Herders argue that with books their knowledge gets a chance to survive longer.
- After some less successful attempts with publishing traditional knowledge in culturally less appropriate forms, we designed and made a three hours long slow film. This film became an unexpected success. Viewers not only enjoyed watching the film and having a deeper than ever insight into herders' knowledge but many of them expressed later to the herder that they learnt a lot and they use the learnt knowledge in their everyday herding. The storyline of the film is very simple: an ”uncut” video about an afternoon-long, herder dog-assisted herding of 300 sheep on a patchy semi-natural pasture made with two cameras and a drone. Later, the first author narrated the whole film by answering the questions of the researcher. The Hungarian version of the film has >730 000 views (December 2024), and >115 000 viewers watched the whole film.
- Conferences are a big challenge for TKHs. To lessen stress, for local language conferences we developed a dialogue-based presentation style, where the herder(ess) answers the researcher's questions (agreed upon before), while at foreign conferences the herder(ess) speaks in her/his mother tounge while the slides have rich English content.
- Personal encounters are missing in most forms of publications. Online seminars turned out to be a useful tool for cross-continental 'virtual personal' discussions. Students got a chance to ask their personal questions after or during the 1-1.5 hours long presentations. Herders were also enthusiastic what and how foreign students asked from them.
- Personal visits by scientists to TKHs' pastures and families can help build bridges between cultures and between scientists and TKHs. Experiencing TKHs' life in their own environment gives a chance to scientists to cross the boundary line between the scientific and traditional knowledge systems. In our case, many of these scientists watched the slow films in advance, which helped them ask respectful, adequate and specific questions while on the pasture. Personal visits by a TKH to like-minded people and herders abroad, especially to other continents helps them understand their own culture, increase the understanding of the value of their knowledge. Cross-cultural similarities of how to care for the livestock and what challenges others have help TKHs (reciprocally) to overcome the feeling of loneliness with their problems.
- Facebook is a great opportunity for TKHs to network, even internationally (cf. automatic translations). Having photo and video cameras in the mobile phones helps THKs to document their world themselves and share them directly without any liaison person. This is a new and great opportunity to share (publish) ideas, feelings, knowledge, stories, challenges directly. The group of Hungarian Women Herders especially expressed their happiness of having a closed FB group where they can freely share their everyday stories with other women working in pastoralism.

Discussion

Alternative publications are often still in the experimental stage, but it is clear that publishing traditional ecological knowledge not only in scientific papers and books is crucial to reach diverse stakeholders and potential partners. Herders argue that with these publications, they feel the increased respect towards knowledgeable herders both from the public and from scientists and conservationists. They also became aware of the crucial importance of finding new ways of intergenerational knowledge transmission of their knowledge.

IYRP (the UN International Year of Rangelands and Pastoralist, 2026) could efficiently help promote awareness raising around the issues of pastoral people, especially their adaptive knowledge, role of women and prospects of pastoral youth, as these have vital role in the future of pastoralism. As the number of herders decrease, they get more isolated, thus networking through IYRP could be a key mechanism for developing a better future for pastoral people.

Acknowledgements
Experience shows that there is a lot to learn by European TKHs and scientists from Indigenous Peoples and their allies, how collaborations and common publications can work under various circumtances. We are grateful for our Indigenous partners for their teachings. This work is supported by the Horizon Europe BIOTraCes project (101081923).

How grazing management influences biocrust community composition in the Northern Territory rangelands

Eastaughffe, J[1]; Cowley, R[1]; Materne, C[1]; Williams, W[3]; Parker, N[3]; Vega Cofre, M[2]

[1] Department of Agriculture and Fisheries, Northern Territory; [2] The University of Queensland, School of the Environment, St Lucia, Queensland; [3] The University of Queensland, School of Agricultural and Food Sustainability, St Lucia, Queensland

Key words: biocrust, community composition, rangelands, grazing management

Abstract
Biological soil crusts are an important indicator of the long-term productivity of grazed landscapes. Healthy biocrust communities can improve soil fertility by increasing soil stability, enhancing moisture retention, as well as facilitating both carbon and nitrogen cycling and fixation. The Rain Ready Rangelands project, funded through the Australian Government Future Drought Fund analysed biocrust health on three producer demonstration sites in central Australian woodlands and shrublands and the Barkly Tablelands Mitchell grass regions of the Northern Territory. In this paper we focus on a producer demonstration site located approximately 250 km northwest of Alice Springs in tall open Acacia shrublands with deep red earths, sandy red earths, red clayey sands and deep sandy loams over mixed short grasses.

Samples were collected under varying grazing intensities (with distance from water and inside vs. outside cattle exclosures) and with different grazing management (current vs. recommended grazing management). To detect the functional contribution of these communities baseline samples were collected and analysed for biocrust species composition, total carbon and nitrogen and DNA analysis. 16S rRNA marker gene sequencing was used to profile bacterial community diversity along grazing gradients from watering points, and inside and outside cattle exclosures.

Bacterial community composition shifted significantly with distance from water at the central Australian sites. Diversity was highest at the most disturbed site 50 meters from the water point at one of these locations, while community composition had not diverged inside vs. outside newly established exclosures after the first year. Changes in total carbon and total nitrogen were observed only with distance from water, with enhanced C and N adjacent waterpoints compared to all other distances. The ecological implications of these changes are being further investigated. We plan to monitor these sites through time to see if alternative management regimes and cattle exclusion results in different trajectories in biocrust community composition and function.

Introduction
This research took place in the Alice Springs region of the Northern Territory. As a part of a broader project called Rain Ready Rangelands, we established a Paddock Challenge demonstration site on a large cattle station covering

over 2700 km^2. We aimed to illustrate the benefits of positive grazing management strategies such as adjusting stocking rates to safe carrying capacity on land condition by measuring vegetation and biocrust communities across sites.

Biological soil crusts, also known as biocrusts are often referred to as the 'living skin' of the soil surface (Weber et al. 2022). Inhabiting the upper centimetres of soil between and under vegetation in dryland and savannah ecosystems, biocrusts play a central role in primary production. Biocrusts functional influence on soil fertility and plant growth can provide us with an indicator of how management can promote drought resilient soils (Eldridge and Delgado-Baquerizo 2017; Williams et al. 2021). Hence, we measured biocrust responses to grazing intensity and management through sampling biocrusts, and soil C and N.

To ensure long term productivity of grazed landscapes, sufficient replenishment of nitrogen is required. Nitrogen accounts for a large proportion of the soil-derived nutrients that pastures require. Among other functions, cyanobacteria, bacteria and other microorganisms that make up biocrusts have the capacity to fix nitrogen and cycle nutrients (Belnap 2003).

Environmental DNA sequencing of 16S rRNA gene, at terrestrial field sites identifies bacteria at the genus and species levels, providing detailed information about overall composition and abundance of microbial communities. There was no current knowledge in this region of biocrust communities and the effects of trampling by livestock. Thus, we set out to discover the diversity of biocrusts and their associated microbial communities. As management entails very large areas in a climate controlled by low rainfall, we designed this component to encompass the landscape scale effects at a micro-scale.

Methods

Samples were collected in April 2023 along two transect lines north and south of 2 long established bores (permanent ground water supplies for livestock). Samples were collected from deep red earths, sandy red earths, red clayey sands and deep sandy loams. Biocrust samples were collected from three land systems: Bushy Park (Broad alluvial drainage floors and floodplains with deep red earths), Kanandra (coarse textured brown alluvial plains of deep sandy loams and sandy read earths) and Sandover (Flat or gently undulating desert floodplains and levees with red clayey sands and deep sandy loams) (Perry et. al. 1962 & Grant 1983R). Pastures were dominated by mixed short grasses and forbs including E*nneapogon polyphyllus* (Oatgrass), *Aristida contorta* (Kerosene grass) and *Eragrostis kennedyae* (Lovegrass).

The exclosure was erected in a representative area of productive country, aiming to explore differences between the paddock/watered area treatment versus no grazing. The fenced cattle exclosure was located 1 km from a Bore. Biocrust monitoring sites were strategically located along transects at varying distances from a watering point (50 m, 500 m, 1-2 km, 6 km). Three types of biocrust samples were collected for DNA, C and N and biocrust microcosms.

Quadrats (n =3) were randomly placed on the ground at each distance from water and photographed. DNA samples were collected using a 50 mL Falcon Tube and a spatula. In each Falcon Tube 3 sub samples of the top 1 cm of soil were collected and combined (n=3 per quadrat). Equipment was cleaned with alcohol wipes between each sample. Total C and N samples were prepared by using a spatula to collect three subsamples 10 x 10 x 5 cm depth (n=3 per quadrat). Biocrust microcosms were collated by collecting 4 surface subsamples using a spatula and placed in a petri dish (n= 3 per quadrat). This methodology was repeated twice at each site, giving us three composite samples of each type from every site location (n=12 per site).

Environmental DNA was extracted using the Qiagen DNeasy® PowerSoil Kit. Amplicon sequencing of the 16S rRNA gene was amplified by polymerase chain reaction (PCR) using the primers799F (5'-

AACMGGATTAGATACCCKG-3') and 1193R (5'-ACGTCATCCCCACCTTCC-3') (Lane, 1991) for bacteria profiling, and sequenced using the MiSeq System (Illumina) platform. The taxonomy for the 16S rRNA gene reads from sequencing was assigned using blastn from QIIME2 against the SILVA (v138.1) (Quast et al. 2012) database.

Total carbon (C) and total nitrogen (N) in soil samples was performed using the Elementar Vario Macro cube analyzer in CN mode at UQ lab….

Results

Distance from water effect on Central Australian biocrust microbial communities

The composition of biocrust communities varied with distance from water (PERMANOVA R^2=65%, F=10.9, P<0.001), although alpha diversity remained consistent. The community composition at a distance of 50 meters from the water was significantly different (P < 0.001) from all other distances (Figure 1).

Although not statistically significant, the 6 km biocrust communities did separate out from all other distances, whereas samples from between 500 m and 1-2 km from water showed significant overlap in composition (Fig. 1). In total, 60 operational taxonomic units (OTUs) were identified with a relative abundance greater than 1% in the biocrust bacterial community. ANOVA analysis (p < 0.05) on the relative abundance revealed that 47 of these 60 OTUs exhibited significant changes based on their distance from the water.

The biocrust composition was represented by members of the Acidobacteriota, Actinobacteriota, Armatimonadota, Chloroflexota, Firmicutes, and Proteobacteria. From a general overview, several members of the Acidobacteriota and Chloroflexota, were reduced in their relative abundance at 50 m from water, in contrast to several members of Firmicutes that increased their relative abundance at the shortest distance from water.

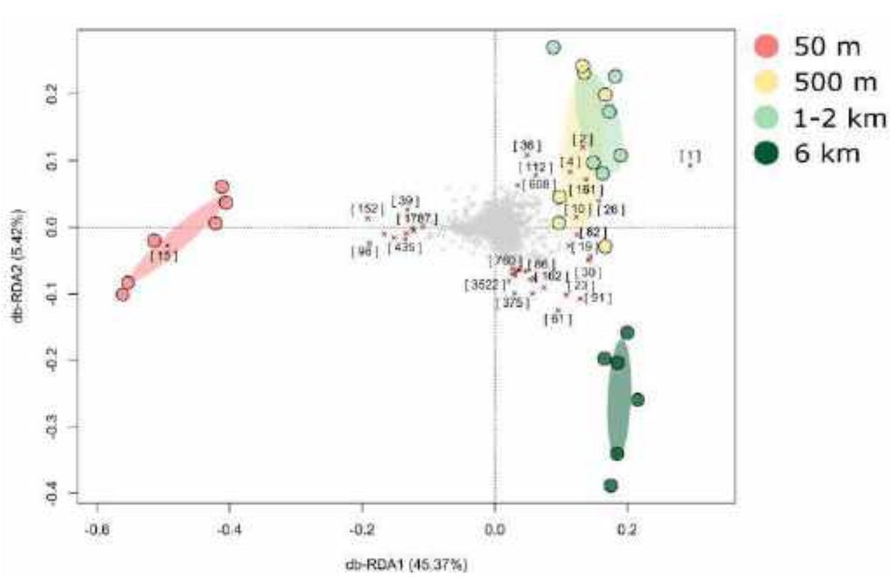

Figure 1. Separation of biocrust community composition between 50 m and 6 km from water clearly evident in Distance-based Redundancy Analysis (db-RDA) ordination plot. Constraint by distance as per PERMANOVA analysis. Discriminating OTUs are shown in brackets.

Distance from water effect on total C, total N, and C:N ratio

Total nitrogen and carbon (but not C:N ratio) varied with distance from water and at 50 m they were both more than double the levels found at all other distances (Table 1, Figure 2).

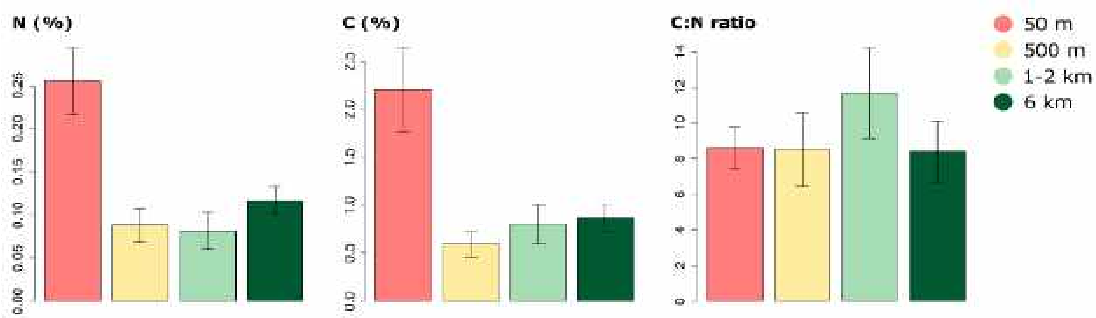

Figure 2: Bar graph of total carbon (%), total nitrogen (%), and C:N ratio by distance from water (50 m, 500 m, 1-2 km and 6 km). Error bars represent standard errors

Table 1. Total carbon (%), total nitrogen (%), and C:N ratio by distance from water (50 m, 500 m, 1–2 km and 6 km). Means and Standard Deviation, different letters represent significant differences as per post hoc analysis ($P < 0.05$)

Distance	Total Nitrogen (%) Mean SD	Total Carbon (%) Mean SD	C:N ratio Mean SD
Mount Denison			
50 m	0.26 ± 0.09 b	2.21 ± 1.06 b	8.57 ± 2.86 a
500 m	0.09 ± 0.05 a	0.60 ± 0.33 a	8.51 ± 4.98 a
1-2 km	0.08 ± 0.05 a	0.80 ± 0.51 a	11.66 ± 6.20 a
6 km	0.12 ± 0.04 a	0.87 ± 0.34 a	8.39 ± 4.22 a

Effect of excluding grazing on biocrusts

The exclosure effect (inside versus outside) on alpha diversity and composition was evaluated across all sites. There was no effect of the first year of exclosure on alpha diversity (Shannon's index) and composition (results not shown).

Discussion

The biocrust microbial community in extensive grazed rangeland paddocks was relatively stable in its composition and diversity with the exception of heavily trampled high use areas immediately adjacent waters.

The study on biocrust community composition found an increase in the relative abundances of several Firmicutes populations at the closest distance from the water points (50 m). While Firmicutes are known as plant growth-promoting bacteria (Amaresan et al. 2020), they have also been found to effectively remove ammonium and total nitrogen from wastewater (Yue et al. 2024), which is possibly related to the increased N content at the 50 m point from water.

The higher levels of total C and N at the water points are likely due to animal manure and urine inputs, as cattle often congregate and camp close to the water points. The animals graze out several kilometres daily, harvesting resources as they graze pastures and browse from the surrounding paddock. The stocking density and time spent were highest closest to water, leading to a translocation of resources to campsites and water points, which accumulates these resources from long distances into a smaller site closer to the water (Augustine et al. 2013). Given that only the heaviest grazing and trampling impacts immediately within the 50 m vicinity of stock water points had differences in C and N, it is unsurprising that exclosures surrounded by moderate to low grazing had little impact on soil C and N.

Key words: Monitoring ground cover, biocrusts, rangelands, savanna

Abstract

Biocrusts play a pivotal role as ecosystem engineers, mitigating soil erosion, enhancing soil stability, and enriching nitrogen availability in rangelands. In northern Australian savannas, prescribed fires are a common land management strategy. However, fire impacts biocrust function, making it important to monitor biocrust cover to assess ecosystem health and guide sustainable land management practices. In this study, we investigated land cover with a focus on biocrusts, before and after prescribed fire events at Victoria River Research Station in the Northern Territory.

A 2.6 km^2 patch situated more than 2 km from water in the north-west corner of a 14.7 km^2 paddock was burnt in October 2022. Cattle were left in the paddock both during and after the fire. High-resolution PlanetScope imagery was used to track changes in land cover between July 2022 and June 2023. Reference sites that included bare soil, biocrusts (95% coverage) and vegetative cover (grass, shrubs and trees), were collected in the field. Crust Index was employed to discriminate between land cover classes. Using supervised classification with a random tree classifier, we achieved 90% accuracy in identifying these land cover classes across multiple time points.

Post-fire, early wet season, biocrust cover decreased by 10.8%, from 67 ha pre-burn to 39 ha, partially due to an increase of 10% in vegetation cover (189 ha to 215 ha). Grass canopies had obscured the biocrusts underneath them. Bare soil areas expanded by 20%, from 7.9 ha to 9.7 ha, likely due to cattle preferentially utilising the burnt areas post fire during the following wet season. These findings underscore the importance of monitoring and adaptive strategies such as spelling paddocks from grazing post fire, essential for sustainable and resilient ecosystems.

Introduction

Australian rangelands cover vast areas across the country and are essential components of the nation's environmental, societal, and industrial dynamics. However, these landscapes are under increasing pressure from climate change and degradation, which threaten native vegetation, diminish landscape functionality, and cause local extinctions of various biota, including shifts in fungal and bacterial community structures (Hodgkinson & Wang, 2020). Biocrusts are unique and diverse communities of microorganisms, including bacteria, cyanobacteria, fungi, algae, lichens, mosses, and liverworts, that inhabit the soil surface and its upper layers. These biocrusts are predominantly found in regions with limited water availability and sparse vegetation cover (Weber et al., 2022). Occupying much of the soil surface in rangelands, biocrusts play a critical role as ecosystem engineers by mitigating soil erosion, enhancing soil stability, and enriching nitrogen availability. Disturbance factors such as fire and grazing significantly influence these biocrusts (Belnap & Eldridge, 2001).

In the Australian rangelands, prescribed fire is commonly used as a tool to manage vegetation density and regeneration (Nielsen et al., 2020). However, fire impacts biodiversity, including biocrusts, which provide several ecosystem services, such as reducing soil erosion and replenishing nutrients. Therefore, monitoring land cover changes, including biocrust distribution during prescribed fire events, is crucial for assessing ecosystem health and informing decision-making for sustainable rangeland management practices.

Remote sensing is essential tool for monitoring land cover and land use changes, and is a popular tool among agriculturalists and rangeland ecologists (Wabnitz et al., 2008). Detection and mapping for regional distribution of biocrust can be implemented using remote sensing with different platforms, spaceborne, Airborne, and Unmanned Aerial Vehicles (UAVs) (Rieser et al., 2021). Utilising satellite imagery offers a variety of benefits, primarily in its ability to generate a comprehensive temporal range of data. This capability allows for the quantification of both spatial and temporal changes within specific regions.

Multispectral satellite with high spatial resolution is considered to detect biocrust for large scale areas. Several studies have revealed that numerous species face limitations in producing detectable spectral signatures (Baxter et al., 2021). Biocrust's spectral signature resembles both soil and vegetation due to the dynamic states of microphytes that only actively photosynthesise when moist. This results in biocrusts appearing soil-like when dry and exhibiting a vegetation appearance when wet, and engaged in photosynthesis (Rozenstein & Adamowski, 2017).

To address this complexity, specialised methodologies have been developed, including the Crust Index, which utilises the normalised difference between red and blue spectral bands to detect cyanobacteria-dominated biocrusts (Karnieli, 1997). This approach leverages the unique reflectance properties of cyanobacteria, distinguished by the presence of the phycobilin pigment, which strongly reflects in the blue spectral region compared to sandy substrates (Karnieli & Sarafis, 1996).

In northern Australian rangelands, research on biocrust distribution and its response to prescribed fire remains limited. In this study we investigated land cover changes, including biocrust dynamics, before and after prescribed fire events, using high-spatial-resolution imagery from PlanetScope (3 m resolution). Cyanobacteria-dominated biocrusts, known to be prevalent in northern Australian rangelands (Williams et al., 2014), were analysed using the Crust Index to elucidate their spatial distribution and response to fire-driven disturbances. This research contributes to bridging knowledge gaps in biocrust area distribution and informs sustainable land management practices in the rangelands.

Methods

The study was conducted over a 2.6 km^2 area located at the Victoria River Research Station, Northern Territory, Australia. A prescribed fire event was carried out in October 2022, with cattle remaining in the paddock both during and after the fire. Reference data were collected in the field to establish baseline conditions for land cover classes, including bare soil, biocrusts (95% coverage), and vegetation (comprising grass, shrubs, and trees). High-resolution imagery from PlanetScope (3 m spatial resolution) was employed to monitor land cover dynamics over the study period, spanning from July 2022 to June 2023.

The Crust Index was applied to differentiate land cover classes, particularly for detecting cyanobacteria-dominated biocrusts (Karnieli, 1997). A supervised classification approach using a random tree classifier was implemented to categorize the land cover into predefined classes. This method achieved an overall classification accuracy of 90%, effectively capturing temporal changes across multiple observation points.

Results

In this research, the spectral analysis is crucial in evaluating land cover changes employing crust index (Fig 1). The fire event significantly altered land cover dynamics within the study site, which included four primary classes: vegetation, bare soil, and biocrusts. The vegetation cover expanded from 189.27 hectares before the fire event during the dry season (July–September 2022) to 215 hectares after the fire event in the post-wet season (April–June 2023). Biocrusts exhibited a pronounced seasonal pattern, with coverage peaking at 67.18 hectares pre-fire and declining to 39.07 hectares post-fire. Conversely, bare soil areas increased from 7.9 hectares before the fire to 9.7 hectares following the fire in the post-wet season.

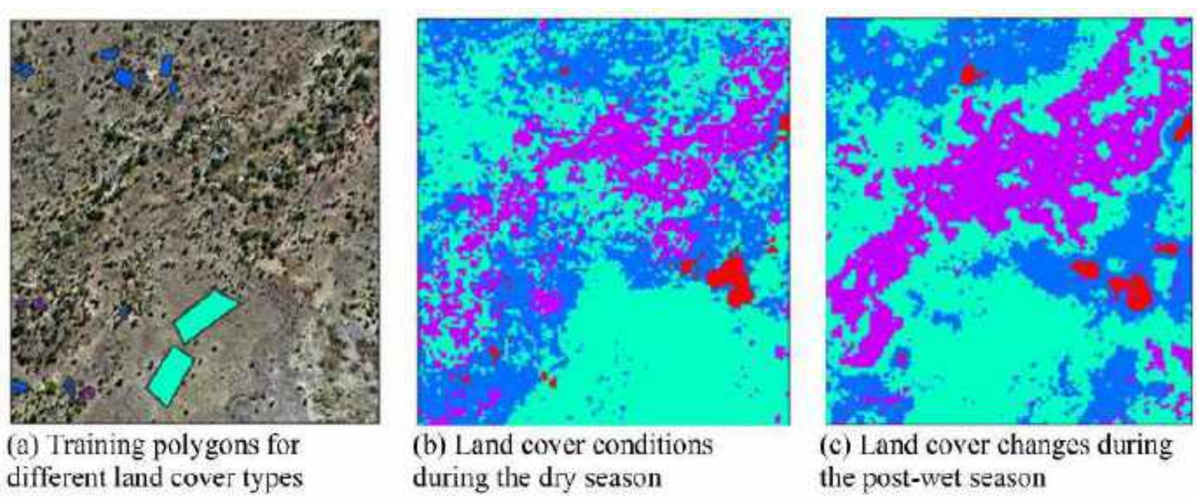

Figure 1. Seasonal land cover changes: (a) Training polygons for different land cover types: blue represents biocrusts, light green indicates grass, purple denotes trees and shrubs, and red corresponds to bare, degraded soil. The Crust Index effectively discriminated biocrusts from vegetation and bare soil during (b) the dry season (pre-fire) and (c) the post-wet season (post-fire).

Discussion

Post-fire rainfall introduced challenges in accurately capturing the spectral signatures of biocrusts, as increased vegetation cover overshadowed biocrust reflectance (Swe et al., 2023). Our findings underscored the discriminative capabilities of the Crust Index in capturing the spectral response differences among individual classes in every season. The pronounced recovery of vegetation—particularly grasses, trees, and shrubs—after the fire was driven by consistent rainfall, highlighting the resilience of rangeland flora to disturbance events. Bare soil areas expanded by 20%, likely due to livestock preferentially grazing in burned regions during the subsequent wet season. These findings highlight the complex interactions between fire, rainfall, and land cover dynamics in rangeland ecosystems. They also underscore the importance of post-fire management strategies, such as resting paddocks from grazing, to allow the recovery of vegetation and biocrust communities.

Key words: biological soil crust; bio-priming; germination; grasslands

Abstract

Biocrusts are a living complex of microscopic organisms (cyanobacteria, bacteria, fungi, algae, lichens, liverworts, mosses) that cover the upper soil between vascular vegetation in arid and semi-arid rangelands. As providers of ecosystem services, they are a nature-based solution for landscape regeneration, but site- and species-specific knowledge is often missing. We tested the hypothesis that biocrusts differ in their effect on grass germination. Our focus was Mitchell grasslands with tussock grass *Astrebla lappacea* because degraded semi-arid western Queensland requires effective regeneration techniques. We used characteristic descriptions of biocrusts in testing the effects of biocrust as soil surface or as separate seed inoculum on germination success in glasshouse and laboratory experiments. Germinations increased slightly on a biocrust surface compared to a sand-only control. Although differences were not statistically significant, germination was greater than in sand in 71.4% of inoculum treatments and rate was significantly faster in one-third of treatments. With promising early findings, we conclude that biocrusts can improve germination of *A. lappacea*, with optimisation in next-steps research such as inoculum field experiments across landscapes. Biocrusts hold promise as a nature-based solution to address the global problem of degraded rangelands.

Introduction

Mitchell grasslands are dominated in their natural state by *Astrebla* tussock grasses and cover about 57 million hectares of Australia's rangelands ("Mitchell Grasslands", 2021). *Astrebla lappacea* (Lindl.) Domin. (Curly Mitchell grass) is one of four abundant *Astrebla* species. It is a highly desirable perennial grass that provides ecosystem stability, having a 20 to 30-year life span and considerable drought tolerance (Lambert et al., 1990). Death of *Astrebla* tussocks is accentuated by heavy grazing during drought, which causes the problematic colonisation of annual grasses in the interstitial spaces when *Astrebla* cover is reduced (Orr & Phelps, 2013). Regeneration techniques are required to successfully and cost-effectively restore these landscapes. Focussing on nature-based solutions, we studied the role of biocrusts in the target grasslands. Biocrusts provide a multitude of ecosystem services including stabilising soils, carbon and nitrogen fixation and cycling, and water cycling (Weber et al., 2016). Biocrusts influence vascular plant establishment due to their position in the upper soil layer and surface where seeds are dispersed (Bowker et al., 2022; Weber et al., 2016). However, plant germination responses to biocrusts are variable and are site- and species-specific (Havrilla et al., 2019; Peter et al., 2016). Research into the effects of biocrust surfaces and inoculums on the germination of other species has been conducted (Bowker et al., 2022; Jiménez-González et al., 2022; Muñoz-Rojas et al., 2018; Peter et al., 2016; Serpe et al., 2006) with mixed findings. To fill knowledge gaps relating to Mitchell grasslands, we explored the interactions of biocrusts and *A. lappacea* seed, and tested in a first step how different types of biocrusts affect germination success. This study aimed to test two hypotheses:

1. Biocrusts enhance germination of *A. lappacea.*
2. Differently developed biocrusts have different effects on germination of *A. lappacea*.

Methods

Biocrusts were collected from 21 sites across western Queensland between April and May 2024. Mean annual rainfall varies across the region between 380 and 530 mm. The wettest months are November to March with 70% of annual rainfall (Climate Data Online, 2024). Sites spanned nine land types and consisted of intact, open woodlands and grasslands to degraded areas with low or no ground cover and soil erosion. Spatulas were used to collect the top 5 mm of soil surfaces with biocrust. *A. lappacea* seed was collected from wild populations near Julia Creek (141.7442°E, 20.6909°S) in May 2024, dried and stored at room temperature. Germination tests using a sub-sample of 20 naked caryopses were undertaken in a Thermoline Scientific STAR700 Climatron with LED lights set at 12 hourly diurnal cycles (32°C day, 25°C night). The number of seeds that had germinated (5 mm radicle visible) were counted over 30 days.

Glasshouse pot trials were conducted to test effects biocrust have when on the soil surface. Naked *A. lappacea* caryopses were imbibed in water for 18 hours. Three replicates for each of 21 biocrust sites plus a sand control were randomly allocated to pots and the surface covered by biocrust. One soaked seed was sown ~5 mm. Bottom-up watering was used and water availability reflected wet-dry cycles. Mean counts of pasture grass germination were used for analyses. Biocrust inoculum trials were conducted to determine whether differently developed biocrust affect germination of *A. lappacea* differently when applied directly to seed. The top 2 mm of each biocrust sample was passed through a sieve (~0.5 mm). Sieved biocrust (1.5 g) was combined with 1mL of DI water to create a separate inoculant for 21 samples. Sand was used for a control. Six *A. lappacea* naked caryopses were immersed in each inoculant and the control then sealed in Petri dishes using parafilm. Petri dishes were placed in the climatron. Equal volumes of DI water were used throughout the experiment to moisten inoculants. The number of germinated seeds were counted over 29 days. Germinated seeds were those meeting Internation Seed Testing Association guidelines (International Seed Testing Association, 2013).

One-way ANOVA with a Kruskal-Wallis test for non-parametric data tested whether germination with biocrust, compared with a sand control, was significantly different. Spearman's rho was used to determine effect size of correlations between biocrust characteristics and germination. A generalised logistic model with time as a covariate was fit for proportional data to extrapolate germination rates with biocrust inoculum. Significance was determined by examining the 95% confidence intervals of odds ratios and whether one was between the lower and upper confidence interval. Jamovi (The Jamovi Project, 2024) was used for statistical analysis.

Results

Experiment 1: Effects of biocrust surface on seed germination

Mean counts of all pasture grass germination, including seeds already in the seedbank and sown A. lappacea, were analysed. Emergence of seedlings was greater than the control in 47.6% of treatments and 33.3% of treatments had germination equal to the control. Correlations between biocrusts characteristics and germination were analysed (Figure 1). Significant correlations ($p<0.05$) were observed between germination and both water availability in land types biocrusts were sourced from, and crust colour.

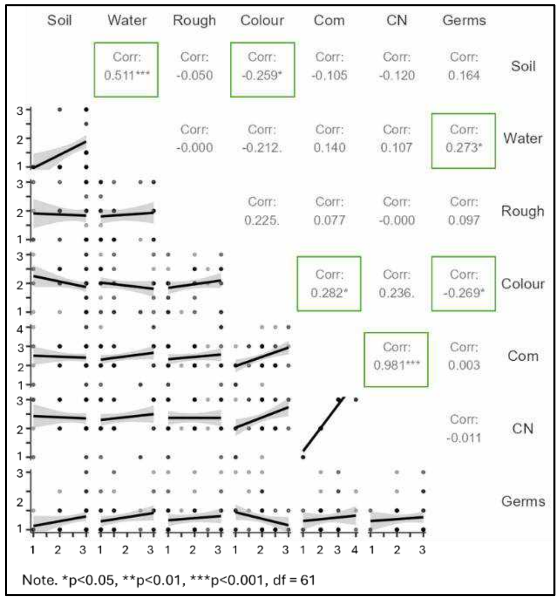

Figure 1. Correlation between biocrust characteristics and germination of pasture grasses in surface trials (Spearman's, asterisks indicate significance). Axes numbers represent classifications: Soil (1= Shallow, gravelly or sandy, 2= Texture contrast, 3= Heavy clay); Water (1= Low availability, 2= Moderate, 3= High); Roughness (1= Smooth, few pores, 2= Few pores, raised surface, 3= Rough due to liverworts, mosses or lichens); Colour (1= Light to intermediate, 2= Dark, 3= Green); Community (1= Light cyanobacteria, 2= Intermediate cyanobacteria, 3= Dark cyanobacteria with lichens, liverworts and/or mosses, 4= Dark dominated by lichens, liverworts and/or mosses); Carbon and Nitrogen (0= Bare ground, 1= Some organic matter/litter, little biocrust, 2= Light to intermediate cyanobacterial biocrust, 3= Dark cyanobacterial biocrust or dark biocrust with lichens, liverworts and/or mosses)

Experiment 2: Effects of biocrust inoculum on seed germination

Germination tests in paper towel revealed that 5% of *A. lappacea* seeds from the sub-sample germinated. Emergence was greater than or equal to the non-insulated control in 71.4% of biocrust inoculum from the 21 treatment sites. When data was extrapolated using a generalised logistic model, for treatments with increasing probability of germinating over time, one-third of sites were significantly faster compared to the control. Treatment sites grouped by land type revealed 77.8% of land types reached greater than 50% germination within the 30-day testing period. Community composition affected mean germination. Germination was greatest with light cyanobacterial inoculum (58.33 ± 35.36%). Intermediate cyanobacterial had 36.36 ± 19.46% and dark cyanobacterial crust with liverworts, mosses and lichens had 42.86 ± 16.27%. Dark biocrust dominated by liverworts, mosses and lichens had equal germination to the control (16.67%). Whilst cyanobacterial biocrust inoculum enhanced germination, mean germination for various biocrust communities was not significantly different to the control in these experimental conditions ($p>0.05$).

Discussion

In this study we aimed to develop an understanding of how biocrust and A. lappacea interact and determine whether biocrusts at various successional stages affect seed germination differently. Germination of the studied seeds was 5%. Naked A. lappacea caryopses usually have around 90% germination rate when dormancy is not a barrier (D. Phelps, personal communication, October 16, 2024). In our study, seed was harvested in May and experiments performed in August, so dormancy is a likely reason for the low germination rates in preliminary germination tests. Despite this, we found some support for our hypothesis that biocrusts affect germination. One way biocrust may enhance germination is through improved water relations. There is conjecture over effects of biocrust on water capture, movement and retention. Like our findings, others (Canton et al., 2020; Ming et al., *2024) found that cyanobacterial biocrusts decreased run-off and retained water for longer than bare soils, especially in upper layers. Adessi et al., (2018) attributed increased water retention to extracellular polymeric substances (EPS); there is agreement that EPS contributes to better soil structure, aeration and water infiltration. In our study, soil texture influenced water availability as the sand control had higher evaporative rates (NP observations), resulting in poorer biocrust development, and reduced water retention. With less water available in the sand control, germination rates were lower than biocrust treatments.*

We also found some evidence to support the hypothesis that differently developed biocrusts affect germination differently. Significant differences in germination in our experiments are likely due to differences in biocrust colour. Biocrusts are generally darker than the parent material they grow on and exhibit lower albedo, especially biocrusts with organisms like cyanobacteria that contain more chlorophyll and UV protecting pigments such as scytonemin (Kidron et al., 2022). Higher albedo associated with light cyanobacterial biocrusts likely accounted for increased germination in our experiments (Fig.1). *We discovered that germination success was enhanced to varying degrees when seeds were primed with biocrust inoculum. This supports previous studies that have demonstrated that 'bio-priming' seeds with cyanobacteria enhanced germination in some species native to Western Australia (Chua et al., 2020; Muñoz-Rojas et al., 2018). In our study, the number of germinations may have been lower in some land types, but the speed at which germination occurred was higher. This would have the potential for seed to germinate and establish before water runs out. Biocrust enhanced germination rates for 71.4% of site inoculums and, for most treatments, inoculum-seed mixture remained moist, so water availability was probably not a barrier for germination in those with lower rates. Our observations are supported by studies where no significant difference in water retention was observed when induced biocrusts were ground up rather than being left intact (Colica et al., 2014). We found effects of biocrust inoculums were site-specific and this is consistent with findings of other studies (*Havrilla et al., 2019; Peter et al., 2016).

Overall, biocrust enhanced germination of *A. lappacea*, although not significantly, and minor differences in germination were observed for differently developed biocrusts in the context of this study. Conclusions are based on limited data and replications as few biocrust samples were available so should be considered preliminary in this field of research. Additionally, identification of genera or species was outside the scope of this study and more testing for inoculums is recommended. Given the effects of biocrust are site- and species-specific, further research into the effects of biocrusts on germination of *A. lappacea* in field experiments is essential for development of effective nature-based solutions to rangeland regeneration.

Abstract

The biocrust microbiome that occupies the surfaces of rangeland soils globally are key contributors to carbon sequestration, nutrient cycling and sustain vegetation cover. Previously, research in northern Australia has demonstrated N inputs from biocrusts of 5 kg/ha seasonally that accounts for approximately one sixth to half of the annual pasture N demand. Biocrusts are important indicators of rangeland health, and we address how management actions can facilitate their survival under climatic extremes.

We explored the resilience of biocrusts to fire and grazing at two long-term research sites at Kidman Springs (NT) and Wambiana (QLD), respectively. At Kidman Springs in our first DNA analysis (metabarcoding) we examined the recovery of biocrusts after one year of burning, on plots 2 and 4 year prescribed burning regimes, carried out late dry season. Biocrusts were resilient to fire and recovered in the first wet season with no grazing pressure, as there were no differences in composition between the control and late 2- and 4-year burns. However, DNA analysis from nearby grazing exclosures showed that after 60 years of no cattle grazing, biocrust composition had significantly diverged from grazed areas. Furthermore, in our second DNA analysis (metagenomics) we included samples from 2, 4 and 6 years prescribed fires, burnt early and late in the dry season, and we collected samples at the dry and wet season, demonstrating that there was significant variation in biocrust bacterial composition between all fire treatments and soil types. Bacterial genes responsible for nitrogen fixation were sensitive indicators, that responded to seasonal conditions. Biocrusts also had significantly more nitrogen and carbon than bare degraded soil.

At Wambiana, moderate stocking rates maintained good land condition and strengthened nitrogen fixation potential of biocrusts. Key indices of landscape function including biocrust cover were informed by land condition and climatic conditions. Moderate stocking rates combined with wet season rotational spelling on average every

three years also facilitated nutrient cycling. Recently, we have shown that discrimination of biocrusts using satellite imagery is a feasible monitoring tool on a landscape scale. We can track changes in ground cover including biocrusts both spatially and temporally. Bare ground covered with biocrusts are sensitive indicators of landscape function.

Introduction

Tropical and dry savannas in Northern Australia are one of the largest intact mixed grass-woodland ecosystems globally. They cover >17% of Australia (tropical savanna, 1.9 million km^2, subtropical savanna, 272,000 km^2), where 99% remains as native vegetation of which >65% is grazed native vegetation, and ~35% are conservation zones or natural vegetation (DCCEEW, 2024.). They contribute to 12% of the existing tropical savannas in good environmental condition, and its conservation value is of global significance (Woinarski et al., 2007). The vegetation is diverse, from the eucalypt-dominated woodland to open woodland, shrubland and tussock grassland. The savanna structure is shaped by anthropogenic activity, herbivores, and fire (Cowley et al., 2014). Beef production in Northern Australia contributes $17.6 billion to the economy, carrying over 60% of the total herd of the Australian cattle industry. While most grazing lands are in good condition, a combination of drought, overstocking and intense selection for preferred land types has led to significant degradation in many areas. Fires are also common in these savanna landscapes and can cause changes in ecosystem characteristics such as physiological function, species composition and structure at multiple scales from leaf to landscape (Barger et al., 2016; Cowley et al., 2014).

Recent studies have highlighted the importance of biocrusts across these landscapes (Chilton et al., 2022; Williams et al., 2014) where cyanobacteria dominated biocrusts are estimated to cover 617,000 km^2 (~28%) of the soil surfaces (Fig. 1a), (Williams and Driscoll 2012, unpublished data). Biocrusts form an expansive protective cover on the soil surface (Fig. 1c-d), and serve important ecological functions including soil stabilization, nitrogen fixation and carbon cycling (Williams et al., 2018, Williams et al., 2014, Elbert et al., 2012). These microbial communities are dominated by a diverse suite of cyanobacteria and liverworts, together with micro-lichens, mosses, bacteria, algae, and fungi (Williams et al., 2014). Nitrogen fixation by cyanobacteria and other diazotrophic bacteria provides a direct source of bioavailable N for plants that fluctuates seasonally (Williams et al., 2018, Barger et al., 2016). Loss of biocrust cover (Fig, 1d) results in erosion and degradation of critical soil resources (Eldridge and Delgado-Baquerizo, 2017).

Biocrusts, are important post-fire to boost plant-available nutrient pools in savannas globally, although are less well understood in the context of fire in Australian savannas (Weber et al., 2016; Williams et al., 2018). Recovery of biocrusts post-fire varies with fire regime, locality, time since fire, biocrust community type, and broader geographic range (Palmer et al., 2020, Weber et al., 2016). The impact of fire on biocrusts depends on fire intensity, frequency, and patchiness (Johansen, 2001). In the Great Basin (USA) interactive effects of fire and cattle grazing on biocrust communities, can mediate the effects of invasive grass species and regulate site resistance to invasive species and future fires (Condon and Pyke, 2018). In the northern Australian savanna, we quantified how biocrusts responded to fire and grazing.

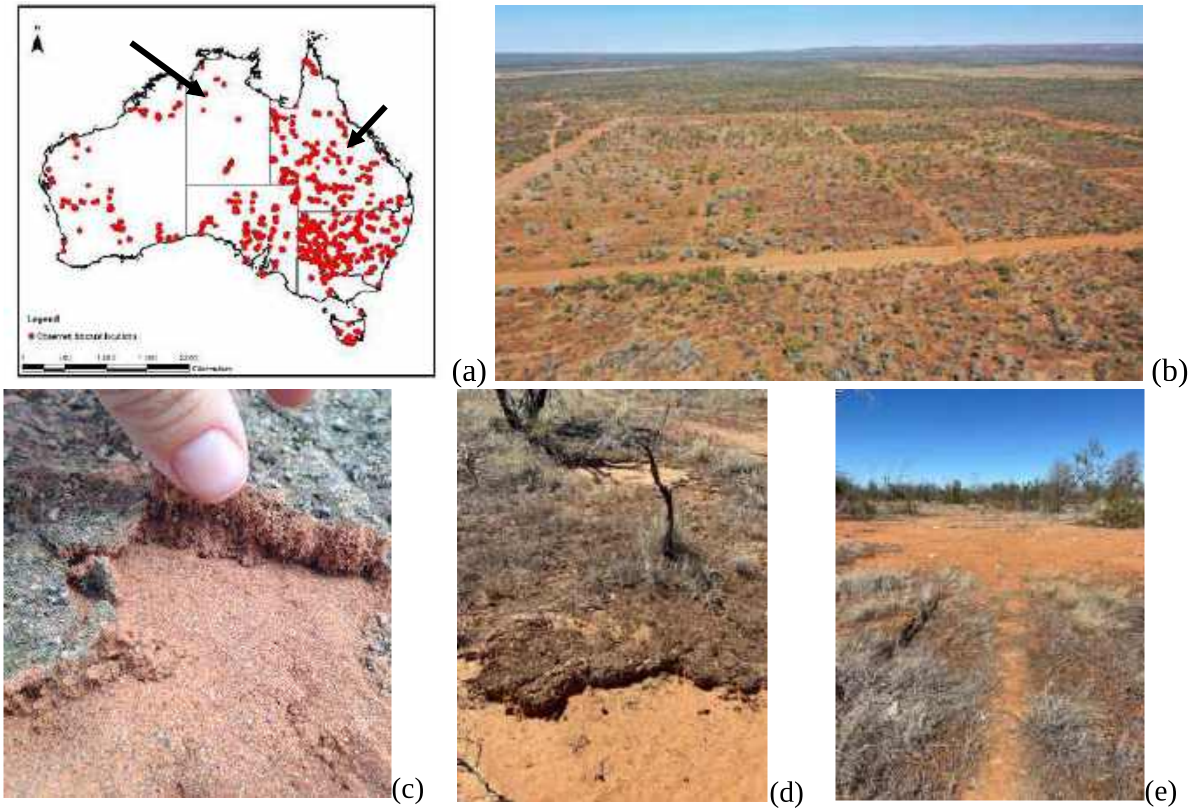

Figure 1 (a) Current survey points recording the presence of biocrusts across Australia compiled from published works and authors' unpublished data (arrow indicates Kidman Springs (left) and Wambiana (right), (b) Kidman Springs fire plots on calcarosols, (c,d) examples of biocrust (state 1) securing the ground cover with erosion caused by cattle 'camps' and water washing the degraded areas away, (e) results of erosion and compaction with no biocrust and ongoing trampling (state 2).

Background

At Victoria River Research Station (VRRS) in the Northern Territory, a cattle station at Kidman Springs, biocrusts have been subject to long-term fire trials for 30 years (1994–2024), with fire intervals of no fire (controls), 2, 4 or 6-yearly burning and season, early (June) or late (October) dry season (Cowley et al., 2014). Since 2013, wet season resting from grazing followed the two-yearly burns but were applied to all treatments. The fire plots (Fig. 1b) are set across two soil types (calcarosol and vertosol) and divided into 16 x 160 m x 160 m square plots, separated by fire breaks. On each soil type there are two replicated plots for each treatment and four unburnt control plots. At VRRS there were two 50-year cattle exclosures approximately 20 ha in size (Bastin et al., 2003) where we compared grazed and ungrazed biocrust diversity for sites that had no regular fire regimes (Vega-Cofre et al., 2023). Separately, in October 2022, a late burn was carried out across a heterogenous 2.6 km^2 Conkerberry paddock containing patches of grass, sparse cover and degraded areas (Fig. 1c-e.). Planet Scope imagery (3 m resolution, 8 MS bands) was used to determine the effect of fire and grazing on biocrust cover pre- and post-fire events (Myint Swe et al., these proceedings). Biocrust cover was substantiated by ground-truthing. Cattle were fitted with tracking collars and left to graze over the course of the following wet season.

The overall aims of these research projects were to provide in-depth studies of the effects of fire and grazing management at a local and commercial scale. This was intended to demonstrate the benefits of burning at the right time, and to contrast the effect of carrying stock post-fire with wet season resting. Additional research took place at the long term Wambiana grazing trial, Charters Towers, Qld, (1997–2023) where the impacts of heavy stocking, moderate stocking and moderate stocking with rotational wet season spelling (resting) on biocrusts were assessed.

Our central aims in the above studies were to determine pasture and biocrust recovery post-disturbance that would result in healthy soils and sustainable levels of ground cover. In doing so we can provide an accurate and rapid assessment of degradation events and post-disturbance monitoring of ground cover recovery at several levels. In turn we can provide support for land managers to sustainably manage Australia's extensive northern savanna. We discuss recent international research together with preliminary findings to understand the importance of biocrusts in the Australian rangelands.

Biocrusts, indicators of soil health

Where biocrusts exist in the rangelands they are both a protection against erosion as well as a useful indicator of soil health, cover and therefore stability and soil function or its potential (Aye et al., 2024). Moreover, biocrusts remain a relatively intact form that can be measured during both periods of stability and climate extremes such as drought. Based on a global drylands' dataset, Chen et al. (2020) found biocrusts formed alternative stable states:

1. Biocrust cover, ~80%; vascular cover, ≤10%, balance bare unprotected soil
2. Biocrust and vascular cover, ≤10%, balance bare unprotected soil
3. Vascular plants (vascular cover, >50%; biocrust cover, ~50%

At Kidman Springs evidence of these states were found across much of the 2.6 km^2 burnt Conkerberry paddock (e.g. Fig. 1c-d). Game camera records from the following wet season (W. Williams, unpublished data) showed the gradual degradation of new grass plants, biocrusts, and ongoing erosion of the soil surface with a further estimated 20% loss in functional integrity (Than Myint Swe et al., this publication), likely caused by ongoing cattle trampling, exacerbated by a significant loss of carbon and nitrogen in degraded areas (W. Williams unpublished data). Our results reflect many other studies that demonstrate the loss of resources that occurs with the loss of biocrusts (Zhang, 2024).

The effects of fire and grazing on biocrust communities and the subsequent influence these factors have on nutrient cycling and pasture quality is highly relevant for land management on grazing properties in northern Australia (Vega-Cofre et al., 2023). In this 2017 study, Vega-Cofre and coworkers found there were significant effects of grazing on bacterial community composition in the vertosol soils that were generally associated with increased cyanobacterial taxa in the 0–1 cm. Our findings demonstrated that the presence of livestock in rangelands increased the proportional representation of cyanobacteria whereas they were not strongly impacted by fire management (Vega-Cofre et al., 2023). Further analyses showed many cyanobacteria and bacteria were associated with nitrogen fixation and cycling. In the more frequently burned sites (early and late season 2-years, both soil types), there were significant impacts of fire management on the overall composition of bacterial communities (unpublished results).

At the Wambiana trial, biocrust cover was highest in the moderate stocking with rotational wet season spelling treatment. Here biocrust cover was dominated by cyanobacteria that bound soil particles, reduced erosion, sequestered carbon, fixed nitrogen, and improved soil fertility (Büdel et al., 2018; Williams et al., 2018). The results emphasised the advantages of wet season spelling combined with moderate stocking rates adjusted seasonally, as effective management strategies in these landscapes (Williams et al., 2021).

Challenges include extreme rainfall variability, intensified drought, and inherently nutrient-poor soils. In drought-prone environments, monitoring the presence and integrity of biocrusts connects landscape function and soil health. Biocrusts that protect and enrich the soil will support long-term ecosystem integrity and economic profitability of cattle production in rangelands (Williams et al., 2021).

Acknowledgements

We acknowledge the traditional owners of Kidman Springs. Many thanks to students, volunteers, researchers and landowners alike, these projects were a team effort. This project was also funded and supported by Meat and

Livestock Australia, Department of Agriculture and Fisheries Northern Territory, Department of Primary Industries Queensland, and the University of Queensland.

Key words: Rangelands, data platform, restoration, biodiversity, decision-making,

Abstract

Rangelands, spanning over half of Earth's land, include ecosystems like grasslands, deserts, savannas, and mountains. They support biodiversity, vital ecosystem services, and the livelihoods of pastoralists, livestock keepers, and farmers. However, rangelands face threats from agriculture, mining, urbanization, and infrastructure expansion, leading to land degradation and increased pressure from rising livestock product demand.

The global Rangelands Data Platform addresses these challenges by serving as a repository for rangeland data, supporting informed decision-making on their management, protection, and restoration. Accessible to the public, the platform raises awareness, supports scientific research, and guides investments in sustainable practices.

By providing data for global advocacy and community resilience, the platform contributes to initiatives like the UN Decade on Ecosystem Restoration and promotes the sustainable use of rangelands. This effort ensures the preservation of their ecosystem services and cultural heritage for millions worldwide.

Introduction

Rangelands, covering over half of Earth's terrestrial surface (Reid et al., 2014), are diverse ecosystems that include grasslands, deserts, savannas, tundra, woodlands, wetlands, and mountainous areas. These landscapes support biodiversity, provide essential ecosystem services, and contribute to food security and poverty alleviation for millions worldwide (Asner et al., 2004). Approximately 91% of rangelands are extensive, characterized by open landscapes with minimal boundaries and limited crop agriculture, while 9% are mixed-use areas combining grazing with cultivation. Communities such as pastoralists, hunter-gatherers, and crop farmers rely on rangelands for livestock production, cultural heritage, and socio-economic activities.

Despite their global importance, rangelands face growing pressures from urban expansion, large-scale agriculture, mining, and climate change. These challenges contribute to land degradation, affecting 25-35% of rangelands globally, and reduce their ability to provide critical ecosystem services. Addressing these threats requires effective governance, restoration, and sustainable management practices. International efforts, such as the UN Decade of

Ecosystem Restoration and the declaration of 2026 as the International Year of Rangelands and Pastoralists, underscore the urgency of protecting these ecosystems.

To address these challenges, the "Sustainable Investments for Large-Scale Rangeland Restoration" (STELARR) project was launched in 2023. Funded by the Global Environment Facility (GEF), STELARR aims to reverse rangeland degradation, enhance productivity, and reduce poverty through sustainable livestock value chains. The initiative prioritizes inclusive benefits for women and youth, fostering resilient livelihoods and economic opportunities. It reinvests profits from sustainable livestock practices directly into rangeland restoration, creating a self-sustaining model for long-term environmental and economic benefits.

Central to STELARR's mission is the development of a global rangelands data platform, led by the International Livestock Research Institute (ILRI) in collaboration with GMV and Vizzuality. This platform serves as a comprehensive repository for rangeland data, enabling the collection, sharing, and analysis of critical information. It supports policymakers, scientists, and local communities in making informed decisions and promotes evidence-based strategies for sustainable management. By highlighting the ecological, economic, and cultural value of rangelands, the platform facilitates targeted investments, monitors changes, and enhances awareness at local, national, and global scales, ensuring the long-term health and sustainability of rangelands worldwide.

Methods

The development of the Rangelands Data Platform employs an iterative methodology that combines user-centred design (UCD) principles with agile practices to meet stakeholder needs and align with the STELARR project's goals. It begins with a discovery phase that gathers and analyses information across business, design, scientific, and technical domains. This phase evolves iteratively, incorporating new insights to ensure the platform remains adaptable.

Business discovery is central to this phase, defining governance structures, identifying stakeholders, and setting objectives and use cases. It also maps needs, analyses existing initiatives, establishes metrics for success, and identifies potential risks. Five key user groups are prioritized: remote sensing and GIS experts, climate and ecosystem management professionals, land management and conservation specialists, community-based approach experts, and agriculture and livestock managers. Their feedback shapes user profiles, use cases, and platform features, ensuring relevance, transparency, and trust.

The design phase adheres to UCD principles, engaging stakeholders to refine platform features through workshops, discovery sessions, and prototype testing. Accessibility is a priority, making the platform inclusive for technical and non-technical users, even those with limited digital literacy or connectivity. Iterative development ensures adaptability to evolving needs.

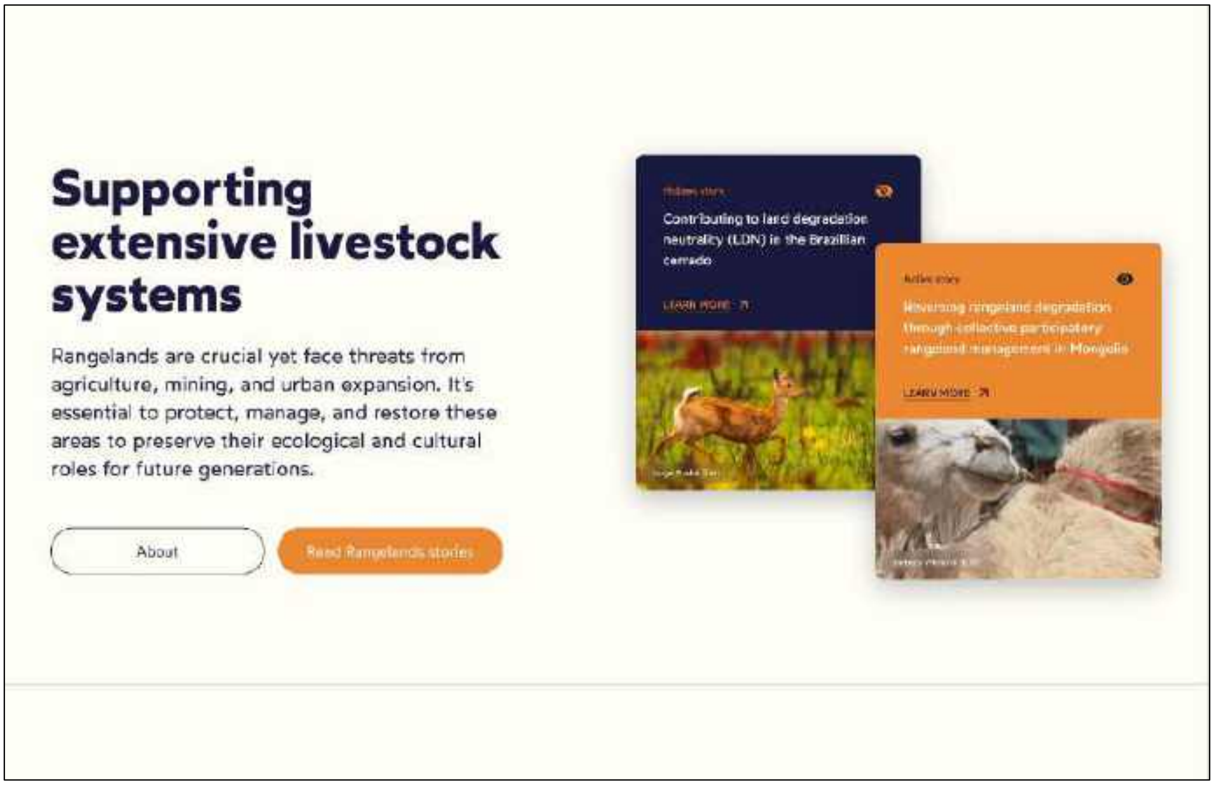

Figure 1 Screenshot of a section of the Rangelands Data Platform landing page.

Simultaneously, the data and technical discovery phases address the platform's data ecosystem, infrastructure, and architecture. Data discovery evaluates existing datasets, identifies gaps, and proposes new sources, while technical discovery focuses on infrastructure, tools, and sustainability strategies. It addresses data formats, processing needs, and storage solutions, mitigating risks to ensure reliable performance in areas with limited connectivity.

Agile methodology underpins development, enabling flexibility and responsiveness. Iterative, time-boxed sprints deliver functional features regularly, guided by continuous stakeholder feedback. A cross-functional team of data scientists, designers, and developers prioritizes a backlog of features and ensures efficient delivery through continuous integration, rigorous testing, and adaptive planning. Post-sprint retrospectives refine processes and align the platform with STELARR's objectives, ensuring it meets diverse user needs.

This structured approach guarantees a user-centric, adaptable, and sustainable platform that addresses the challenges and priorities of rangeland management while remaining aligned with STELARR's broader goals.

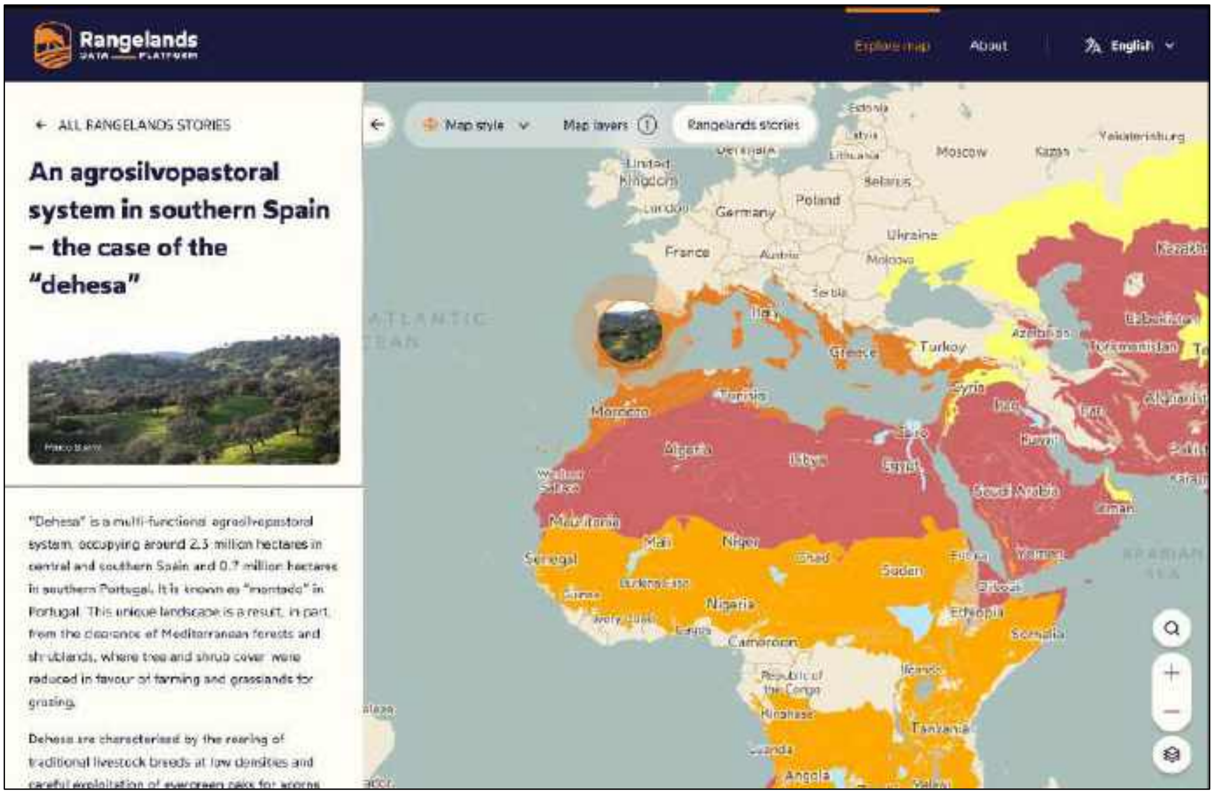

Figure 2 Screenshot of a rangeland story featured on the Rangelands Data Platform.

Results

The Rangelands Data Platform integrates diverse geospatial and contextual datasets within a scalable framework, facilitating comprehensive analysis of rangeland ecosystems. It currently incorporates datasets addressing ecological, productive, and contextual dimensions, with a flexible architecture designed for continuous expansion based on stakeholder feedback and emerging needs. The platform also features case studies that illustrate how changes in rangelands impact local communities, livestock, and natural resources, while showcasing efforts to protect rangelands, wildlife, and the livelihoods dependent on these ecosystems and extensive livestock systems.

The platform is built upon a foundational dataset that defines global rangeland systems by selecting seven of fourteen biomes or rangeland types, based on World Wildlife Fund's (WWF) classification of terrestrial ecoregions, as defined in the ecoregions layer by Dinerstein et al. (2017). This dataset serves as a spatial mask, enabling users to visualize and explore data specific to rangelands, with the ability to filter by individual biomes or their constituent ecoregions. Building on this foundation, the platform incorporates a range of ecological datasets, such as time-series net primary productivity (NPP) data from Moderate Resolution Imaging Spectroradiometer (MODIS) to capture vegetation dynamics, the Anthropogenic Biomes of the World dataset from Socioeconomic Data and Applications Center (SEDAC) to highlight human impacts on ecosystems, and the World Dryland Areas dataset from UNEP-WCMC to define global dryland boundaries. Additionally, datasets on tree cover loss and tree cover gain from Global Forest Watch provide insights into changes in forest cover over time. Other contextual datasets further enrich the platform, offering valuable information on conservation priorities, threatened species, surface water extent, livestock systems and density, population distribution, pastoralist communities, and indigenous territories. As the platform evolves, the collection of datasets will continue to grow based on ongoing stakeholder feedback, providing a robust foundation for analysing the ecological, productive, and social dimensions of rangelands.

Figure 3 Screenshot of the Rangelands Data Platform, displaying the ecoregions within the rangeland systems and the Net Primary Productivity (NPP) for the year 2001.

The platform's technical infrastructure is designed for efficient data processing and seamless visualization, enhancing user interaction with diverse datasets. Vector datasets are processed using Python, converted into MBTiles, and hosted on Mapbox to ensure optimized performance. Raster layers are retrieved from Google Earth Engine and processed within Google Cloud Functions, where they are dynamically styled and transformed. This allows the creation of new layers, such as NPP change (calculated from the first and last years of the time series) and total livestock density (aggregating the number of animals per grid cell). The cloud-based processing approach ensures the platform can efficiently handle large datasets and generate real-time, customized visualizations. The system leverages Google Cloud Platform, with containerized applications managing the frontend, backend, and data workflows. Terraform automates resource provisioning for scalability, while Cloud SQL supports relational data storage. Strapi is employed to manage metadata and style configurations for both vector and raster layers, enabling easy updates. Key statistics, such as rangeland metrics, are embedded within the corresponding Mapbox layers, enabling the frontend to retrieve and present this information to users in an interactive and accessible format.

By combining this robust technical foundation with a diverse and expanding set of datasets and case studies, the Rangelands Data Platform offers a flexible, scalable resource for advancing the understanding and management of rangelands. Its ability to incorporate new tools and datasets, driven by ongoing stakeholder feedback, ensures that the platform remains relevant and adaptable to evolving research and policy needs.

Discussion and outlook

The rangelands data platform is design to become a transformative tool for rangeland management, driven by continuous stakeholder interaction and technological advancements. It aims to meet the diverse needs of policymakers, scientists, local communities, and conservationists.

Regular consultations and feedback sessions have been crucial in developing the current version, providing insights into the specific needs of different user groups. However, many more will still be necessary to fully address the platform's goal. Training programs and workshops are also expected to enhance stakeholders' capacity to utilize the platform effectively.

Future developments will enhance the platform's capabilities by incorporating more localized data and success stories on rangelands restoration, improving analytics, and fostering greater collaboration among stakeholders. Continuous improvement through stakeholder engagement and technological innovation will ensure the platform remains a vital resource for sustainable rangeland management.

In conclusion, the rangelands data platform represents a significant advancement in rangeland conservation. Its evolution and stakeholder interaction position it as an indispensable tool for promoting sustainable practices, enhancing biodiversity, and supporting resilient livelihoods. As it grows and adapts, it will play a crucial role in achieving global rangeland conservation and sustainable development goals.

Acknowledgements
The development team would like to thank the users engaged during the discovery phase for their availability and the valuable feedback provided, which has been instrumental in shaping the platform's design, functionality, and alignment with real-world needs. In addition to the paper's authors, special thanks go to Iker S. Requerey, Kevin Sanchez, Bárbara Chaves, Irene Rodríguez Vara, Cristina Jaramago, Daniel Caso and Yulia Belyakova from Vizzuality for their significant contributions to the platform's development and their thoughtful peer review of this paper.

Abstract

Globally, rangelands contribute to biodiversity (above- and below-ground), climate change adaptation and mitigation, ecosystem restoration, wildlife habitat and human well-being. However, these critically important ecosystems are degrading at unprecedented rates, due to lack of investment and awareness. Further limiting these investments are the vast knowledge gaps on the status of rangeland health, including the ability to reliably measure the impact of rangeland restoration interventions on key indicators of ecosystem health. We propose that building and implementing a global rangeland monitoring framework, aimed to build consistent datasets, will enable the comparison of management practices across diverse systems, track the efficacy of interventions over time, and provide the evidence-base to inform policy and practice. In addition, we see an additional benefit of such a system is the contribution to the various standards around value chains from rangeland systems, ultimately providing additional income to pastoralists and value chain actors. Within the STELLAR (Sustainable Investments for Large-scale Rangeland Restoration) project, we have conducted a review of standards and their associated monitoring frameworks across the rangeland value chains in the Americas, Central Asia, and Africa. We collated the variables and indicators within each framework and found wide disparities in indicators monitored, monitoring techniques, and assumptions made. Variations in how data are collected and which variables are included demonstrated a lack of consistency across frameworks. For example, the Land Degradation Surveillance Framework (LDSF) is a comprehensive field based method that collects multiple indicators of soil health, land degradation and vegetation diversity, but does not include local knowledge or socio-economic variables. We call for a framework that combines systematic field-based assessments, with citizen science and remote sensing to deliver accurate assessments of rangeland health indicators at scales relevant to stakeholders (pastoralists, value chain actors, land managers, standards experts, and policy makers) and to track interventions over time.

Introduction

Rangelands are incredibly vast ecosystems and provide multiple critical ecosystem services and livelihoods for millions of people. Yet, rangelands are highly degraded, with soil erosion being dominant in dryland systems (Vågen and Winowiecki, 2019). Therefore, there is an urgent need for rangeland restoration efforts. A significant obstacle to attracting private investment in rangeland restoration, as Burrows (2024) points out, is the absence of reliable and straightforward performance indicators. Livestock value chain development (LVCD) offers a promising pathway for driving investment and improving rangeland management. By involving actors across the livestock value chain - including the commercial sector - LVCD can help establish sustainable and climate-resilient systems. This involves directing investments toward the resource base (rangelands) to enhance productivity and enable targeted restoration efforts. Furthermore, LVCD can build international momentum for rangeland restoration through collaboration among key stakeholders, alliances, and evidence-based approaches. However, the lack of globally validated standards, tools, and frameworks for assessing restoration progress has hindered effective scaling of robust value chain models, particularly in developing nations.

Ecological monitoring involves tracking changes in ecosystems by measuring specific variables and indicators across space and time. Indicators are measurable attributes of an ecosystem that provide critical insights into its health and functionality (Suter 2001). These indicators can either directly quantify significant ecosystem attributes or services - such as vegetation biomass as an indicator of productivity - or indirectly measure elements correlated with processes or features that are more challenging to assess directly. An ecological monitoring framework offers a systematic approach to observing, evaluating, and interpreting ecosystem conditions and their dynamics over time. Its primary purpose is to enhance the understanding of ecological processes, identify changes or trends, and support informed management decisions (Schlesinger and Bernhardt 2013).

To address these gaps, we aim to co-develop a comprehensive framework for monitoring rangeland health that can be applied across various value chains and landscapes.

Methods

A first step in this development process was to conduct an extensive review of existing monitoring frameworks. An initial review assessed 30 monitoring frameworks, including 15 connected to sustainability standards, 11 based on field methodologies, and five relying on remote-sensing techniques. Additionally, a review of 65 publications - across topics of rangelands, grasslands, savannas, restoration, degradation, drylands, monitoring, and surveillance - was conducted to identify current practices and best approaches in rangeland monitoring. This review assessed 59 biophysical and 18 socioeconomic indicators across the frameworks. To assess the frameworks, we rated them based on the number of indicators assessed under the following categories: 1) Soil health; 2) Vegetation; 3) Hydrology; 4) Landscape Level; 5) Faunal Diversity; 6) Community Indicators; 7) Ease of Implementation; and 8) Data Collection and Integration. If a framework had five or more variables measured under each category, it was scored high. We also conducted interviews with key informants, including standard developers and commercial sector representatives, to better understand practical challenges and priorities for LVCD investment. Further, a consultation workshop on the proposed global rangelands monitoring framework and indicators was held with representation of 22 organizations to provide feedback and suggestions.

Results

The results of this review illustrated that no one monitoring framework adequately covered all aspects of socio-economic, biodiversity, and animal health and diversity. While some frameworks were excellent in biophysical indicators and ease of implementation (the Land Degradation Surveillance Framework (LDSF), others were strong in the socio-economic and community indicators (Sustainable Fibre Alliance) (Table 1). Furthermore, there was little overlap in indicators, making it difficult to use data from different frameworks to compare and assess rangeland health. However, from the 59 biophysical indicators and the 18 socio-economic indicators assessed we narrowed down to a list of 10 biophysical indicators and 12 socio-economic indicators, see below. These indicators were narrowed down through a multi-step process including: 1) Assessing whether the indicators adhered to the SMART indicator framework (Specific, Measurable, Attainable, Relevant, and Timebound); 2) Multi-stakeholder consultation workshops; and 3)Key informant interviews. This process will continue through the next six months to finalize the list.

Biophysical Indicators
Soil: Soil organic carbon content, soil compaction, soil erosion prevalence, bare ground cover
Vegetation : Annual primary productivity, herbaceous cover, woody cover
Biodiversity: diversity and density of grasses, forbs, woody vegetation
Hydrology: soil-water infiltration capacity

Socioeconomic indicators
Rangeland Enterprise: Rate of return on investment, palatable forage cover, livestock density/health, presence of a feasible management plan, governance structure, secure land tenure
Community Livelihoods: Income inequality, local ecological knowledge utilized, education, employment diversity

Table 1: An evaluation of 11 rangeland health frameworks according to the number and type of soil, vegetation, hydrological, biodiversity, landscape, and community indicators, and the framework's ease of implementation and infrastructural integration. Dark green represents the highest rating, followed by light green, yellow, and pale red representing the lowest rating.

Discussion

There is a clear need for a comprehensive monitoring framework that combines globally relevant, validated indicators while also capturing the unique nuances of local contexts. This framework should generate reliable evidence of the impacts of restoration activities and support investments in sustainable rangeland value chains. We recommend integrating robust field-based methods with citizen science and remote sensing technologies. This combination will allow for the establishment of accurate baselines and facilitate long-term monitoring of key biophysical indicators, all while providing geo-referenced data on the location and types of actual interventions taking place on the ground. Such an approach would provide the necessary evidence to support adaptive management, guide policy decisions, and attract further investment in sustainable rangeland management.

Mobilizing luxury brands' value added as investment in rangelands

Abstract

Rangelands generate a multitude of products and services. Some pass into value chains delivering branded luxury products. Luxury value chains are stakeholders in rangeland restoration. The juxtaposition of their perceived excess and exclusivity with the harshness of subsistence production in adverse environments is widely recognised. Luxury also conveys uniqueness, quality and provenance. Ongoing efforts at "fast fashion" and "affordable luxury", have demonstrable impacts on rangelands. In the STELARR (Sustainable Investments for Large-scale Rangeland Restoration) project we argue that product differentiation using rangelands' provenance is established across products as diverse as meat, cosmetics and clothing. We identify models for luxury brands' investment in rangelands directly and investigate the entry points available for that investment. Context for these models' operation includes rapidly developing functionality of standards and certification relating actions in the rangelands to sustainability indicators and onwards to support claims at the retail level. Technology that enables information capture, transmission and visualisation offers opportunities for product differentiation and a product story that supports a luxury price. Global trade's move to products' verified sustainability credentials offers a convergence of value chain actor's interests and capabilities. Owners of luxury brands then have the opportunity both to advance and support their own claims by appropriate investment in rangelands; and to exclude competition all along the value chain from brands not achieving the markups associated with luxury sales. Seven investment models are identified, with entry points for deal structures to engage luxury value chains. Across the Americas, Central Asia, and Africa we identify on-going initiatives that enable the investment models, including the Rangeland Stewardship Council, and industry- and national-level actions, on the interface between sustainability and value chains. We call for a broader embrace of value chain development which aligns the high retail margins of luxury brands with the incentive to invest in rangelands.

Introduction

Rangelands support numerous value chains which deliver food, fibre and industrial products within and beyond the rangelands' geographic reach. Rangelands also deliver ecosystem services across a variety of spatial, functional and organisational contexts to deliver public and private goods (Fisher, Turner, & Morling, 2009). From the concept of "Land Value Chains" (Raschio, 2017), networks extending into international markets enable rangeland products to be sold and re-sold, transformed and marketed far from their rangeland origins. Some rangeland products find their way into luxury value chains. The current study identifies and examines links between the value added and branding of these products, and the rangelands.

The mobilisation of sustainability is not a new concept for delivery of value addition in supply chains and social development outcomes. Rangelands have in the past successfully attracted investment into value chains (De Groot et al., 2013; Ferwerda, 2015), including programs for Payments for Environmental Services (PES) which have had a variety of orientations around environmental degradation (Pappagallo, 2018), but have occurred at limited scale.

Method

This paper is a synthesis of current knowledge on the connection between luxury brands and rangelands, to identify models and entry points for investment by brand owners under the STELARR (Sustainable Investments for Large-scale Rangeland Restoration) project.

Results

Estimates of the extent of degradation of the World's rangelands vary, but up to one third of their area is reckoned to be either degraded or under threat of degradation (Herrera Calvo, 2024), with some estimates much higher (Ding et al., 2017). Rangeland degradation has numerous symptoms, causes and consequences, both public and private. Knight and Overbeck (2021) conclude that restoration cost estimates per hectare are highly variable and context specific but can extend to the tens of thousands of dollars.

Rangeland preservation is widely acknowledged as requiring a convergence of stakeholder interest supported by organisational models and community. The STELARR project addresses rangeland restoration, for which associated models are less well documented. Pastoralists' enterprises and associated value chain and environmental actors might represent a convergence of stakeholder interest (Reij et al., 2020; Shames & Scherr, 2020), but cost levels are such that Leake (2021) remarks on "a significant need for restoration … that can seldom be paid for by the land manager or farmer of that land".

Opportunities for value chain-related financing of rangeland restoration have been examined by Teno (2022) in the context of the large scale Great Green Wall initiative. Recognition of business more generally as a stakeholder in rangeland restoration is taken up in UNCCD's business sector engagement strategy (Voigt, 2013). The STELARR project sets out to design, demonstrate and support rangelands' products and provenance as a basis for luxury brands' investment in rangelands directly, and at the landscape scale which has evaded investments at the level of value chains. Enhanced mobility of communications and preferences across national and cultural boundaries have produced a recent "democratisation of luxury" which has enhanced access to luxury.

This access has affected the rangelands: the much discussed "cashmere crisis" is presented by some as the increased demand (often in blends and in lower quality products) implicating animal welfare and overgrazing (Darbalaeva et al., 2023; Lauesen, 2019). Jones and Jones (2018) describe "sustainable luxury", and an "ideological product", mobilised to include employment conduct and conditions, animal welfare and other sustainability concerns by Cavender (2018) to state that brands express "core values" through their stance on sustainability, but despite luxury brands' embrace of information technology as a means of communicating with consumers, they do not use these channels to "tell a story" featuring sustainability. Further, provenance plays a significant role in branding: cashmere's provenance and its associated "heritage" and "spiritual home" are central to customers' perception of a cashmere brand (Collins & Weiss, 2015). "Product integrity", "craftsmanship" and "relationship to place" are also central to cashmere marketing (McLaren-Hankin, 2013), as are "authenticity, heritage and craftsmanship" (Towers, Perry, & Chen, 2013). However, these communications of provenance refer to the place of manufacture, and not the place of origin of raw materials: the rangelands.

Value chains exhibit differing relationships to their rangelands resource base, and stakeholder systems reflect this. Mobility of pastoralists requires particular resource governance forms; customary access and non-private ownership requires others; grazing and cultivation pressure across public/private boundaries accentuate pressure on public rangelands and on the bodies administering them. The demanding logistics and quality requirements of luxury products impose high costs along these lengthy value chains. Beyond storytelling, certification and standards are playing a role. Some 35% of global cashmere production, 42% of mohair and increasing proportions of luxury camelid fibres, are certified for sustainability, animal welfare and social functions (TextileExchange, 2023). Little peer-reviewed research reports on certification within the supply chain for high value brands, but a study of CSR actions by Towers et al. (2013) found that procedures were informal and based on trust, rather than documentation. Danka, Grochowska, and van Rijt (2017) identify barriers to use of certification as complexity of the supply chain, problems with traceability, and a lack of universally accepted standards. Further, they have limited informational links to unified guidelines on land degradation neutrality (Chasek et al., 2019).

Discussion and conclusions

Luxury brands increasingly extol their sustainability credentials in publicly available reports featuring targets and verification procedures. Mixed farm production systems, and a plethora of product standards and certifications, have provided a limited foundation for investment in rangeland restoration related to single products' value chains. Textile Exchange certification and its promotion throughout the South African mohair industry, broad based standards for cashmere, and whole-of-chain initiatives in fine wool, have all developed over time. In different settings, precisely targeted sourcing arrangements for high valued beef branded as promoting rangelands (Lerma, Díaz Baca, & Burkart, 2023), and the vicuna species-preserving actions of luxury fibre brands in the Andes (CITES, 2019) have also played a role.

With regard to land-based investment such as rangeland restoration, clear benefits to investors have been elusive, even where tightly geographically defined (Bourne, Muller, de Villiers, Alam, & Hole, 2017). The best-known large scale private sector engagement program is "Business4Land", from which projected private sector benefits (drawn from several sources) are presented in table 1.

Table 1. Private sector incentives for rangeland investments

Private sector benefit	Mechanism
Risk mitigation	Improved delivery of both environmental services and marketable products and raw materials Access to scarce or unique raw materials
Enhanced productivity	Production generated from concentration of effort on several aspects of productivity (sustainable intensification)
Corporate responsibility	As able to be demonstrated along value chains
Brand value	Product differentiation based on credible claims Identification with International Year of Rangelands and Pastoralists Inclusion of rangelands and pastoralists in product provenance
Innovation in processes	Improved focus based on reliable volumes and qualities of product Scale of operation
New markets	Attracting new consumers to differentiated products. Carbon markets
Regulatory compliance	Addressing local, national or international requirements for access to resources, raw materials and markets
Government incentives	Tax and resource access incentives Climate related incentives

Source: Authors' compilation; (Herrera Calvo, 2024)

From the juxtapositions of luxury, sustainability and issues of high value branding, several models emerge which provide entry points for investment in rangeland restoration by the owners of high value brands. several are proposed as a source of finance for rangeland restoration:

- location-based investments (planting, soil and water management) which facilitate access to raw material supply from that location and support from communities and policy actors
- brand promotion by social investments (schools, community assets)
- attachment of brand identity to investments in rangelands which support endangered species
- strategic partnerships with high profile actors in rangeland conservation

Information flows are central to this process, and along with associated stakeholder actions, are presented in annex 1. Synthesis of reporting on high value apparel brands using rangelands-based natural fibres reveals difficulties in recording of investments, quantification of baselines and progress in rangeland productivity, and the establishment of value chain performance metrics which reconcile public and private benefits.

At the pastoralist level, mixed enterprises and multiple uses of rangelands across varied landscapes obviates the need for holistic rangeland standards rather than a 20th Century- product and process standards. A Rangeland Standard is under development in association with the STELARR project. Data and its collection and curation has represented a barrier to change by value chain actors including policy makers, resource managers, as well as the owners of high value brands investing in rangelands' restoration. An information platform combining remote sensing with ground-based verification is under development in association with the STELARR project. is targeting three luxury value chains for investment by high value brand owners, using a variety of entry points: cashmere in Mongolia and Afghanistan; mohair in South Africa; and vicuna in Peru and Argentina.

A disturbance triangle: The case for the interactive role of prairie dogs with fire and ungulate grazing in the Great Plains

Duchardt, CJ; Porensky, LM; Hennig, JD; Augustine, DJ

Key words: Biodiversity, Burrowing mammal, Grassland, Pyric-herbivory, Rangeland

Abstract

Global biodiversity declines have been hastened by the suppression of once-widespread disturbance regimes. In recent decades, restoration of the fire-grazing interaction has helped address these declines in the North American Great Plains. Conversely, relatively little attention has been paid to another historically ubiquitous disturbance agent -- the black-tailed prairie dog (*Cynomys ludovicianus*). While some research exists on the interaction between large ungulates and prairie dogs, scant work recognizes the triangle of historical and current interactions among large ungulates, fire, and prairie dogs, and research on interaction between the latter two disturbances is especially rare. Upon reviewing the literature, 34 sources discussed the fire-prairie dog interaction, but only one empirically tested the direct effect of prairie dogs on fire. Despite this research gap, historical fire patterns, current fire management activities, and unpublished data indicate prairie dogs likely reduce wildfire spread and/or intensity. We advocate for a paradigm shift in Great Plains rangeland management that considers prairie dogs as the third corner of a "disturbance triangle," and further exploration of these more complex disturbance interactions worldwide

Introduction

Most grassland and shrubland ecosystems evolved in the context of various interacting disturbances (Fuhlendorf and Engle 2001). The periodicity, spatial extent, and intensity of disturbances helped shaped the floral and faunal composition of these systems; thus, systematic suppression or alteration of historical disturbances during the past few centuries has led to decreased biodiversity and ecosystem health in myriad rangelands (Truett et al. 2001, Garnett et al. 2010). In the North American Great Plains, European settlement has coincided with reduced fire frequencies, novel grazing patterns of ungulates, and large-scale conversion of grasslands to row crop agriculture (Fuhlendorf et al. 2012; Augustine et al. 2021). Altered disturbance regimes on remaining grassland patches facilitate encroachment of woody species and homogenized herbaceous structure further contributing to biodiversity reduction (Ratajczak et al. 2016).

Accordingly, restoration of historic disturbances and their interaction has become a major goal of rangeland ecologists and conservation biologists alike (Sayre et al. 2013). While the ranges of native large herbivores including bison and elk (*Cervus canadensis*) have contracted since European settlement and fire has been long-suppressed, the fire-grazing interaction has been mimicked using domestic livestock and native grazers like bison on both public and private rangelands via patch-burn grazing, with evidence that this management approach can support both livestock and biodiversity goals (Fuhlendorf et al. 2009). Despite progress towards the reintegration of fire and grazing as interacting disturbances, most grassland management paradigms continue to ignore another interacting disturbance that was historically ubiquitous across the Great Plains: burrowing mammals, and specifically, the black-tailed prairie dog (*Cynomys ludovicianus*).

As a keystone species, black-tailed prairie dogs are an important prey item for numerous avian and mammalian predators including the endangered black-footed ferret (*Mustela nigripes;* Hoogland 2006). Prairie dogs are also ecosystem engineers, living live in dense colonies with hundreds or thousands of individuals that together consume vegetation and actively clip it to optimize predator visibility (Hoogland 2006). Their digging and shrub clipping helps to aerate soil and reduce the rate of woody encroachment (e.g., Barth et al. 2014), burrows provide habitat for rattlesnakes (*Crotalus* spp.) and burrowing owls (*Athene cunicularia*), and the short, sparse vegetation structure they generate is ideal for the imperiled mountain plover (*Charadrius montanus;* Duchardt et al. 2019). This same engineering that provides so many ecosystem benefits can also reduce forage availability for livestock in certain contexts (Augustine and Derner 2021). This conflict is largely responsible for eradication programs that have reduced current prairie dog populations sizes to 5% of historical estimates (Miller et al. 1994). While there is evidence that prairie dogs can negatively affect livestock production, recent research indicates that this conflict may be contingent on factors like interannual precipitation variability (Connell et al. 2019, Augustine and Derner 2021). Moreover, forage *quality* is often greater on colonies because prairie dogs maintain vegetation at an early phenological state and can shift species composition towards more nutritious plants (e.g., Connell et al. 2019).

While researchers and managers have acknowledged relationships between fire and grazers (e.g. Fuhlendorf and Engle 2001), and between grazers and prairie dogs (e.g., Augustine and Derner 2021), less consideration has been given to the other side of this triangle: prairie dogs and fire; few studies exist on impacts of fire on prairie dogs, and we are unaware of any experimental studies demonstrating the effects of prairie dog ecosystem engineering on fire behaviour. To address this knowledge gap, we 1) review the literature on influence of fire on prairie dogs and prairie dogs on fire and 2) propose a framework by which to consider the historic role of prairie dogs within the fire-grazing interaction.

Methods and Results

We hypothesized that fire would have a similar influence on prairie dogs as grazing, facilitating expansion of prairie dogs into burned areas (+). Conversely, because prairie dogs not only remove biomass like other grazers but also lead to soil disturbance, we expected a suppressive effect of prairie dogs on fire (-) (Fig. 1). To better understand both sides of the fire-prairie dog interaction, we reviewed the primary literature using Google Scholar and Academic Search Premier. We conducted our Google Scholar search between 20–23 October 2023 using ["prairie dog" OR "Cynomys"] and "fire", which returned 10,900 hits. We exhausted all 100 pages that Google Scholar generates (1,000 hits) on 23 October 2023. We completed the Academic Search Premier search on 25 November 2023 using the same search terms, which returned 758 hits. We reviewed titles for relevance then searched for the terms: "fire", "burn", and "fuel" within each relevant source. If a source contained any of these keywords, we downloaded the source for a subsequent full review, which yielded 98 documents. Upon review, we deemed 38 of these resources as relevant; 34 addressed the fire → prairie dog interaction either theoretically or empirically. Most of these resources (n = 29, 85.3%) merely discussed the directional effect of fire on prairie dogs; text referencing fire influences on prairie dogs predominantly appeared in introduction, discussion, and management implications. A small portion (n = 5, 14.7%) of the literature empirically explored the effects of fire on prairie dogs, with overwhelming support for a positive effect of fire on prairie dogs, mainly by facilitating expansion into burned areas (e.g., Milne-Laux and Sweitzer 2006, Augustine et al. 2007).

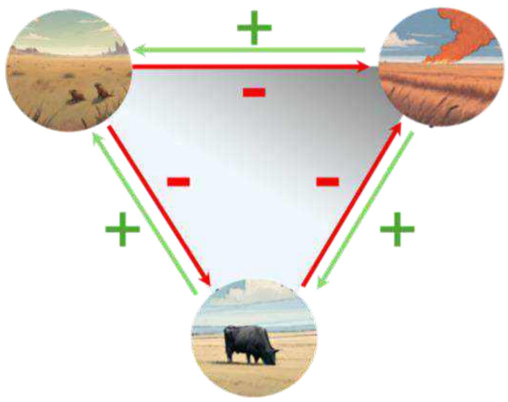

Fig. 1. Proposed disturbance triangle between fire, ungulate grazing, and prairie dogs within the Great Plains of North America.

Few sources discussed, let alone tested, the prairie dog → fire interaction. Only 6 sources mentioned this potential interaction, typically by identifying prairie dogs as potential engineers of fire breaks without direct supporting citations (or in some cases, citing resources which themselves made statements without supporting research citations). Only one source, a dissertation (Strawn 1995), empirically tested the effects of prairie dogs on fire, and found a 20% reduction in fire coverage on burned prairie dog colony as compared to an adjacent area that was also burned, although this was tested somewhat indirectly with burn tiles and with mixed efficacy (personal communication, S. Strawn). Strawn (1995) also indirectly explored the effect of fire on prairie dogs and tested the prairie dog-grazing interaction, finding support for positive interactions between prairie dogs and grazers.

Where the literature is incomplete, scientists often turn to natural history to begin considering mechanisms; such first steps are crucial in identifying future research need. Potential evidence for prairie dogs reducing fire intensity or size can first be found in historical fire return intervals. Although we know of no dataset that would facilitate modeling these dynamics directly, abnormally small or infrequent fires relative to predicted frequencies could be interpreted as an indication of the role of prairie dogs. For instance, Porensky et al. (2018) highlighted the incongruity of fire-intolerant big sagebrush (*Artemisia tridentata*) persisting in portions of northeastern Wyoming, where fire-free intervals were estimated at ~7 years (Perryman and Laycock 2000). Researchers posited several potential factors leading to discontinuity of fuels, including disturbance caused by prairie dogs (Porensky et al. 2018).

More direct observations of the role of prairie dogs in influencing fire exist. The Anderson Creek Wildfire was the largest recorded fire in Kansas history, burning across 161,774 ha in 2016. Many structures were destroyed, and hundreds of livestock were killed, but on one ranch the losses were not so steep. Free-roaming bison on the Z-bar Ranch were observed moving to prairie dog towns during the fire. The fire did not carry across the colony, and all bison survived (Browning and Browning 2016, Magnus McCaffery, Turner Ranches, personal communication). Based on discussions with managers, it also appears that prairie dogs are taken into consideration when crafting burn plans, either as a means of "catching" (helping to limit) fire (David Lucas, Fish and Wildlife Service), or as a hindrance to fire spread in more arid systems (Ana Davidson, Colorado Natural History Program).

Discussion

While potential interactions between fire and prairie dogs appear straightforward, we found little evidence in the literature of previous research focused on this relationship. Little is known about the effect of prairie dogs on fire, barring a few references in the literature, and only one empirically-based dissertation chapter. The lack of research on how prairie dogs influence fire extends to other taxa as well, highlighted by a recent review (Foster et al. 2020). Therein, authors highlight the effect of animals on fire regimes are often overlooked, and studies incorporating the effect of fauna typically focus on mega-herbivores. However, prairie dogs consume and clip vegetation, reducing fuel availability and altering vertical structure. Prolonged occupation of a colony is associated with altered vegetation composition favoring annual forbs, often with a drastically reduced shrub component relative to the surrounding area (e.g., Duchardt et al. 2019); as a result, they also influence the composition of fuels, drastically reducing the availability of coarse fuels that would burn hotter and longer. Together with increased annual forb cover, burrowing activities increase bare ground, reducing fuel continuity. Despite a lack of empirical research, anecdotal evidence from numerous fires on the Great Plains supports this hypothesis.

We encourage a paradigm shift towards this multi-disturbance model not only because it appears to be more is more ecologically accurate, but also because it could be increasingly important for future management of these imperiled systems. Management on remaining rangelands in the Great Plains must necessarily factor in economic considerations; therefore, we do not expect every pasture or property within native prairie dog range to contain prairie dogs. Indeed, this would not have been the case historically and would be infeasible now. However, as our understanding of ecological processes grows, so should our management toolbox. Rangeland biodiversity in the Great Plains was not historically maintained by just fire and bison grazing, and we do managers a disservice by ignoring the unique ecosystem services that prairie dogs can provide. These include a potentially effective approach to address woody encroachment, one of the largest threats to portions of the Great Plains (Morford et al. 2022).

The fire-suppressive force of prairie dogs may be important for wildfire management in the future. By reducing woody encroachment and fuel availability, prairie dogs have been observed to reduce fire effects locally, as in bison herd survival on the Z-bar ranch fire, and more broadly in terms of fire spread on the Marshall, Wildcat Creek, and Gilbert Ranch fires. Nevertheless, these interactions have yet to be empirically tested. A better understanding of these dynamics is crucial, given fire frequency has nearly quadrupled in the Great Plains in the past decade, relative to the 1980s and 1990s (Iglesias et al. 2022) with more frequent megafires in the southern plains (Shore 2019).

Further research is needed on how prairie dogs influence fire behaviour in prescribed burns and wildfires. Further investigation of manager perceptions of prairie dogs in the context of fire may also be informative. We hope that continued research and discussion may do for the fire-prairie dog interaction, and the disturbance triangle as a whole, what we have observed with the fire-grazing interaction over the past 25 years. Although the restoration of any historical disturbance is dependent on both ecological and social context, much work has already been done to educate the public on the important ecological services these diverse disturbances can provide in grassland and rangeland ecosystems. Although incorporating prairie dogs into the grassland disturbance paradigm may be an uphill battle, we hope that this is at least a first step in that direction facilitated by a broader understanding of fire dynamics.

Acknowledgements

We thank the Thunder Basin Research Initiative and multiple ranchers, agencies and NGOs for discussing these ideas and informing this work. We note that a longer version of this manuscript, which includes a number of case studies on specific Great Plains fire-prairie dog interactions, is currently in review with *Bioscience.*

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Promoting rangeland literacy through development of agents of change and high-impact education resources

Wu, XB[1]; Dixon, S[1]; Goodman, L[2]; Treadwell, M[1]; Keshwani, J[3]; Poling, N[1]; Ingram, E[3]; Yockers, B[4]; Macik, M[1]

[1] Texas A&M University, College Station, Texas, USA; [2] Oklahoma State University, Stillwater, Oklahoma, USA; [3] University of Nebraska, Lincoln, Nebraska, USA; [4] Independent, Jenks, Oklahoma, USA

Key words: agents of change; educator cohorts; high-impact learning resources; rangeland literacy

Abstract

The sustainability of Great Plains rangelands and their ecosystem services is under threat by woody plant encroachment and climate change. Restoring coupled fire and grazing processes through pyric herbivory and mixed species grazing can effectively support rangeland ecosystem function, services, and resilience, but the adoption and public and policy support of these practices have been limited. The aim of the Educator Cohorts of the Prairie Project was to develop agents of change in secondary and undergraduate education through faculty and curricular development and action research to promote rangeland literacy. We organized three 2-year Educator Cohorts each of which starting with an intensive summer workshop focused on current science of rangeland ecology and ecosystem services as well as current learning science and high-impact pedagogy. It was followed by monthly online meetings and individual consultations focused on professional development, community building, and supporting participants in design, implementation, and assessment of their projects. Our work on developing rangeland literacy had four foci: (1) fire and grazing are fundamental processes of rangelands, (2) ecosystem services of rangelands are essential for all, (3) woody encroachment negatively impact these ecosystem services, and (4) pyric herbivory and mixed species grazing are effective climate-smart practices for sustaining rangelands and their ecosystem services. Cohort participants developed high-impact learning modules/lesson plans related to fire and grazing, implemented them in their own classes, assessed the impact on student learning, and presented their work and findings in professional or education conferences to engage peer educators to promote awareness and facilitate adoption to broaden the impact. Pre- and post-surveys of the students in the classrooms of the cohort participants and project team members have shown significant changes in knowledge and attitudes related to rangeland literacy, especially the roles of fire and grazing in sustaining rangelands and their ecosystem services.

Introduction

The Great Plains rangelands are a cornerstone of U.S. livestock production, biodiversity, and other ecosystem services, including water regulation, carbon storage, and wildlife habitat (Wilcox et al. 2022). However, these landscapes are under severe stress due to woody plant encroachment and increasing frequency and intensity of droughts and wildfires associated with climate change, which collectively diminish the rangelands' capacity to sustain these ecosystem services (Derner et al. 2018). Woody plant encroachment, in particular, has transformed millions of acres of open grasslands into woodlands, reducing forage availability and biodiversity (Archer et al. 2017).

Two promising approaches to counter these threats are pyric herbivory, a management strategy that integrates fire and grazing to create a heterogeneous landscape (Fuhlendorf et al. 2009), and mixed species grazing with cattle, goats and/or sheep. They have been proven as effective climate-smart practices that can reduce woody plant encroachment, impact of drought, and the risk of wildfire while increasing livestock production (Wilcox et al. 2022). Despite their efficacy, adoption of pyric herbivory and mixed species grazing remains low due to misconceptions, cultural resistance, and a lack of public and policy support.

Recognizing the role of education in addressing these barriers, the Prairie Project launched its Educator Cohorts Program designed to cultivate agents of change in secondary and undergraduate educational institutions through faculty development, curriculum enhancement, action research, and peer engagement. It emphasizes the development, implementation and dissemination of high-impact educational resources that include the key concepts of pyric herbivory and mixed-species grazing for sustainable rangeland management. It aims to empower educators as agents of change and equipping them with the knowledge and tools needed to foster rangeland literacy among secondary and undergraduate students. In addition to rural audiences, the Educator Cohorts Program intentionally targeted urban and suburban audiences, who represent the majority of policymakers and voters in the Great Plains region, seeking to build broad-based support for sustainable rangeland management.

Methods

Each of the Educator Cohorts spanned two years, with three staggered cohorts implemented to allow one year of overlap between them. The participants of the cohorts were educators from middle and high schools as well as colleges who were offered benefits such as travel support, stipends, and opportunities for continuing education or graduate credits. There were three main components of the cohorts' activities:

Summer workshop - Each cohort started with an intensive summer workshop and all cohort participants were required to attend this six-day workshop led by experienced facilitators from the Prairie Project's Education and Extension (E&E) team. During the workshop, the participants explored (1) the current science and practice of pyric herbivory and mixed-species grazing and how these affect the sustainability of rangelands and their ecosystem services in the Great Plains region, and (2) the current learning science and active learning pedagogies (peer instruction, case studies, authentic inquiries, citizen science projects, etc.). They then (3) participated in field tours of Prairie Project's research and demonstration ranches and met with researchers, extension specialists, and ranch managers to discuss and observe the research and management practices. Each participant (4) designed a learning module or inquiry project specifically tailored to their own class, as well as an associated assessment for assessing the impact of the module on student learning.

Implementation and assessment - During the following fall and spring semesters, participants refined and implemented their learning modules or projects and conducted assessment research of student learning. A collaborative learning community, comprising facilitators and cohort peers, provided ongoing support through (1) monthly online meetings to share progress, reflect on successes and challenges, and brainstorm solutions as well as (2) one-on-one consultations with facilitators for personalized guidance in module implementation and assessment research.

Broader engagement - In the second year, participants presented their curriculum designs, implementation strategies, and research findings at professional conferences and outreach events. These presentations aimed to inspire peer educators to adapt these learning modules and resources, professionals and ranch managers, while also recruiting participants for future cohorts. Potential venues include the Society for Range Management and Ecological Society of America meetings, the National Center for Case Study Teaching in Science conference, the Life Discovery–Doing Science Biology Education Conference, and the Lilly Conference on College and University Teaching.

The work of the educator cohort focused on developing ***rangeland literacy*** which had four key components: (1) fire and grazing are fundamental processes of rangelands, (2) ecosystem services of rangelands are essential for all, (3) woody encroachment negatively impact these ecosystem services, and (4) pyric herbivory and mixed species grazing are effective practices for sustaining rangelands and their ecosystem services. A survey focused on rangeland literacy was developed and all cohort participants administered this survey before and after the implementations of their learning modules, in addition to any other assessments they used, to assess student learning gains in rangeland literacy.

Results

High-impact learning module development and implementation

Over 30 participants of the Educator Cohorts have developed effective learning modules and projects in both secondary and high-education settings. They employed diverse approaches of high-impact pedagogies, from active and experiential learning, case studies, game-based learning, technology-enhanced learning, free response questions (FRQ), authentic inquiries, and course-based undergraduate research experiences (CURE). Many of them incorporated the use of Prairie Protector game developed by the Prairie Project team and/or the Rangland Analysis Platform (RAP) along with other activities to engage students and develop deeper understanding and place-based relevancy. All participants developed effective assessments, both formative and summative, for and of their students learning.

Impact on student learning

Preliminary results from the pre and post surveys have shown significant positive impact of the education modules and projects on rangeland literacy of the students. For example, through an inquiry project focused on fire and grazing, significant changes occurred in student understanding of the effect of woody plant encroachment on both livestock production and biodiversity (Fig. 1a, b), rangelands providing ecosystem services to both rural and urban residents (Fig. 1c, d), and the importance of fire in rangelands and its suppression leading to woody encroachment (Fig. 1e, f).

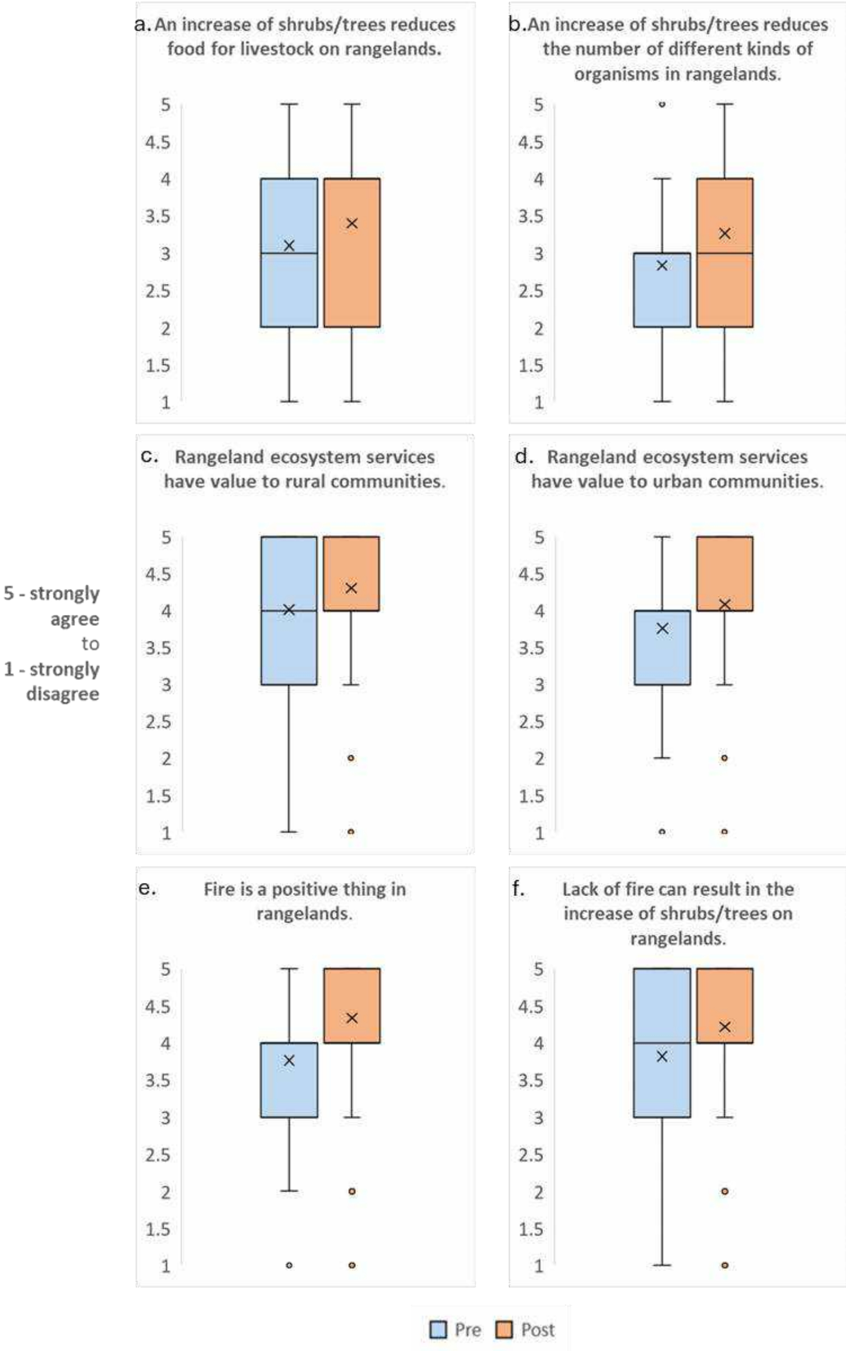

Figure 1. Pre- and post-survey results showing changes in student rangeland literacy.

Engaging peers as agents of change

The Educator Cohort participants has presented their work, often in collaboration with the Prairie Project E&E team members, in national and international conference in science and education, such as the Society for Range Management annual meetings, Ecological Society of America annual meetings, the Wildlife Society conference, National Science Teaching Association conferences, Advanced Placement Annual Conference, National Association of Biology Teachers conference, and the Lily Conference. Several of the participants have also presented, some together with their students, in regional conferences such as Nebraska Summit on Math and Science Education, Nebraska Association of Teachers of Science meeting, Oklahoma Academy of Science conference, Texas Chapter Wildlife Society meeting, Texas Society for Ecological Restoration conference.

Prairie Project E&E team members and the cohort participants have also collaborated in organizing symposium/organized sessions featuring our E&E work, including a symposium, an Ignite session, and a workshop at the SRM annual meetings, an organized session at ESA annual meeting, an organized session at the AP Annual Conference, and an educator workshop in Austin Texas.

Discussion

The Prairie Project Educator Cohorts have successfully developed agents of change who are advancing rangeland literacy and fostering support for climate-smart management practices. The educators' work has led to significant improvement in their students' rangeland literacy, and they have become effective advocates of rangeland literacy and high-impact pedagogy with their peers. By combining ecological science with innovative education strategies, the program provides a scalable model for addressing complex environmental challenges. Challenges remain, including the need to scale the program to reach more educators and students and to secure sustained funding for long-term impact. Future initiatives should prioritize policy engagement, broader dissemination of resources, and the integration of new technologies to enhance learning experiences. Continued investment in such initiatives will be critical for ensuring the sustainability of rangelands and their vital ecosystem services.

Acknowledgements

This work was supported by the USDA-NIFA Sustainable Agricultural Systems program (Grant Number 12726253). We thank the participating educators and institutions for their invaluable contributions to this initiative. This study was approved by the Institutional Review Board (IRB) of Texas A&M University (IRB2023-0659D).

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Developing teachers and faculty to be change agents promoting the value of rangelands: impacts of the Prairie Project Educator Cohorts

Dixon, STS

Texas A&M University, College Staton, 2258 TAMU, College Station, Texas, 77843, USA, stsdixon@tamu.edu

Key words: teacher; faculty; training; development; rangeland literacy

Abstract

Creating spaces and opportunities for teachers and faculty to become agents of change is central to promoting public understanding of the ecological and societal values of sustainable rangeland production and ecosystem services. One promising effort was the Prairie Project Educator Cohorts, which targeted the four domains of Clarke & Hollingsworth's (2002) Interconnected Model of Teacher Professional Growth. Housed within the overall Prairie Project (a federally funded grant collaboration between Texas A&M, Oklahoma State, and the University of Nebraska, Lincoln), the program trained educators from grades 6-16 on the threats to grasslands and effective management solutions. Participants from schools across TX, OK, and NE learned about pyric herbivory and mixed-species grazing during a summer workshop and field tour, then incorporated their new knowledge into a course of their choice during that fall or spring. A team of Extension professionals and teaching experts from the three collaborating universities led monthly online cohort meetings and were assigned to each educator as mentors. To assess the effectiveness of the Educator Cohorts, a summative qualitative evaluation was conducted. Data were collected through focus groups and individual interviews conducted over Zoom, and observations during cohort meetings. Thematic analysis was employed using an inductive approach to analyse the data. Findings revealed that the educators had significant advances in their knowledge of pyric herbivory, multi-species grazing, and the severity of the impact of woody plant encroachment. They also expressed that they were able to create powerful research-driven learning experiences for their students. Additionally, educators served as agents of change by sharing their instructional materials with their colleagues and supervisors and their new knowledge with friends and family who managed land. These data provide evidence that a comprehensive cohort program be an effective approach to professional development programming for educators that ultimately increases the rangeland literacy of their students.

Introduction

Empowering educators to be agents of change is an important way to get future generations interested and engaged in rangelands. Educators have a significant impact on their students' awareness of and orientation toward science (Keller et al. 2017). Equally, they have the ability to disseminate information horizontally to their peers within the profession (Supovitz et al. 2010). With experience and expertise, educators can be opinion leaders in their fields through sharing novel recommendations and innovative ideas (Fairman and Mackenzie 2015). Thus, creating spaces and opportunities for teachers and faculty to become agents of change is central to promoting rangelands and related best management practices. The aim of this study was to investigate the experiences of instructors who completed the Prairie Project Educator Cohorts - a two-year professional development program for K-12 teachers and higher education faculty from schools across Texas, Oklahoma, and Nebraska.

Housed within the Prairie Project (a federally funded grant collaboration between Texas A&M University, Oklahoma State University, and the University of Nebraska, Lincoln), the program trained teachers and faculty about the science of rangelands with an emphasis on the threats to the land and management solutions to overcome them. In the first year of the program, educators learned about pyric herbivory, mixed-species grazing, and high impact teaching strategies during a virtual summer workshop. The technical content was delivered by Prairie Project research scientists who the educators later got to meet in-person through a multi-state field tour.

Next, the educators incorporated their new knowledge into their curriculum via an active learning strategy of their choice. The lessons they created ranged from interrupted case studies to collecting data in the field and creating public service announcements. For support, each educator was assigned two mentors from a team of Extension professionals and teaching experts from the three collaborating universities. Further assistance was provided by the mentors through monthly online cohort meetings that included continuous education. In the second year, each educator led one monthly meeting to share about the design, implementation, and evaluation of their classroom project. Educators were required to give a similar presentation at a conference or professional setting of their choice. The educators received funding for travel and classroom supplies, and a stipend.

The conceptual framework for this study combines two existing theories and a model. The first theory is the theory of teacher change (Wayne et al. 2008), which focuses on teachers changing their knowledge or behaviour as the result of participating in specific activities. The second is the theory of instruction (Wayne et al. 2008), which promotes that teachers make changes based on increases in their knowledge. Both of these theories are leveraged in the Prairie Project Educator Cohort program. These theories align well with Clarke & Hollingsworth's (2002) Interconnected Model of Teacher Professional Growth.

Methods

This study employed a phenomenological research design, specifically existential phenomenology, to examine the perspectives of the educators who completed the Prairie Project Educator Cohort program. This qualitative research approach involved seeking detailed descriptions and interpretations from participants to understand the meaning of their lived experiences.

The sample population consisted of all the K-12 teachers and higher education faculty who completed any of three cohorts of the program (Cohort 1 2020-2022; Cohort 2 2021-2023; Cohort 3 2022-2024). Twenty six educators participated in the study (eight men and 18 women). The grade level breakdown was one middle school teacher, 12 high school teachers, and 13 faculty members. No other demographic information was captured.

Data were collected through two focus groups (one conducted in May 2022; the other in June 2024), and 16 individual semi-structured interviews completed between 2023 and 2024. Both the focus groups and interviews were conducted and recorded via Zoom and varied in length between 45 minutes and 90 minutes long. The same questions were used for the focus groups and individual interviews and included prompts such as: "how and why did you choose the instructional strategies for your lesson?", "how did your students react to the lesson?", "how have you shared your instructional materials beyond our official Prairie Project outlets?", and "in what ways did the Prairie Project contribute to your ability to serve as an agent of change?".

The focus groups and interviews were transcribed verbatim through online audio to text converters. An undergraduate student worker then listened to each recording while reading the corresponding transcript to correct any errors.

Evaluation coding (Rallis & Rossman, 2003) was used to analyse the transcripts to examine the significance of the Prairie Project Educator Cohort program. As noted by Saldaña (2016), evaluation coding can consist of multiple coding methods as the data analysis has to align with the structure of the program evaluation. Two members of the project staff were involved with coding. Independent and collaborative coding took place to create a codebook and gain confidence in the consistency of how the codebook was being applied. The codes were then organized into themes. Theme identification was an inductive, reflexive process that occurred over multiple meetings through critical discussion.

Results

Four overarching themes were identified from the dataset: educator development, educator takeaways, agent of change, and program feedback.

Educator Development

The first theme focused on changes in skills, knowledge, and attitude among the educators. Even though most of the educators were familiar with grasslands and rangelands, their specific knowledge of prescribed fire, patch burn grazing, and multispecies grazing increased through their participation in the cohort program. Two quotes captured many of the sentiments in this theme. One educator shared, "I think the biggest impact would just be more knowledge on something I thought I knew a lot about". Another said, "Good stuff. Yeah. I didn't have a lot of information on [mixed-species grazing]. That was all pretty new knowledge for me". The educators either thought they knew quite a bit about the topics and they were able to learn significantly more from us, or they learned something new and were enthusiastic about it.

The educators also expressed that their teaching (content delivery, classroom management, etc.) was impacted by their experience. One person described a "lightbulb moment" she had when a speaker said that it was important to make sure that they were not teaching to themselves and their learning preferences, and to keep their focus on being student-centred. The educator said she began to reflect on how she taught in the past and then made adjustments to make her classroom more inclusive to the different ways students learn. She claimed, "it made me a little bit more empathetic, which is a good thing to me as a teacher...it probably helps me make my classroom more inclusive".

Educator Takeaways

The second theme focused on educator gains that were not related to personal growth. Besides being equipped with new knowledge and resources, a big takeaway for the educators was the community they developed both among themselves and with the program facilitators. One educator remarked, "And so it just gives me another group of people that I've met and been able to engage with and could call colleagues, basically at some at some level. It may not be that you're engaging with them regularly. But if I were to email anybody, Oh, yeah, I'm happy to help, or, you know, like, that's the that's the general sentiment across the group yet. you know. So I think it really built another new collaborative group of people which is fantastic".

On a related note, others appreciated the respectful and encouraging environment that was created. One teacher said, "Hearing from other teachers and faculty that they were dealing with that as well was kind of nice to make me maybe not think I was the only one that was struggling with that". The monthly cohort meetings became a brave space for educators to share successes and challenges with each other.

Agent of Change

The third theme highlighted the ways educators acted as agents of change regarding rangeland science and best management practices. This included how they shared their new knowledge and the curriculum items they created with others beyond the program requirements. A faculty member shared, "I've shared the unit with…a plant taxonomist here that teaches biogeography actually. And she was really interested…I've shared some of the information in passing our Dean as a former plant taxonomist as well." Others were agents of change in their personal networks. An educator stated, "My understanding of rangeland management changed a lot during this process, and you know that was great for me from the education standpoint. But still, personally raising cattle and having some very good friends that have some pretty big operations up in the northern part of the state, you know, just being able to pass that information on to them. And when they've got questions, they can kind of lean on me a little bit more".

Program Feedback

The fourth theme encompassed reflections on the program components had a significant impact, as well as ideas for program improvement. Most of the educators expressed that they valued being able to have resources that connected students to local relevant science and something students could see within their neighbourhoods. A teacher said, "just cool to be part of something region wide...it was useful for the students. I think it helped with engagement for them to see that the topic we're talking about are really important throughout the whole Great Plains“. Another teacher shared how one of her students enthusiastically told her, "this it legit, Miss!" as he was able to understand the real-world application of what they had just learned in the classroom.

Additionally, the educators appreciated the autonomy they had to create their lessons. One person remarked, "I thought that was one of the real strengths of the program. And it wasn't really prescriptive which I think opened up creativity and allowed us to, in some cases, use some of our own strengths in that project".

The most common piece of program feedback was that the educators wished they had more opportunities to meet and collaborate in-person with each other. However, a couple of educators also noted that while they would have liked to have spent more time together in-person, that it would not have been feasible due to the demands of the academic year.

Discussion/Conclusions/Implications

These findings align with the growing body of literature that emphasizes the importance of professional development that enhances content knowledge and fosters a supportive community of practice. In the first theme underscores the importance of continuous learning in professional development programs. Additionally, the reported changes in teaching strategies highlight the program's influence on pedagogy and suggests that such programs should not only focus on content knowledge but also support educators in adopting reflective and adaptive teaching practices that enhance student engagement and learning outcomes (as proposed in the conceptual framework).

The sense of community described in the second theme is consistent with research on professional learning communities. The ability to reach out to fellow educators and facilitators for advice or support not only enhanced participants' sense of belonging, but also contributed to a culture of ongoing professional dialogue. This sense of camaraderie and mutual support may serve as a catalyst for sustaining the changes in teaching practices initiated by the program.

The third theme illustrates the broader impact of teacher training programs, where educators extend their influence beyond their classrooms and contribute to the community at large. The educators' roles as agents of change underscore the importance of equipping them with not only content knowledge but also the confidence and resources to share that knowledge with others.

One of the most notable positive aspects was the opportunity to connect students with local science, which helped make the content more tangible and engaging for learners. This finding supports the idea that placing educational content within a local context can enhance its relevance and foster greater student interest.

Overall, the findings from this study suggest that the cohort program had a profound impact on educators' professional development; educators were empowered to become agents of change. Future program improvements should focus on enhancing opportunities for in-person collaboration while maintaining the flexibility and autonomy that educators found valuable.

XII INTERNATIONAL RANGELAND CONGRESS AUSTRALIA 2025

Comodity production increased with mixed-species grazing and pyric herbivory

Walker, JW[1]; Wilcox, BP[2]; Fuhlendorf, SD[3]; Rector, MF[1]

[1] Texas A&M AgriLife Research, San Angelo, Texas 76901, USA, john.walker@ag.tamu.edu; [2] Department of Ecology and Conservation Biology, Texas A&M University, College Station, Texas, USA; [3] Department of Natural Resource Ecology and Management, Oklahoma State University, Stillwater, Oklahoma, USA

Key words: Angora goat; cattle; patch burn grazing

Abstract

Woody plant encroachment (WPE) is a global problem to which browsing herbivory and pyric herbivory are potential sustainable solutions. This study aimed to compare the efficacy of goat browsing and prescribed fire to mitigate WPE on rangelands in different seral states. The effect of browsing and fire in a 2 x 2 factorial design was investigated on rangelands in different seral states, namely woodland, savanna, and grassland. The different seral states were created by mechanically removing woody plants on 2 ha areas to a canopy cover of about 20% (savanna), 5% (grassland), or no removal (woodland). Three 2 ha areas, one in each seral state, were planned to be burned annually, but we were only able to burn in two years and those burns were not effective. Weaned calves were planned to graze for 10 months at a light-moderate stocking rate of 16 ha/AUY. However, because of drought, the average stocking rate was 28 ha/AUY. Angora wether goats grazed for 6 months at an average stocking rate of 20 ha/AUY resulting in a 230% higher stocking rate on multispecies compared to single species grazed pastures. Calf average daily gain (ADG) was higher (P=0.04) on the single species treatment than the mixed species grazing (0.46 vs. 0.54 kg/day, respectively). Because lighter calves have higher market value the economic difference was less than the difference in ADG. Over the three-year study Angora fleece weight averaged 2.4 kg/hd. The value of fleece production on mixed-species grazed pastures was USD 31.60/ha, resulting in a total value of production of USD 61.44/ha compared to USD 32.26 USD/ha on single species grazed pastures. The increased stocking rate due to mixed species grazing on this study was greater than reported in other studies co-grazing goats and cattle.

Introduction

Before the advent of mechanized agriculture, grasslands and savannas accounted for nearly 40% of the earth's surface; today, the remaining intact grasslands and savannas cover only a little over 20%. Rangelands are hotspots of wildlife biodiversity, large repositories of soil carbon, and source areas for clean and abundant water. In addition, they support most of the world's livestock production and are critical for pastoral societies as well as advanced commercial animal production. Despite their importance, grassland biomes are imperiled worldwide. As many as half of them have been converted to croplands or altered by afforestation. The remaining grassland biomes are being degraded by other factors, including invasive species and woody plant encroachment (WPE). The proliferation of trees and shrubs on rangelands is one of the most striking land-cover changes of the last 100–200 years. Since the 1940s, the range management community has aggressively worked to reverse woody proliferation, relying heavily on mechanical and chemical brush control, with the primary goal of increasing forage production for livestock. Enormous amounts of money, effort, and time have been spent on reversing WPE, but the results have generally been short-lived. Emerging research has identified some management strategies that are extremely promising, not only for maintaining livestock production across the Great Plains but even for increasing it. Examples include pyric herbivory and mixed-species grazing. Pyric herbivory can facilitate the use of prescribed fire by eliminating the need to rest pastures before and after the burn while simultaneously enhancing forage quality and increasing heterogeneity. Mixed species grazing by adding a browsing herbivore helps control woody species and increases animal production.

The objective of this research was to investigate the effect of mixed species grazing and pyric herbivory on WPE and their effect on livestock commodity production.

Methods

The experimental design is a 2 x 2 factorial of with or without pyric herbivory and mixed species grazing with goats. These treatments were conducted on four 48 ha pastures. In addition to the WPE management treatments, woody plant thinning treatments were done before implementing these treatments (Fig. 1). Woody plants were thinned to three levels of canopy cover removal, namely: control (woodland, i.e., no bush removal); savanna (woody plant removal to approximately 20% canopy cover); and grassland (woody plant removal to approximately 5% woody plant cover). These levels of brush control correspond to an Oak/Juniper Woodland Community, Midgrass/Oak/Mixed Brush Savannah, and Historical Climax Plant Community, respectively, in the NRCS Ecological Site Description (ESD) for Low Stony Hill (Site ID: R081BY337TX) the predominant ESD on the study site. Each thinning treatment was done on eight 2 ha blocks in a stratified random manner based on the two soil types present. The thinning treatments aimed to estimate the effect of different initial stages of WPE on the effectiveness of WPE management treatments.

Weaned calves were grazed on all four pastures shortly after weaning in October at a light moderate stocking rate of about 16 ha/Animal Unit Year (AUY), where an AU = 454 kg. Calf stocking rate was kept variable to achieve about a 40% utilization of key species and to try and maintain adequate fine fuel for the prescribed fire treatments. Freshly shorn Angora wether goats browsed from October through March, ie. spring shearing. Goats were planned to be stocked to achieve about a 90% increase in stocking rate compared to cattle only pastures. Animals were weighted on and off pasture, and mohair weighed at spring shearing. Grazing years spanned two calendar years and are referred to by the year when grazing ended.

Randomly selected 2 ha polygons in each of the three woody plant thinning treatments on the two pastures in the pyric herbivory treatment were planned to be burned every year. However, because of drought conditions and lack of fine fuels prescribed fires were only conducted in January 2022 and March 2024.

Because prescribed fires for the pyric herbivory treatment were not conducted as planned and were ineffective when conducted, calf weight gains were analysed only for the effect of grazing treatment and year with analysis of variance. The value of calf weight gain was calculated using local market reports to determine the difference between the values of similar size and class of calves at weaning and their value when removed from the pasture. The value of goat production was calculated from fleece weight and the price of mohair at local markets for each year less the cost of shearing (USD 5.00/hd).

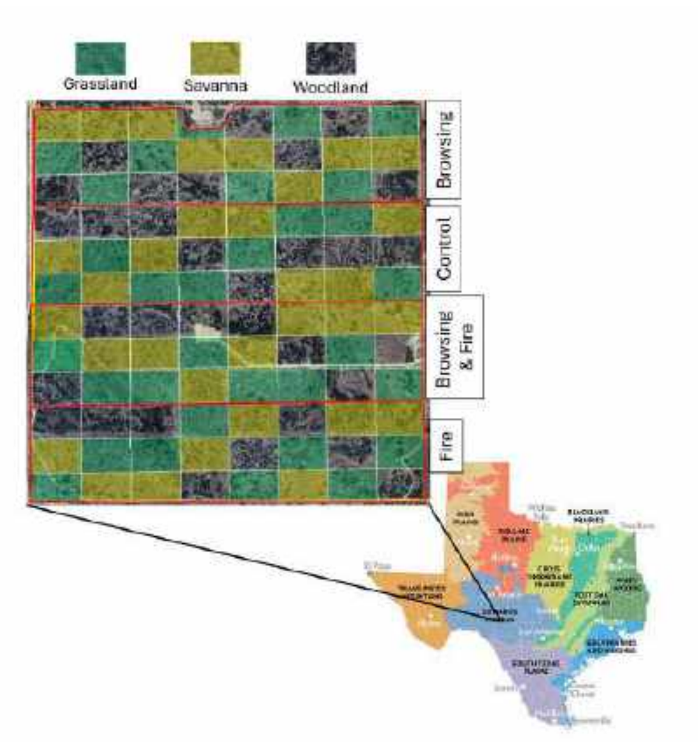

Figure 1. Study area showing 49 ha treatment pastures outlined in red and stratified and randomly distributed 2 ha areas cleared to 5% 20% or uncleared representing grassland, savanna, and woodland, respectively.

Results

During this study, precipitation was 70% of the average, and the calf stocking rate was adjusted to compensate for the deficiency in precipitation (Table 1). The adjustment in cattle stocking rate was done by removing animals sooner than planned. Cattle grazed for the planned duration in only one of the four years of the study and were not grazed in 2023 because of drought (61% of average precipitation). In contrast, goats grazed every year for the planned duration, but they were lighter than expected, resulting in a slightly lower stocking rate. Average stocking rates were over twice as high on the mix-species (12.2 ha/AUY) compared to the single species (28.5 ha/AUY) grazed pastures for the 3 years cattle grazed.

Table 1. Planned and actual stocking rates for during the study period. Years refer to the year grazing ended, and actual grazing spanned two calendar years, beginning in the fall and terminating in spring or summer.

	Planned	2021	2022	2023	2024
Precipitation (mm)	631	452	437	386	506
Calves					
Number	5	4	5	0	5

ha/AUY	17	15	22	24	22

There were no grazing treatment x year interactions (*P*>0.21) for cattle performance metrics. As expected, the average daily gain (ADG) and gain/hd of calves in the single species grazing treatment were greater (P=0.09 and 0.04, respectively) than in the mixed species grazing treatment. The value of the weight gain on the single species treatment was also greater but not significantly. The value of the mohair produced doubled the per ha value of livestock products on the mixed species grazing treatment. The yearly differences in cattle weight gain reflected differences in precipitation.

Table 2. Effect of grazing treatment (single-species vs. mixed-species) and year on livestock production.

	Grazing Treatment			Year			
	Single	Mixed	P-value	2021	2022	2024	P-value
Average daily gain (kg)	0.54	0.46	0.09	0.45[a]	0.40[a]	0.65[b]	<0.01
Gain (kg/hd)	115	98	0.04	85	118	118	0.07
Value (USD/ha)	32.26	29.84	0.12	11.11[a]	35.24[b]	46.80[c]	<0.01
Mohair (kg)		2.4					
Value (USD/ha)		31.60					

Discussion

The two important results of this study were the small difference in cattle weight gain between mixed and single species grazed pastures, given that the stocking rate on mixed species grazed pasture was over twice as high as the single species grazed pasture, and the difficulty of conducting patch burn grazing in areas where annual precipitation is less than 650 mm. Cattle on the single species grazing treatment gained 17% more per head than cattle on the mixed species treatment. The increased stocking rate on the mixed species grazed pastures was much greater than previously reported in other studies. A general recommendation is that 2 breeding goats can be added for each cow without decreasing the stocking rate (Merkle et al. 2014). Animut (2008) calculated a theoretical increase in stocking rate of 60% by adding goats to single species cattle grazing. On an animal unit (AU) basis, those recommendations are equivalent to about 0.3 – 0.6 goat AU/cow AU; our replacement rate was 1.2 goat AU/cow AU or two - four times higher. The season of grazing was primarily responsible for the higher carrying capacity of goats in this study. Goats were grazed in the dormant season because this is the season when their potential impact on juniper encroachment is highest (Taylor 2008) and when their consumption of juniper is highest (Walker et al. 2013). Juniper is not a limiting forage on these rangelands and dormant season grazing minimizes diet overlap with cattle and thus minimizes the effect of the high stocking rate on cattle performance.

Per ha income from mohair production on the mixed species treatment was almost as much as the value of the gain on calves on the single species grazing treatment. This is a result of several factors: on an AUE basis, there were more goats than cattle and the high value of mohair that averaged about $3.80 USD/kg. Angora wether goats were used for this study because they require minimal management and are predator resistant. This makes them an easy class of livestock to incorporate into a cattle operation.

The lack of adequate fine fuel to conduct the planned prescribed burns and the fact that when the burns were conducted the continuity of fine fuel was insufficient to carry fires across the burn unit was a result of insufficient precipitation and soil disturbances caused by the mechanical removal of woody plants. Deferment for several years is recommended on rangelands in fair to poor condition to accumulate adequate fuel for an effective burn (Hanselka 2009). The inability to meet planned burning objectives indicates that patch burn grazing will be difficult to accomplish in areas with less than 650 mm of annual precipitation, unless pastures are in excellent condition.
